The claim of diminished virulence was tested in the following manner: Before beginning the inhalations a small portion of the sputum from Case IV. was mixed with sterilized water and injected into the thoracic cavity of three rabbits. The animals were killed five weeks later and a localized tubercular lesion at the site of injection was noted, while transparent miliary tubercles were just visible on the pleura and pericardium. These lesions contained bacilli. The patient having begun to breathe hot air for four hours daily, a small portion of his expectoration was taken every five weeks and injected in the same manner into the thoracic cavity of three rabbits. This was repeated three times—that is, the last set of inoculations was made three months and a half after the treatment had been begun. Each set of rabbits was killed at intervals of five weeks and notes of the autopsies made. They were found to have all developed tubercular lesions containing bacilli, and in the last lot as well as in the others, miliary tubercles occurring at some distance from the site of injection were demonstrated. These tubercles were sufficiently advanced to be macroscopical, and did not differ materially in their appearance from those which had been produced in the animals inoculated with material expectorated by this man before the treatment was instituted. Five weeks being very nearly the earliest date at which secondary tubercle distant from the original lesion appears, microbes capable of causing such manifestations within this limited time can have lost none of their virulence. No diminution in the pathogenic properties of the bacilli seems therefore to have been produced by breathing the heated air.

Although difficult of absolute demonstration, it is most probable that the temperature of the air-cell itself can be influenced but very slightly, no matter how high or how low that of the inspired air may prove to be. The intense vascularity of the lungs, the fixed temperature of the blood rapidly circulating through them (which is relatively low when compared to that of the heated atmosphere furnished by the apparatus), the moisture and infinite subdivision of the surfaces, and the very slow admixture which takes place between the tidal and residual air, all conspire to rob the incoming current of its heat and to confine the possible variations of temperature in the air-cell within very narrow limits.

The inference held out as conclusive that, because the breath on expiration measures as high as 45° C. (113° F.), the air in the air-cells must necessarily be much warmer is fallacious, for the expired air is in a great part composed of the last inspiration still surcharged with its recently acquired heat. As the bacilli in the bronchial secretions must necessarily be brought in much more intimate contact with the hot air than those imbedded in solidified areas of lung or in impermeable tubercular masses, the failure of the latter agent to diminish their virulence to any appreciable degree is most significant.

CONCLUSIONS.

1st. The therapeutic value of hot-air inhalations in phthisis is doubtful.

2d. The evidence obtained by the bacteriological study of the cases presented does not confirm the assumption that inhalations of heated air can either prevent the growth of the tubercle bacillus in the lungs of living individuals or diminish the virulence of this microbe when it has gained access to them.

CHRONIC TONSILLITIS.[1]

BY E. FLETCHER INGALS, A.M., M.D.,
PROFESSOR OF LARYNGOLOGY, RUSH MEDICAL COLLEGE, CHICAGO.

SYNONYM: Hypertrophy of the Tonsils. This affection is characterized either by dilatation of the lacunæ by their retained secretions with hypertrophy of the glandular tissues about them, by distention of the lacunæ without hypertrophy of the glandular tissue, or by simple hypertrophy of the glandular tissue, while the lacunæ are but little involved. About two-thirds of the cases occur in males. The disease is said to be most frequent between the ages of fourteen and sixteen, though it occurs very frequently in younger children, and it is sometimes congenital. It is observed occasionally in middle life, but the tendency to it diminishes with advancing years.

Anatomical and pathological characteristics.—The tonsil is enlarged, and either of a pink, bright red, or yellowish-pink color; but most frequently it is a little lighter than the natural color of the mucous membrane. The bright red color is not common. In this affection the tonsil may measure from three-eighths to one and one-eighth or more inches in diameter, and it usually weighs one or two drachms. In some instances the tissue is very friable, so that it can be readily broken up by the finger, while in others it is exceedingly firm and like fibrous tissue to cut. Usually there will be a collection of secretions in some of the lacunæ, forming little yellowish points at the surface. If a probe is passed into these a considerable quantity of cheesy matter may often be removed. In rare cases the lacunæ are involved with out hypertrophy of the glands: I have seen within the last year several cases in which a number of the diseased follicles with their retained secretions were visible on each side, and yet the whole gland was not larger than normal.

If the gland is very large, it may seriously interfere with respiration so as greatly to impair the patient's general health; the patient being much as one who lives in a cellar, with only half the normal allowance of oxygen. It is claimed by some that hypertrophy of the tonsils increases the tendency to diphtheria in young children, and adds much to the danger from an attack of this disease. Persons with this affection are much more subject to attacks of acute tonsillitis than those in whom the tonsils are not enlarged. In a few cases permanent deformities result from enlargement of the tonsils. The most pronounced of these is the pyriform chest, caused by the upper portion of the thorax being forcibly distended and the lower retracted with each inspiration, until finally the condition becomes permanent. This could hardly happen in a child fifteen or sixteen years of age, but in young children, where the bones are soft and the cartilages elastic, it is an easy matter for such changes to occur.

Etiology.—Among the causes of chronic tonsillitis are: repeated acute attacks of inflammation of the gland, the strumous diathesis, diphtheria, scarlatina, and measles. Occasionally the disease seems to be hereditary, as it is not infrequent to find families in which several members have had hypertrophy of the tonsils, and the parents before them. Chronic follicular pharyngitis is said to be a cause, but appears only a concomitant. Acquired syphilis is sometimes a cause with adults. In May, 1888, Dr. Gradle, of Chicago, presented a paper to the American Medical Association, in which he advanced the opinion that chronic follicular tonsillitis is of bacterial origin. To prove this theory he cited the fact that secretions taken from one of the lacunæ and placed under the microscope will be found swarming with bacilli, though he admitted they were not of a specific variety, but of various kinds. This admission seems of itself almost sufficient to disprove the hypothesis. The decomposition of any animal substance is necessarily attended by the development of a large number of bacilli, and the fact that they may be seen microscopically is no more reason for believing that the bacilli cause the disease than the macroscopic discovery of maggots in a carcass would be for supposing we had found the cause of the animal's death.

Symptomatology—Inquiring into the history of chronic tonsillitis, we frequently find evidence of hereditary origin, but in most cases the patient has suffered from frequent attacks of acute inflammation of the gland, or the disease has had its beginning in an attack of diphtheria or scarlatina. When the tonsils are much enlarged the respiration is more or less obstructed, and the voice is altered in resonance and quality. Partial deafness, due to pressure of the gland upon the Eustachian orifice or to extension of the inflammation, is not uncommon. Occasionally the senses of taste and smell are much impaired as a result of this disease, and it is said that in rare instances even the sense of sight has been affected. Patients rarely experience pain, but not unfrequently they complain of a sensation as of a foreign body in the throat, which they are continually trying to swallow. In children where the disease has existed for a considerable time, the patient's mouth is almost constantly open, the eyes dull, and there is an appearance of lack of intellect which is almost characteristic of the disease. Hoarseness is common, but more frequently the voice sounds as though the patient was talking with something in the mouth. Many of these patients become easily fatigued on taking exercise, because the blood is not properly aërated. Sometimes the obstruction to respiration is not marked in the daytime, but is

[1] Read before the Mississippi Valley Medical Association, at Evansville, Indiana, September 11, 1889.

very pronounced at night as the patient sleeps, and if the tonsils are very much enlarged it may be extremely difficult and so noisy that it is impossible for others to sleep in the same room. In rare instances there is actual danger of suffocation. I have seen two cases of chronic tonsillitis in young children where I thought it a very serious matter to allow the glands to remain for even a few days. Cough is sometimes, though rarely, present. It is especially apt to occur at night, and may be due partially to the enlargement of the tonsils and partially to the elongation of the uvula, which is a frequent attendant. In young children swallowing is sometimes quite difficult from the mechanical impediment.

The enlarged glands may be easily seen, and usually upon the surface of each the orifices of three or four crypts about an eighth of an inch in diameter are plainly discernible. In some cases, even when the tonsils are much enlarged, as we look into the mouth the gland can hardly be seen and we notice only an unusual fulness on each side of the fauces, until the patient retches, when the tonsils are rolled out so as almost to touch in the middle line.

Diagnosis.—The diagnosis may be easily made by inspection, but occasionally, where the anterior pillar of the fauces hides the tonsil, palpation may be necessary to determine the exact size of the gland.

Prognosis.—When the tonsils enlarge in early childhood they will sometimes disappear about the fourteenth year. Hypertrophy of the tonsils occurring in youth or in early adult life will often disappear about the thirtieth year; however, in the meantime the general health may have been greatly injured, or some of the special senses permanently impaired. We must remember, also, the tendency to frequent acute inflammations, and the possibility that this affection predisposes to serious attacks of diphtheria.

Treatment.—Excision is the most satisfactory treatment, but for simple hypertrophy I am accustomed to recommend those who do not wish operative procedures to moisten the finger, dip it into dried alum and rub it thoroughly into the gland once a day. This treatment must be continued for several months, and will be effectual in some cases in which the glands are quite soft. Another method is to inject into the gland with a hypodermic syringe iodine, ergotine, or carbolic acid. The tincture of iodine may be injected to the amount of five or ten minims; or, in a similar way, ergotine one to ten grains with alcohol, or carbolic acid one to three grains with water or glycerine, commencing always with the smaller quantities. Counter-irritation has sometimes, though not often, been found useful. Linimentum ammonii applied daily about the angle of the jaw will occasionally reduce the size of the glands. Electrolysis has also been recommended, one needle being passed into the tonsil, the other electrode being applied by means of a wet sponge externally, or both needles being inserted in the gland. The method is tedious but sometimes effective. Chromic acid is also used for reducing the glands, either in solution or in the form of crystals. In applying the crystals only a small amount should be used, and it is better to fuse it on a probe so that there will be no danger of its dropping into the throat.

The galvano-cautery has been highly recommended for the reduction of these enlarged glands. When it is used a small pointed electrode about one-fourth of an inch in length and from one-sixteenth to one-eighth of an inch wide should be heated to a white heat and plunged into each tonsil in one or two places at each sitting. The operation should not be repeated in less than three days, and it is usually best to wait a week or ten days. This will eventually reduce the size of the gland, but it is a tedious process. In the majority of the cases twenty or thirty sittings will be required and each one will give the patient almost as much discomfort as the removal of the gland by the tonsillitome. But we occasionally find people who strenuously object to the use of the knife and who will submit to treatment by this method. Occasionally when the glands are soft ten or twelve operations will suffice.

Excision is doubtless the best treatment for the majority of cases. The direction was formerly given, and is still found in some of the works on surgery, that the gland be seized with a pair of forceps and cut out with a bistoury, much care being used to avoid cutting important arteries; but many modern surgeons have come to believe that the tonsillitome is far superior to the bistoury for this operation. I think it is always to be preferred. There is a large variety of tonsillitomes, and of these there are many instruments that will answer the purpose very well, but I have found Mathieu's (Fig. 1) most satisfactory for all sorts of cases. This instrument may be readily taken apart for cleaning or sharpening. It is made in two or three sizes, but the larger will answer for nearly every case, though a smaller one is desirable for young children.

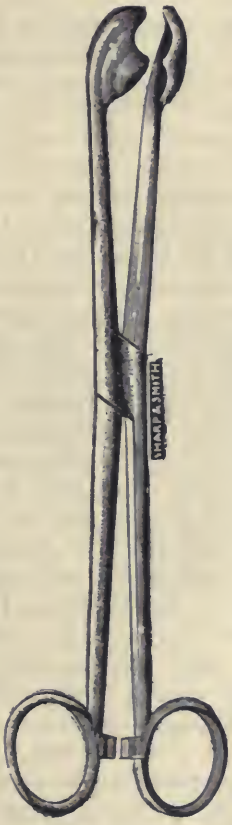
In using any tonsillitome it is well to have an assistant make firm pressure back of the angle of the jaw with the finger in order that the gland may be thoroughly exposed, and whenever it is adherent to the anterior pillar of the fauces the adhesion should be broken up before excision is attempted. In using this instrument place the ring, containing the knife, around the tonsil and with the other hand press it firmly against the side. Then with a single movement of closing the hand, the spear is forced through the gland, the latter pulled well through the fenestrum and at the same time the knife is released and

cuts its way through so that the whole painful part of the operation requires only the fraction of a second. Some surgeons advise simply clipping off the surface of the tonsil, hoping that the remainder may be absorbed, but I believe it is far better to remove all the diseased mass, if possible, and the nearer we come to this the better it will be for our patient. Remember that in the perfectly healthy throat no tonsils can be seen.

FIG. 1.

Mathieu's tonsillitome.

FIG. 2.



Ingals's tonsil forceps.

There are some cases in which the patient is subject to frequent attacks of tonsillitis, but in whom at other times there is very little enlargement of the gland, so that it cannot be removed when inflammation is not present. In such cases Lennox Browne recommends us to wait until inflammation and swelling of the gland occur, and then to remove it, as this is the only way in which a thorough operation can be made. There is a serious objection to removing a tonsil when inflamed, in that it is liable to bleed excessively, but in the cases just mentioned there is no choice unless we adopt other methods of destroying the gland. The galvano-cautery seems to me best adapted to the treatment of these cases. In the only instance where I have followed Mr. Browne's suggestion alarming hemorrhage occurred and continued in spite of all the approved methods of checking it until the patient fainted.

It is usually an easy matter to remove the tonsils in adults or in tractable children. But if the child from fright or other reasons refuses to submit, it must be held by main force, and the mouth must be pried open, and the teeth kept apart by a gag, if the ordinary operation is to be performed. But with most children it seems to me a cruel thing to operate in this way. I do not think an adult could suffer more mentally, going to his own execution, than a little child in having the tonsils removed. The first tonsil might, in many instances, be removed without much distress, but the removal of the second inflicts an amount of torture which children should not be called upon to endure. It is my rule with all children who are timid about the operation to administer chloroform or ether, and remove the glands with the steel-wire snare.

Exceptionally we find the tonsil of such form that it may be easily caught by the snare, but usually the wire will not hold. To overcome this difficulty I have had made a tonsillotomy forceps (Fig. 2) which gives perfect satisfaction. It is so constructed that as the blades grasp the tonsil the wire may be easily slipped over them, and must necessarily engage the base of the gland. To remove the tonsils by this method the child is first given an anæsthetic, and laid upon its abdomen with the face close to the edge of the table, then the gag is introduced and the mouth opened widely. The forceps are held by the thumb and second finger of the right hand, like an ordinary dressing forceps. The loop of the snare is then slipped over the blades toward the joint of the instrument, and the snare itself is supported by the little finger of the same hand. While an assistant presses the tonsil inward with his finger behind the angle of the jaw, the operator passes the blades of the forceps back to the pharyngeal wall, and then, as they are opened, draws them forward against the anterior pillar of the fauces, when they are pressed firmly down above and below the tonsil with care to engage simply the gland. The blades are then locked, and the loop of the snare slipped over them and tightened, when it will slide down beneath their ends and cut off the mass. As soon as the snare is firmly applied the forceps may be removed if desired. When the tonsil has been caught properly, the wire loop will slide under it, and the whole gland will be enucleated. In this operation there are two points for special caution: Be careful not to injure the anterior pillar of the fauces with the forceps, and not to engage the tip of the uvula in the snare as it is slipped over the blades.

I have usually used two snares in performing the

operation; having caught the first tonsil and tightened the snare, the forceps have been disengaged and applied with the snare to the other tonsil before the first one was removed, the object being to prevent bleeding until both glands were secured. There is one objection to this method—the first tonsil may be easily secured, but being drawn out of its bed fills the fauces so that it is sometimes difficult to catch the other.

In my recent operations I have taken out one tonsil, have then turned the child over, put the gag in the other side of the mouth and removed the other gland in the same way as the first. There is very little bleeding, and as the child is turned upon its face none of the blood can run down into the trachea. After the operation a spray or gargle containing about five grains of carbolic acid to the ounce of water, should be used every two hours when the child is awake, until the throat has nearly healed. If pain is complained of, troches of althea may be used freely, or a small amount of deodorized tincture of opium may be added to the local application.

There are some cases of chronic tonsillitis in which the follicles are mainly involved and the glandular tissue is not sufficiently hypertrophied to require removal, but in which the diseased follicles are constantly filling with secretions which give the patient more or less discomfort and sometimes actual pain, and often cause an offensive breath. This is frequently a source of much alarm to the patient. The treatment usually recommended for this condition consists mainly in the application of caustics. Most authors recommend that all the secretions be carefully squeezed out of the crypts and then either chromic acid or nitrate of silver be applied, fused on a small probe. Applications should be made to only two or three follicles on each side at each sitting. This is effectual in some cases; however, there is no method so satisfactory as cauterization by means of the galvano-cautery. Some laryngologists recommend that the secretions be carefully squeezed out of the crypts before using the galvano-cautery, but it is entirely unnecessary. I use an electrode, the point of which is about half an inch in length by one-eighth of an inch in breadth, which is tested at the time with a current sufficient to heat it to a white heat in one second. This is passed to the bottom of the crypt and the current turned on until the tissues begin to sizzle and smoke; the current is then shut off, the instrument withdrawn, and the operation is completed. I usually cauterize two or three crypts at each sitting, and only those in which I can see the secretions. Cocaine may first be used to prevent pain, but is not generally needed.

There are some cases where it is impracticable for the physician to use any form of treatment a sufficient number of times. These patients may sometimes be able to use the nitrate of silver themselves, if they are shown how to fuse it upon the end of a probe, and to pass it into the crypt. By persistent treatment in this way a cure may usually be effected.

After the removal of enlarged tonsils there is sometimes considerable hemorrhage. The most approved means for checking it are: holding bits of ice in the mouth and applying ice at the angle of the jaw; holding a sponge firmly upon the stump of the tonsil with a pair of forceps, one blade of the forceps in the mouth, the other outside (the ordinary stone forceps are best adapted to this purpose); compressing the stump of the tonsil with the finger, making counter-pressure with the thumb at the angle of the jaw, and rubbing alum upon the cut surface. Sir Morell Mackenzie recommends a mixture of tannic and gallic acids, two drachms of gallic and six of tannic acid to the ounce of water, which is to be supped slowly, or used as a gargle; this, he claims, will stop the bleeding in most cases. By the use of some one of these means I have always been able to check the hemorrhage, with one exception.

A few cases have been reported in which the hemorrhage has been alarming, in some of which the carotid artery has been tied to stop the bleeding, though with equivocal success. One of these which occurred in the practice of Dr. S. E. Fuller, of Brooklyn, two years ago, an account of which was published in *The American Journal of the Medical Sciences* for May, 1888, was widely quoted both by medical journals and the daily press. In that instance the common carotid artery was finally tied, but bleeding did not cease until after the patient fainted. Dr. D. Bryson Delavan, of New York, has shown that tying the carotid artery has but little effect upon bleeding from the tonsil. He suggests that in cases of bleeding after tonsillotomy, fainting should be induced as soon as possible, and to facilitate this and yet prevent excessive hemorrhage, he recommends that the arms and thighs be ligatured close to the body, the patient kept erect, and the bleeding allowed to go on until fainting occurs.

A patient recently came to my clinic on account of frequent attacks of acute tonsillitis. I found that the glands, excepting when inflamed, were not large enough to be removed; therefore, as an acute inflammation was just coming on, I waited a couple of days and then, before the class, removed the glands with the tonsillitome. The glands at the time were not larger than a small almond. The immediate hemorrhage was not excessive, but at the end of my lecture I found that the patient was still bleeding freely. The patient was left in charge of my assistants, Dr. C. H. Guibor, of Beloit, Kansas; Mr. B. W. Sippey, and Dr. A. R. Wittwer, of Cook County Hospital, by whom all of the ordinary methods which I have enumerated were tried one after the other in this case, besides gargles of turpentine, hot

water, and iced alcohol, but none of them checked the bleeding for more than ten or fifteen minutes, until, finally, the patient fainted, after which the bleeding did not recur.

Many patients will ask if removal of the tonsil will alter the voice? I would answer, it cannot injure the voice, and will usually improve it. There is an impression among the laity that removal of the tonsils will in some way injuriously affect the generative organs. I need only mention it to tell you that it is absurd, and that there is no foundation for the belief.

OPEN-AIR TRAVEL AS A CURER AND PREVENTER OF CONSUMPTION,

As Seen in the History of a New England Family.[1]

BY HENRY I. BOWDITCH, M D.,
OF BOSTON, MASS.

"For my own part, I intend to hunt twice a week during my stay with Sir Roger; and I shall prescribe the moderate use of this exercise to all my country friends as the best kind of physic for mending a bad and preserving a good one."—*Sir Roger de Coverley*, chapter xiii. p. 101, Goldschmidt, Edinburgh, 1889.

IT is a curious coincidence that, at the same meeting of the Climatological Association, the President should give you some information gleaned from my recorded cases as to the connection of pleurisy with phthisis, and I should present the history of my father, cured, as I believe, of severe phthisical symptoms by a journey in an open chaise, and by persistent daily walking of from five to six miles during the rest of his life. In connection with this I shall endeavor to show that, by the same persistent open-air treatment of his children during their periods of growth, he was able to prevent the occurrence of the same disease in a large number of his descendants, who, in consequence of himself and his wife being tuberculous, and also first cousins, must have been very strongly *predisposed* to it.[2]

I have a record of this journey as kept by my father in 1808, when he was thirty-five years of age. I found it recently, tied up in a bundle of old papers, which had been resting quietly hidden for over half a century. It is a very compact, precisely written statement of that journey, showing, indirectly at least, its benign effects upon him.

It is eminently suggestive to me of the proper treatment of certain cases of phthisis, and in the hope that it will be suggestive to others also, I now lay it before this Society. To some sensitive minds it may seem to be of too private and personal a character to be placed thus freely before any public assembly. I have no such feeling when questions of human health and happiness are involved.

In 1808 my father was undoubtedly threatened with consumption. He had cough, hemoptysis, anorexia, diarrhœa, and general malaise, with fever and great debility. On August 29th of that year, when thus ill, he started, with a friend as his companion and driver, in an open, one-horse chaise for a tour through New England. At that time it will be recollected that there were no cars, and travel was had in one's own carriage or in public coaches holding nine persons. These were driven over turnpikes or private roads. There were hotels, more or less comfortable, at which travellers could sleep and get food in every town. This record lets us, more or less distinctly, into the feelings, physical and mental, of every day of the month during which the journey lasted. A glance at the map[1] will show that the travellers went from Salem, Mass., down into Rhode Island, thence by way of Connecticut up through the hills of western Massachusetts to Albany and Troy, and back through Massachusetts to New Hampshire, Vermont, and Maine, and then to the home from which he started. During the trip he traveled 748 miles, passed through 113 towns and cities, and the time spent in this daily open-air exercise was thirty days. During that time he went through all stages of feeling of mental discouragement and of physical weakness up to a real enjoyment of life.

Allow me to refer briefly to these changes. Starting from Salem (black) with the prominent signs of phthisis, he was so much exhausted, and had hemoptysis after a drive of twenty-five miles to Milton, that the landlord of the hotel advised his friend to take him home to die, as he could not possibly drive to Taunton the next day, as proposed. (I derive this last statement, not from the journal, but from family tradition.) The travellers were both of them plucky, and not only made that next day's journey, but the sick man felt somewhat better at evening, and notes in the latter part of his record

---

[1] Read before the American Climatological Association, June, 1889.

[2] I am well aware that, since the brilliant discovery by Koch of the bacillus tuberculosis, some writers deny that phthisis *can* be inherited. But surely this opinion I cannot think true. All my medical experience is directly against it. Moreover, we all admit that a certain deterioration of the vital power of the whole, or an abrasion of a part of the body, is necessary for the life and propagation of the bacillus and consequent production of *tubercular* phthisis. Hence, as far as active out-of-door life tends to the production of perfect health in a person or a family, it would seem, *à priori*, that the course pursued by my father, which undoubtedly was of such infinite service in his own case toward the *cure* of phthisis, must have been of great use to his children as a *preventive*, by making them all robust from their earliest years. By so doing he *opposed any tendency* to poor constitutions, impressed on them from their births, which tendencies, if they had not been counteracted from early life, would, I believe, have made his descendants easy recipients of phthisis.

[1] A large map was shown at the meeting marked by circles on the towns where the nights were passed. These circles were entirely black at first, indicating great depression of mind and body, and they became gradually lighter, as the patient got better. Those over the last half of the journey were not only free from any shade, but were surrounded by a red border, indicating the comfortable feeling of returning health.

the condition of the country before arriving at Taunton. His fifty miles since leaving Salem had evidently done no harm, but rather good. Anorexia had gone, as he "dined" (with relish, *apparently*, because he could get nothing else) "on bacon and eggs." Arrived at New Bedford next day, he feels able to visit a friend. He examines a factory. He makes remarks on the inhabitants he met and their employments. Though still having some fever, he feels so much better that much darkness is removed from the circle. Still more refreshed after a night's sleep, and having still less fever, he visits a coal mine recently discovered in the vicinity.

From this time there is almost steady improvement. He visits Newport (109 miles from Salem), admires the harbor, but notices its lack of shipping (to which in Salem with its fleets of ships and their long, wealth-bringing East India voyages he had been long accustomed). At Providence (141 miles from Salem) he finds friends and has pleasant meeting with them. Nothing is said of illness. On the contrary, he has his "Rosinante harnessed" the next day, with the intention of driving *out of his intended route*, in order to visit the cotton factories at Pawtucket Falls. Arriving at Hartford (195 miles from Salem) he is altogether better, finds good fare and a fine hotel. He meets there the judges in their circuit, and has pleasant and profitable conversation with them at the hotel at which they were stopping for the night.

At New Haven (256 miles from Salem, and twelve days of open-air travel) he calls on President Dwight, of Yale College, and regrets that the eminent Prof. Silliman is absent. He visits the library, and finds it wanting in most of the modern English, French, and German scientific works he had been so long acquainted with, and had studied in Salem. At New Haven he makes, for the last time, any allusion to his health, in the following words: "I have a little pain in my breast, but my appetite and general health are good."

After this date, till he arrived home, his record seems like that of a common traveller. He makes no complaints, but describes brightly the places, friends, and others met, exactly as if he were well and travelling for pleasure only.

At Albany he makes an especial and extra journey to Troy with a party of transiently met friends, leaving his chaise for nearly two days in the former city. He found the trip "very pleasant." On return to Albany from Albany to Troy, he had driven 432 miles in nineteen days.

Starting for home, he appears delighted while travelling through a "picturesque" country and meeting at the various hotels intelligent company whose society he was able generally to enjoy.[1] He visits the village of Canaan, and describes in detail what he saw of the Shakers, and heard an extraordinary sermon delivered *at* him, among others, as one of the "outside mankind." I forbear quoting from it. His appetite was becoming ravenous; they would not give him at one tavern, as he says, "half as much as I wanted for my dinner." Finally, he arrived home at Salem, so the record states, "in much better health than he had when starting."

His subsequent course in regard to himself and to his children induces me to believe that the journey, though benefiting him immensely, had not wholly cured him; but it had proved to him the absolute need he had of regular, daily, physical, open-air exercise. Afterward, under walks of one and a half to two miles, taken three times daily during thirty years of life, all pulmonary troubles disappeared. He died in 1838, from carcinoma of the stomach, one lung presenting evidences of an ancient cicatrix at its apex, both being otherwise normal. He was sixty-five years old—*i. e.*, thirty years after the journey.

Having thus experienced, in his own case, the vast benefits resulting from constant, regular exercise out of doors, he apparently determined that his children should be early instructed in the same course. As soon as we were old enough, he required of us daily morning walks down to a certain well-known divine's meeting-house, about three-quarters of a mile, or a mile, from our home. I remember them very well for the tricks played with my brothers on our way down, and for sundry twinges of conscience, felt even at this moment, at the thought that we sometimes decided that the *sight of the "weather-cock* on Dr. Bentley's steeple," though seen more than a quarter of a mile from our proper destination, was near enough to our father's directions!

If any of us, while attending school, were observed to be drooping, or *made the least pretence* even to being not "*exactly well*," he took us from school, and very often sent us to the country to have farm-life and out-of-door "play to our hearts' content." Once he told me to go and play, and to "stay away from study as long as you choose." In fact, he believed heartily in the old Roman maxim, of a "a healthy mind in a healthy body."[1] In consequence of this early instruction, all of his descendants have become thoroughly impressed with the advantages of daily walking, of summer vacations in the country, and of camping out, etc., among the mountains. These habits have been transmitted, I think, to his grandchildren in a stronger form, if possible, than he himself had them.

You will readily agree with me that such habits

[1] This was not always the case, however, for at one town he met one gentleman, "a member of Congress," who was apparently stupid enough. "He scarcely spoke a syllable during the evening."

[1] Mens sana in corpore sano.—Juvenal.

are among the surest guarantees against the prevalence of phthisis in a family. Before detailing the actual result of these habits upon our family, I must state the prospective chances of our escape from the malady. My father married his cousin, who, after long invalidism, died of chronic phthisis in 1834. Certainly a consanguineous union of two consumptives foreboded nothing but evil. They had eight children (born respectively in the years 1805, 1806, 1808, 1809, 1813, 1816, 1819, 1823). Two (born 1809 and 1813—*i. e.*, one and five years after the journey) died, one at eleven and the other at birth. All the others either are now alive, or they arrived at adult life and married and have had children and grandchildren, but not a trace of phthisis has appeared in any of these 93[1] persons.

Now I ask the consideration of this question: To what cause can we attribute this extraordinary immunity from the disease which is generally regarded as showing the influence of heredity and of consanguineous unions more, perhaps, than most other complaints?

If any one can see any other explanation than the influence of this original journey upon the health of one of the great-great-grandparents, conjoined with his wise management of his own health subsequently and his fastening upon his descendants, even to the present day, the virtues of open-air life, I hope he will frankly say so. Truth should be forever our motto, and the man who will convince me of the error of any scientific, or apparently scientific, statement I may utter, and which, if not corrected, may lead others astray, I regard not as an opponent but as my foremost friend.

I submit these facts and thoughts for candid, mature, and *practical consideration* and *use* in the treatment all are called to make of this terrible scourge of all parts of this Union. For my own part I fully believe that many patients now die from want of this open-air treatment. For years I have directed every phthisical patient to walk daily from three to six miles; *never* to stay all day at home unless a *violent storm* be raging. When they are in doubt about going out, owing to "bad weather," I direct them to "*solve the doubt*, not by staying in the house, but *by going out.*"

A cloudy day, or a mild rain, or the coldest weather should not deter them. If the weather be very cold, let them put on respirators before leaving the house and be thoroughly wrapped in proper clothing for the season. I direct them never to stand still and gossip with friends in the open street, as by so doing they are much more liable to get a chill than while walking. Hence, summer and winter alike, my patients usually get plenty of fresh air uncontaminated in a great part, at least, by the previous breathing of it by themselves or by other occupants of the house. This course, I believe, might be pursued in any part of our common country. I am certain that I know of patients who have become well and able to attend to the business of life under this course. May we not also at times send our patients over short distances in open vehicles, instead of thousands of miles off in ill-ventilated cars to an entirely different climate? Have any of us ever sufficiently tried this open-air journeying *at home*, so to speak—that is, in the region of the country where the patient lives, wherever that may be?

Certainly this proposed course has, at least, two sound physiological principles in its favor, viz.: A gentle exercise, for many hours in each day, of the whole frame, and an almost perpetual change of air drawn in with each respiratory act, as occurs while driving in a carriage, open at the front, and in walking. I have no objection to drugs, properly chosen, and I almost always administer them; but if the choice were given me to stay in the house and use medicines, or to live constantly in the open air without them, I should infinitely prefer the latter course in case of my being threatened with pulmonary consumption.

[1] The number of their descendants amounts now (1889) to 8 children, 31 grandchildren, 50 great-grandchildren, 4 great-great-grandchildren—total 93. It may be noted that of the two who were born in 1809 and 1813, one died when eleven years old (1820) and the other at birth (1813), while the writer and reader of this paper was born twenty days *before the journey began.*

NOTES ON THE PREVALENCE OF DIPHTHERIA AT HIGH ALTITUDES.[1]

BY S. H. CHAPMAN, M.D.,
OF NEW HAVEN.

IN August last, during an excursion to Franz-Josephshöhe—9500 feet high—into the heart of the great glacial region called Gross Glockner, in Eastern Austrian Tyrol, my guide related circumstances of an epidemic occurring during the early spring of the preceding year, in his native village of Heiligenblut, which aroused my curiosity.

On my return to the village of Heiligenblut, which is the starting-point of all excursions into that region of snow, I made inquiries of the factota of the village; of the hostess of the inn, who is the chief personage in all Tyrolean villages; the priest; and the telegraph operatress. Their statements verified and amplified those made by my guide.

Upon my return to Lienz, the nearest post and railway station, I called upon the only physician of the town; who, while being the only physician within a radius of thirty miles, is also the military surgeon in charge of the government hospital for the district of Lienz, and, therefore, a personage of authority and influence. He received me with great

[1] Read before the American Climatological Association, June 25, 1889.

cordiality, and gave me an accurate description of his share in the epidemic, and as accurate statistics of the epidemic as was possible to one who had kept no special record of it. He enlarged the field of my search by describing outbreaks in Lienz proper and in a village called Windisch-Matrei. His statements as to the latter were also verified by the hostess of the inn at that place. These data, culled from various sources, I have briefly transcribed, with such descriptions of localities and circumstances as may tend to illuminate the whole.

The architectural and ground plans of Tyrolean houses are the same; the size only varying according to the wealth of the proprietor. This general plan has been perpetuated for hundreds of years, having been found the best to fulfil certain absolutely necessary conditions of living in so rough a climate. A wide entrance hall, ending in a stone staircase leading to the sleeping-rooms above, paved with stone and roofed with heavy arches of stone, is effectually closed in winter by massive doors. The only entrance in winter is through a narrow door let into one of the great panels. On one side of this hall are two entrances, seldom closed by doors; one into the great stone kitchen and the other into the living room; the only rooms occupied except at night. On the other side of the hall is one entrance, always open, leading into a broad and deep stable. Here are kept the horses in summer, while the sheep, goats, and cattle are on the Alps, high up above the village. But with the first heavy fall of snow the cattle are driven down from the hills. The sheep and goats, horses and cows, pass through the narrow entrance, the huge doors are shut, and there they remain throughout the long winter.

The fluids and solids which naturally accumulate with rapidity, are, occasionally, transported, with some slight attempt at cleanliness, to a great stone pit enclosed by the walls of the house, but situated directly to the rear of the stable. Still the cattle stand fetlock deep in mire. The animal heat from so large a number is so great that the temperature in the stables stands steadily at that of June; finding an escape through the always-open door, the heated air warms the hall; mingling with the heat of the kitchen fires, it diffuses itself through the living-room, and escapes up the staircase to the sleeping-rooms above. An effective and economical steam-heating system.

Lienz, 3100 feet above the level of the sea, is a town of a few thousands of inhabitants. It is situated on an extensive plain, surrounded by mountains. A swift-running river passes through it, into which all the drainage, which is altogether on the surface, runs.

Windisch-Matrei, 3700 feet, is a village of a few hundred inhabitants, situated on a spur of a great mountain, overlooking a deep valley. Mountain torrents rush through it; its single street is paved with cobbles.

Heiligenblut, over 5000 feet above the sea, hangs, like a swallow's nest, to the side of a precipitous incline, hundreds of feet above the brawling stream of ice-cold water fed by the great glaciers four thousand feet still higher. The stones of its single narrow and tortuous street are washed by the constant overflow of a torrent which rushes past to meet the stream in the gorge below. The scenery is forbidding. The surface of the ground seems stone, polished smooth by the storms, and glistening dry under the noonday sun.

Heiligenblut has about half the population of Windisch-Matrei. From June to October a telegraph station is located here. For the rest of the year the post-wagon twice a week, except when winter's snows have covered the roads deep; then communication with the outside world entirely ceases, except for some random visitor whom the Government makes its temporary postman. For six weeks, at least, previous to the outbreak of diphtheria, all witnesses alike testified that Heiligenblut had been entirely isolated.

During the summer the journey from Lienz takes more than twelve hours, so that travellers are accustomed to halt over night. For half the distance the road is too narrow for the ordinary carriage, and so steep and dangerous that one prefers to trust to feet rather than wheels. The road to Windisch-Matrei is, however, a good post-road, and by no means so long or hard. Winter closes upon Heiligenblut in September, and does not let go its hold before the middle of May. In fact, throughout the summer, in sheltered nooks on a level with the village, there are still reminders of winter's severity in the shape of banks of snow.

Early in February, 1887, the only child of the richest peasant of the valley, a boy of ten, sickened and died in three days. The symptoms, as related by the peasant, were grim in their simplicity: "The lad was well; all at once he couldn't swallow; his neck was swollen, and his throat very sore; then suddenly he died." There were no other cases of illness until after the first of March—not such a March as we ordinarily have, but a March of blizzards, of Arctic cold and of snow six to eight feet deep on a level. Then, simultaneously, many children were attacked, and died.

At the end of a week of the "plague," as the peasants called it, notwithstanding the danger attending the journey, a messenger was dispatched for the doctor, who, after a toilsome journey of two days, reached the village. The physician pronounced the disease diphtheria of a virulent type. His treatment consisted of insufflation of sulphur, and poultices to the neck.

His treatment was so unsuccessful that the peasants

had recourse to charms, prayers in the church night and day, and to the aid of an aged peasant—a kind of oracle in the village—whose treatment, the peasants averred, saved more lives than did that of the doctor. It consisted of an ointment of sweet cream and powdered gunpowder.

The physician's statistics were—sixty cases, forty-eight deaths. By the end of March the disease had disappeared. The disease was entirely unknown to the oldest inhabitant. The description of the disease by the physician was somewhat meagre—he adding, to the account by the peasant who lost his son, only these facts: The crisis was reached in from two to three days; besides the swelling of the glands and inflammation of the throat, there was often severe hemorrhage from the nose preceding collapse. There was no attempt made to isolate cases.

Early in April—carried in the clothing of a victim of the outbreak—the disease appeared in Windisch-Matrei. This bundle of clothing was taken over the mountain direct to the latter village, by a route that makes one of the most delightful excursions in summer. But the virulence of the poison had become much attenuated—to such a degree that ten cases only occurred, and of these, six died.

From Windisch-Matrei the disease was caried down the valley to Lienz, appearing there in the latter part of April. The statistics of its outbreak there, however, are too obscure to be relied upon, the evidence going to show that but few cases occurred, and that the mortality was less than half.

The physician considered the disease atmospheric, non-contagious, and uninfluenced by treatment of any sort. As an illustration of his theory, he related the following case: In a family of nine children of poor people, occupying two or three rooms only, two children under ten were simultaneously attacked. Treatment was—nothing. One recovered, the other died, and the remaining seven escaped the disease altogether, notwithstanding that the cases were not isolated.

I have ventured to relate these incidents, perhaps less concisely than was necessary, because of the interest attaching to the question of the development of diphtheria at so high and isolated a spot. It seems possible, from the foregoing data, to draw the following conclusions:

That the latent germ was stimulated into active development in the steaming, fermenting, fevered atmosphere of the stable.

That its virulence was rather increased than diminished by the high altitude and by the rarity and low temperature of the air.

That propagation from house to house was not hindered by the passage of the germ through a rarefied air of very low temperature.

That the impulse of the germ became less and less violent as time elapsed after its first appearance.

That the history of this epidemic seems to show that there took place a special culture of the specific microbe, in definite quantity; that all the cases were attacked by the originally developed microbe; but that, under the wearing action of time and atmospheric conditions, its virulence became more and more attenuated until it again passed into a harmless period of existence or became scattered in localities unpropitious for further development.

HOSPITAL NOTES.

JEFFERSON COLLEGE HOSPITAL.

CLINIC OF J. M. DA COSTA, M.D.

(Reported by E. P. HERSHEY, M.D., Clinical Assistant.)

DIABETES INSIPIDUS CURED BY ERGOT.

October 11. H. Y., æt. seven, last March had an attack of mumps; during convalescence jaundice appeared and remained two or three months. Since April 1st he has complained of great thirst, shortness of breath at night, has great difficulty in breathing and he passes large amounts of water, *i. e.*, six quarts in the twenty-four hours. There is no history of malaria. The appetite is variable. Temperature 99.2°. The heart is excited, there is an extended impulse. No increase in percussion dulness; no murmur. The first sound is slightly increased; the second sharp. There is nothing in the heart to throw light on the case. The lungs are normal.

The tongue is slightly coated, particularly toward the back. The skin is extremely dry, and so marked at night that the mother has to wet it. There is no history of an injury. The digestion has been poor for the past four years. At times the bowels are loose, at others constipated. Early in the case there was flatulency, not so now. A thorough examination for sugar failed to reveal its presence. The specific gravity 1002, acid, pale, and no albumin.

Although no sugar is found in the urine in diabetes insipidus, there is a question whether or not there is something which takes its place, as characteristic of this affection as is grape sugar of diabetes mellitus. Inosite is a variety of glucose occurring in the muscular substance of the heart and other organs of the body, and is said to have been found in the urine of this form of polyuria. Should this be established we may be able to get at the cause.

The ordinary diabetic sugar is not present here. The dryness of the skin, the patient once having had itching and extreme thirst, are like saccharine diabetes.

The most common idea as to the cause of this affection is, that it is due to a state of depressed innervation. It is seen in the recovery from low forms of fever. Women who have much mental anxiety, and not necessarily hysterical, have it. To the category of causes, too, are referred blows and injuries to the head, which bring about the affection by disturbing brain centres; and it has been found in lesions irritating the floor of the fourth ventricle.

The prognosis is favorable. Formerly it was very unmanageable, but since the action of certain medicines has been ascertained, there has been decided advancement in the treatment.

The diet is of no great importance. A mixed one is permitted. Meat, green vegetables, etc., most easily digested may be eaten. Regulate but do not restrict the diet. In order to insure digestion, we shall give him liquor pepsini ℥ss to ℥j at each meal. Look for medicine that will contract the vessels of the kidneys. Ergot is the most valuable here. Some years ago I published eight cases cured by this method; since that, nineteen or twenty were cured by it. Give enough ergot and you will get good results. ℞. Ext. ergot f℥ss three times a day. Caution the patient to drink as little as possible. Take small pieces of ice. For dryness of skin rub in vaseline at night. Another remedy has come up, which has already gained so much notoriety in other affections. Antipyrin grs. ij three times a day is supposed to have a great effect in polyuria. Should we fail with ergot we shall try this remedy.

The patient made an entire recovery.

MEDICAL PROGRESS.

Treatment of Diphtheria with Acid Sublimate Solution.—It is to be regretted that the enthusiasm of medical investigators is not more circumspect. Physicians, as a rule, are too apt to endorse a remedy, and claim for it undisputable curative properties when, perhaps, their own experiences have been most meagre. True, the profession as a whole is of a sanguine nature, and not disposed to be over-critical; and, therefore, newly advanced therapeutic measures when even of but doubtful efficacy will always find scores of ardent advocates. The diseases which fall prey to such "new cures" are invariably those whose therapy is still a matter of debate and investigation. Foremost among these is diphtheria, and glaring headings announcing, "A Cure of Diphtheria," stare at us from the pages of the vast majority of journals that pass through our hands. The results of long and careful investigation, and conclusions based upon numerous results and honest conviction are, however, always to be welcomed.

It is now considerably over a year ago that DR. RENNERT, of Frankfort-on-the-Main, first treated a case of diphtheria with local applications of acid sublimate solution. Since then sixty-two cases of this disease have been similarly treated by him. In every instance the treatment was entirely successful, and now Dr. Rennert submits, in the *Berliner klinische Wochenschrift* of August 26th, the results of his labors to the profession.

Rennert's attention was first called to the utility of the addition of acids to disinfectants by Laplace's article on the subject. He then used acid sublimate solution with great success in the treatment of wounds. The primary results obtained by him when first using the solution in diphtheria so typically describe its action that we reproduce a brief account of the cases:

A vigorous, healthy child had, in spite of all his endeavors, just died of diphtheria. When calling a few hours later, the mother complained of dizziness, headache, weakness and heaviness of limbs, and irritation of the throat. Upon the left tonsil was a thick, white diphtheritic membrane, the size of a quarter. Rennert wrapped a pad of cotton around a pair of forceps, and, after soaking it in the acid sublimate solution, wiped off the diphtheritic membrane with it. There was slight bleeding from a few points, and these were again washed over with the solution; likewise, the other tonsil. There was no other treatment. The woman slept well all night, and awoke the next morning cured. This day the maid-servant was reported ill. In her case the disease was far more advanced, both tonsils being covered with diphtheritic membrane. The patches were wiped away with difficulty, owing to their adherence to the mucous membrane, but the same treatment was applied. The patient's fever sank immediately. The remedy was again applied in the evening and on the following morning. On the evening of the second day she was cured.

Encouraged greatly by these most satisfactory results, Rennert proceeded to test the treatment in a number of cases. The choice of cases in which the acid sublimate solution only may be used is restricted to such in which it is possible to remove all the diseased membrane. Where this is impossible, other therapeutic agents should be used in connection with the solution. In one case of diphtheria extensively affecting the nose, a three per cent. solution of boric acid, locally, was used with great success in connection with the sublimate applications. The intensity or nature of the disease, whether croupous or membranous, should not contraindicate its use.

Regarding the technique of the method, the solution used was composed of 1 part sublimate, 5 parts tartaric acid, and 1000 parts water. Laplace's experiments have shown that this formula exerts a far more intense and rapid germicidal action than a simple sublimate solution of the same strength. For its application Rennert uses a wad of cotton about an inch long and half an inch thick when wrapped around a pincette. After soaking the wad in the solution, he proceeds to wipe off the diphtheritic membrane with it. This is frequently not done without considerable difficulty, and the use of three to five cotton wads are necessary for one side. After the membrane has been entirely removed, wounded surfaces will be left which almost invariably bleed slightly. Then the entire pharynx should be swabbed out with a larger cotton wad soaked in the solution. This procedure should be repeated every six or twelve hours. In the majority of cases the patient is free from fever after the second application, but it should be repeated every morning and evening until healing is complete. The results of the treatment have already been referred to; sixty-two cases were treated, and all recovered. It seemed that the disease was invariably speedily aborted. When the malady was so far advanced that it was impossible to reach or remove all the diseased membrane, Rennert did not attempt to remove completely any of it, excepting that which came away quite easily, but repeatedly touched the diseased surface as far as he could reach with the solution. Simultaneously Rennert treated twelve other cases with other remedies; two died, seven very light cases recovered, and two recovered only after the other remedies had been discarded and acid sublimate solution substituted.

The danger of sublimate poisoning during this treatment is absolutely *nil*. Rennert, by careful measurement, found that the usual cotton wad employed soaked up seven minims of the solution, and the larger wads used at the close of each application sixteen minims. As he never used more than ten or twelve wads in one application, therefore scarcely one and a third fluid-drachms, the amount of sublimate was only one-four-

teenth of a grain; and considering that the majority of this was lost through expectoration, poisoning from such a quantity would be impossible. Rennert strongly points out the absolute necessity for a thorough carrying out of the treatment, and the absolute worthlessness of doing it half way.

The Sacral Operation in Gynecology.—The new method of sacral extirpation of the uterus and uterine tumors is gaining ground in Germany. Recently DR. HOCHENEGG has performed it successfully in two cases, which are reported in *Fortschritte der Medicin* of August 15th.

His method of procedure was as follows: In the first case, free access to the pelvis was first gained by dividing the recto-vaginal and respectively the recto-vesical septum. The carcinomatous uterus was so strongly adherent that the extirpation could not be completed according to the usual methods. The superficial incision was curved; the coccygis was extirpated and the right wing of the sacrum resected below the third foramen; the attachments with the rectum then divided, the peritoneum opened, and the uterus drawn forward; the vessels were then isolated, ligated, and cut through; the cervix then cut through, and the extirpation completed per vaginam. The peritoneum was partially sutured and both wounds drained.

In the second case, the extirpation was for a tumor firmly attached to the uterus. The growth was situated on the left side, was as large as a man's fist, cystic, and intra-ligamentous. Here also the coccygis was excised and the left wing of the sacrum partly resected. The rest of the operation was performed with blunt instruments as far as possible. On account of the firm adhesions of the tumor to the uterus, the latter had also to be extirpated from the cervix, and was removed through the sacral wound. The isolated vessels were then ligated, the stump of the cervix sutured with silk. The peritoneal wound was packed with iodoform gauze, and the sacral wound left open. Healing was rapidly effected, but for some time a small fistula remained in the sacral wound.

The advantages of this new method of operating are as follows:

1. It is of superior value in such cases where adhesions or fixation of the uterus render extirpation per vaginam technically impossible.

2. By means of this operation the retro-peritoneal lymphatic glands can also be removed, which fact is of great importance, as they are often found carcinomatous. The prognosis is, therefore, more favorable.

3. The operation is also practicable for small tumors which can neither be extirpated by laparotomy nor per vaginam. Greater control of hemorrhage and drainage is possible. Finally, the danger of ligating the ureters is greatly diminished.

Pyopneumothorax Tuberculosus.—The method of the treatment of pyopneumothorax in consumptives is one of the most important questions of internal therapeutics. On the one hand it is the connecting link between the treatment of pleurisy and its accompanying complications, while, on the other hand, it is directly connected with the therapeusis of phthisis in general.

While the surgical treatment of pleural exudations has, of late, been almost satisfactorily determined, still the study of tuberculous pyopneumothorax has yielded but poor therapeutic results. Senator, Fräntzel, and Leyden have been of the opinion that the treatment should be restricted to the relief of the principal symptoms; from time to time the air and exudation are removed from the pleural cavity by means of aspiration, in order to afford temporary relief to the patient. Otherwise the treatment was merely for the phthisical condition.

After surgical interference the patients almost invariably collapse and die. Some patients indeed, offer primarily, a general favorable condition; but are sure in spite of all care, to succumb sooner or later. Weyl affirms that over one-tenth of phthisical subjects develop pyopneumothorax; of these about twenty-five per cent. are still in a well-nourished condition when attacked. The results of "thoracotomy" have been far from encouraging; the cases which survive the operation for any length of time are very few in number.

For the past year PROFESSOR LEYDEN has been devoting considerable time in the study of this complication. In an address published in the *Berliner klinische Wochenschrift* of August 5th, he tells of six cases of pneumothorax which came under his treatment, three of which were operated upon.

The first of these, who died a few days after the operation, was suffering from sero-pneumothorax. Such cases, he holds, should be excluded from the operation, as but slight relief is afforded thereby, and suppuration continues actively even after emptying the cavity. Potain, of Paris, treats such cases by aspiration of the exudate and injection of a similar quantity of sterilized air. In one case of a patient suffering from pyopneumothorax, Potain, after a year of treatment, not only succeeded in curing the pyopneumothorax but also the tuberculosis. A second case reported by Leyden survived the operation for four months. Autopsy showed advanced phthisis, amyloid in liver, bowels, and kidneys.

The third case still lives, ten months after the operation. The patient is a man aged twenty-seven years; thoracotomy was performed and a quart of pus evacuated. After the operation the patient's condition was most precarious. He could eat nothing and had severe dyspnœa. Strength was, therefore, maintained for several weeks by gavage. Leyden is of the opinion that the importance of alimentation is not sufficiently taken into consideration. In all diseases where the danger is chiefly in a wasting of strength, or consumption of tissue, proper nutrition of the patient is of all importance. The required proportions of albuminates, fats, and carbohydrates, should be acurately determined in order to effect an increase of the weight of the body.

The result of his observations have proved to him that the patient needs a greater amount of nourishment than the healthy subject. The patient should be compelled to eat what he needs and not only what he wants. Dujardin-Beaumetz and Debove have both highly lauded the efficacy of increased alimenation, especially in the therapeusis of phthisis.

To effect the proper nourishment of the patient moral and mechanical force are often necessary. The moral force of the physician's authority is valuable, but the use of mechanical force in the shape of the stomach-pump (gavage) is sometimes unavoidable. The choice of foods is most important, and should be of such a nature that the patient can both digest and retain them. Unwaver-

ing care and untiring zeal are necessary, on the part of the physician, in the accomplishment of this point. The ground gained is gained but very slowly and can be lost again only too easily. Upon these principles Leyden bases the therapy of pyopneumothorax, subsequent to the operation of thoracotomy. The process of healing is very slow, and pus will be discharged for a long time, yet when the strength is thoroughly reëstablished the danger from pneumothorax may safely be regarded as past.

Sexual Asthma.—DR. A. PEYER, in *Wiener med. Wochenschrift* of August 22d, asserts that a large number of cases of asthma are due to a sexual origin, both in males and females. The sexual disturbances exert an influence upon the sympathetic nervous system, and this, in turn, calls forth the asthmatic attack. In many instances this may be occasioned by sexual excitement, or by the sexual act; or, again, by nocturnal pollutions.

Peyer quotes also sixteen cases of sexual diseases which were undoubtedly the cause of asthma. In the male sex, eleven cases were spermatorrhœa; these were accompanied by functional anomalies, pollution, and impotence. In five cases of asthma in the female, Peyer diagnosed one case of uterine fibroid, one case of leucorrhœa, one case of vaginal and cervical catarrh with hyperæsthesia of the vulva, resulting from masturbation, one case of uterine catarrh with induration, and one of chronic endometritis.

Lactose, a New Diuretic.—PROFESSOR GERMAIN SÉE speaks most highly of a new diuretic, lactose, which, he asserts, is of special efficacy in dropsies arising from cardiac diseases.

About three ounces of lactose given in solution with rum or menthol, produce a diuretic action which could not be realized with five quarts of milk. Sée allows the patient to take any desired diet during the treatment with lactose. The remedy is not so applicable in dropsies of a renal origin. In the latter class of cases, it is necessary to recur to caffeine. Neither lactose nor caffeine causes any vascular compression, as do both digitalis and strophanthus. Lactose should be continued for about ten days; it would be then well to stop for a time, but it should again be used when necessary.

Germain Sée speaks in the highest possible terms of the drug, and says that in it we have the only positively trustworthy remedy in cardiac dropsies.

DR. DUJARDIN BEAUMETZ confirms the results obtained by Sée, but also states that a similar diuretic action will be observed to follow the similar use of grape-sugar, or glucose.

The Operation and Prognosis of Extirpation of the Tongue.—In Professor v. Volkmann's clinic, in Halle, two methods of extirpation of the tongue are employed; if the tumor is so situated that it can be drawn forward to the teeth, the simple operation with scissors and knife is employed. DR. F. KRAUSE, in describing the operation in the *Deutsch. med. Wochenschrift*, says: The patient is narcotized in a sitting posture, a wire loop passed through the tongue, and the organ then removed by scissors or knife, as may be found most convenient. Spurting vessels are singly secured as divided. After the hemorrhage has ceased, the wound on the floor of the mouth is sutured as far as possible, or if only a portion of the organ is removed, the tip is bent over to the side and the two raw surfaces are sutured together, so that the tongue is shortened but retains its breadth. Should the growth be so extensive that it cannot be drawn forward to the teeth, or should the floor of the mouth, palate, or tonsils be also implicated, the second method of operation, with division of the lower jaw, is employed. The patient is, as in the first method, narcotized in an almost sitting posture, a wire loop passed through the tongue, the organ being also secured with strong artery forceps; if necessary, the canine or first bicuspid tooth is removed; a skin incision is then made from the angle of the mouth to the level of the larynx, the tissues over the jaw being at the same time divided to the bone; the periosteum is freed from the inner surface of the jaw and a strip of metal is passed beneath it. The jaw is then divided with a very thin-bladed amputation saw, under constant irrigation with boracic solution. Hooks are inserted into the maxillary canal, and the two halves of the jaw drawn asunder. The soft parts are now divided in a direction corresponding with the skin incision, if necessary as deep as the great vessels. By this means the whole of the diseased tissue and implicated glands can be removed. Spurting vessels are tied at once. The anterior faucial pillar is always divided, and a large drainage tube is placed immediately behind it and brought out at the lower part of the skin incision, thus allowing all secretion or possibly ingested fluids to escape. The remaining portion of the tongue is sutured to the mucous membrane if necessary. Tampons of iodoform gauze are employed, and the bone is sutured with strong silver wire. As to after-treatment, the patient is supported in a semi-sitting posture, and fed from a long-spouted glass vessel, and after each meal the mouth is washed with 3 per cent. solution of boracic acid. The mortality in the severer operation (in 35 cases) was 5.7 per cent.; in 56 partial resections of the tongue without division of the jaw, there was no death.

The results, so far as known, of the cases operated on are as follows: Of the 35 cases of total extirpation, with division of the maxilla, 2 died in hospital, one in eight days, the second five weeks after operation (pneumonia), 16 are known to have died with recurrence, 3 are known to be alive, 1 only, operated on 6 years ago, having no recurrence. Of the 56 partial extirpations, 37 have been followed; of these 2 died with metastasis, four and six months respectively after operation, 19 died with recurrence of the tumor—average duration 10½ months, 9 died from other causes, without recurrence, 7 are still living and have no recurrence of the disease. It must be added that in all the cases the clinical diagnosis was confirmed by microscopical examination, and all tumors not carcinomatous are excluded in the above statistics.—*Medical Chronicle*, September, 1889.

Treatment of Warts.—ALTSCHUL recommends the treatment of warts by Unna's method, namely, mercurial ointment, containing five to ten per cent. arsenic. The ointment is spread on linen, and applied over the wart, which gradually softens, and is finally absorbed without leaving any mark. The method is painless. The treatment of warts by arsenical paste is by no means a new one, and its efficacy has been frequently confirmed.—*British Medical Journal*, September 14, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 28, 1889.

ANTIPYRIN IN DIABETES.

SOMETHING more than two years have elapsed since D. GONNER called attention in the *Correspondenzblatt für Schweize Aerzte*, No. 19, 1887, to antipyrin as a remedy for diabetes. Since then it has received numerous trials, especially at the hands of the French school of physicians, including Huchard, Robin, Dujardin-Beaumetz, Germain Sée, Panas, and others. If the experience of these observers be received, it must be said of antipyrin that, excepting opium, it is the only drug to which a direct and efficient controlling power over glycosuria can be ascribed.

Although the precise position of this remedy in the treatment of diabetes cannot be said to be determined, a number of valuable practical facts may be deduced from the experience of the French physicians, as follows: *First.* It is the milder forms of the disease in which it has been found most efficient. *Second.* It is administered either alone or in combination with sodium bicarbonate, the latter being preferred by Robin. Fifteen grains of antipyrin, combined with twice as much of the alkali, are given four times a day, an hour before or after meals, and this is kept up for from eight to twelve days. Then the treatment is suspended, in order to avoid albuminuria and other toxic effects which excessive administration of antipyrin may produce. This period of intermission is continued until the sugar again returns or increases, say for a week. While the patient is taking the antipyrin a moderate amount of starchy food, even potatoes and bread, it is said, may be taken, to be discontinued again during the intermission, and thus the craving for these foods is supplied. The antipyrin alone is used in the same manner. In the hands of PANAS (*Le Progrès Médical*, April 13, 1889) so small a quantity as forty-five grains caused the entire disappearance of sugar in one case, although it immediately returned when the dose was diminished or the administration ceased. A *third* fact generally acknowledged by those who have had experience with antipyrin is, that it is in no sense a cure for diabetes; simply averting, during its use, the miscarriage of an important variety of food, the hydrocarbons, and thus conserving the energies of the patient. *Finally*, antipyrin should be cautiously used in cases of nephritis, on account of its well-known tendency in large doses to produce albuminuria, although its use should not be altogether interdicted on this account. Whenever, however, in non-albuminuric cases, albumin appears in the urine, it should be discontinued, as it should also so soon as it is found to produce no effect upon the sugar. It is of doubtful efficacy, also, where tuberculosis has occurred in the course of the diabetes, and where, although it diminishes the sugar, the specific gravity of the urine, nevertheless, increases; also in cases where the sugar exceeds three or five ounces per quart. It is to be stated, also, that good effects of antipyrin obtain in the polyuria of diabetes insipidus, as originally announced by Huchard in *Revue gén. de Clinique et de Thérapeutique*, No. 7, 1888.

How does antipyrin act in influencing the glycosuria of diabetes? Very probably through some influence on the medulla oblongata, as suggested by Huchard, who was led to its use in diabetes mellitus by a consideration of its marked effect on other diseases of bulbar origin, as, for example, Graves's disease, its effect as an anodyne, and its effect also observed of converting a diabetes mellitus into a diabetes insipidus. In a word, it must act similarly to opium, and if it produces its effects without the disadvantages of opium, it must prove a valuable acquisition to our armamentaria against diabetes.

THE TREATMENT OF POST-PARTUM HEMORRHAGE.

PROBABLY no subject in obstetrics gave greater scope to the dramatic powers of lecturers on this branch of medicine fifty years ago than post-partum hemorrhage, and the graduate went to the parturient

prepared to "turn out the clots" and grapple with appalling exsanguination.

Increased knowledge of the causes of such hemorrhage and of the physiology of labor, with general improvement in methods and appliances for the conduct of labor, have diminished the frequency and mortality of this complication, and in well-appointed maternities and in the hands of intelligent practitioners death from this cause is rare.

The most frequent cause of bleeding after delivery is failure of the uterus to contract; Credé's method of expressing the placenta, the frequent use of the hot douche, of uterine massage, and ergot generally induce uterine contraction promptly and efficiently. There remain, however, cases in which an abnormality in the contraction of the uterine muscle results in failure to close the uterine sinuses; the means usually employed fail, and a prompt and radical procedure is demanded. An application directly to the interior of the uterus is usually sufficient in these cases. Such may be a hot intra-uterine douche of antiseptic fluid; the injection of vinegar; a bit of ice carried within the uterus, or reflex stimulation of the uterine muscle by the antisepticized hand carried to the fundus.

A more reliable procedure than these, and a permanent check to bleeding, is the use of iodoform gauze as a uterine tampon. BORN and ECKERLEIN (*Centralblatt für Gynäkologie*, Nos. 25 and 26, 1889) report the most prompt and satisfactory results from this treatment. A strip of gauze four inches wide and two or three feet long is carried by the finger or a simple uterine applicator notched like an arrow, to the fundus; usually the presence of a single strip suffices, and the remainder is used to tampon the vagina moderately. Should more than a single length of gauze be easily admitted, the uterine cavity is moderately distended, and an additional strip is used for the vagina. In the absence of iodoform gauze any antiseptic material of similar dimensions may be employed. Such tampons may remain twenty-four or thirty-six hours in position, and may be renewed, with antiseptic douches, whenever required. Arterial bleeding from extensive laceration of the cervix may be promptly checked in this manner.

The value of the iodoform gauze tampon in bleeding from low attachment of the placenta has been clearly shown, and the treatment by this means is an established procedure. There is every reason to urge a similar adoption of the same efficient agent in treating post-partum hemorrhage.

BIOLOGICAL AND CHEMICAL EXAMINATION OF WATER.

WHILE chemical analysis alone is sufficient for accurately determining the quality of water used for most purposes, and is in fact the only method for such determination, its results are not sufficiently comprehensive to enable us to judge positively of the purity of water for dietetic use. Minute living organisms, the pathogenic and saprophytic bacteria, which enter as a factor of supreme importance in deciding the quality of a water from a hygienic standpoint, elude detection by the most delicate processes of chemical investigation. Their presence may be suspected from the determination of impurities derived from sewage, or some other source of pollution, but no reliable judgment can be formed without the aid of bacteriology. On the other hand, the bacterioscopic examination, employed alone, affords important but only partial results. Chemically pure water may contain a large quantity of bacteria, and almost perfect freedom from the latter is not inconsistent with the presence of waste organic matter. In order, therefore, to form a more exact opinion as to the purity of any given sample of water, both the biological and chemical methods of examination should be employed.

Injury to health attributable to impure water is for the most part connected in some way with the presence of microörganisms, and hence the study of the infections is of great moment. Among the infectious diseases which may arise through the use of impure water, Gärtner classes the affections due to the filaria, distoma, amœbæ, etc., but more particularly the diseases caused by bacteria. These disease germs are capable of living for a time in water, and through this medium of infecting the human body.

It is a well-known fact that most natural waters contain some bacteria. They are very abundant in river-water, less so in lake-water, still less in well-water, and least of all in spring-water. Most of these forms are perhaps not positively injurious, but their presence in greater or less quantity may be taken, with some reservation, as a gauge of the relative degree of pollution. The mere number of microörganisms, however, has no necessary or invariable connection with the wholesomeness of a water or the reverse; it is rather the quality or kind of microörganisms that determines this question. Pollution may be derived from such a source as may admit of the possible impregnation of the water with pathogenic germs; such, for example, as

those of typhoid fever. The specific organism may elude detection, but the presence of bacteria in excessive quantity is a sufficiently suspicious circumstance to warrant a sanitary survey of the source of the water and its mode of storage.

While the cultivation test as applied to water analysis has not been practically as successful in isolating pathogenic germs as could be desired, it must be remembered that this mode of investigation is yet in its developmental stage, and that we are gaining knowledge every day. The prospective usefulness of this method of investigation depends on the ability of biologists to distinguish between pathogenic and harmless organisms.

The certain exclusion of all infectious material is the chief object to be attained in establishing the wholesome quality of a water. Now, as many forms of infectious matter are as yet unknown; others exhibit little or no distinguishing peculiarities of growth on the gelatine plate; and as others again, like the typhoid bacillus, present so little that is characteristic that they cannot be distinguished with facility, it would seem that the bacteriological examination, which, for the most part, brings to light only harmless saprophytes, is of little practical value. It must be observed, however, that the filtration process is the only practical means of removing infectious matter from water, and that bacteriological examination is the only means of testing the efficiency of this process. Although we may fail to detect the pathogenic bacteria in drinking-water, we are justified in assuming that a process of filtration which excludes all other forms of bacteria, offers a barrier to the pathogenic forms. Until the method of examination by the culture process was discovered, there was, as Frankland remarks, no available means by which the relative efficiency for the removal of microörganisms of different filtering materials could be estimated, on a quantitative basis. This test is now recognized as being of great practical value, and has been satisfactorily applied in a number of European cities which resort to the plan of purification by filtration as the best means of removing organic impurity.

A good illustration of the importance of the combination of the biological and chemical methods of water examination is presented in the report of the investigation of the water supply of Minneapolis, embodied in the *Transactions of the Board of Health* of that city for the year ending March, 1888, which was conducted independently by Dr. Prudden and Prof. Leeds, with the object of determining the cause of the epidemic of gastro-intestinal disease which prevailed in that city in the winter of 1887 and 1888. Each method of analysis presented important but only partial results, but when combined they supplemented each other's deficiencies, and showed the cause of the disease to be in all probability in the water, which was grossly polluted with sewage and swarming with microörganisms, a teaspoonful of this water being estimated to contain, on an average, 30,000 living bacteria. Dr. Prudden succeeded in isolating, from the contents of the intestines of a fatal case, bacteria which do not belong in the intestinal canal, and which are capable of producing acute gastro-enteritis, with or without fatal results, in rabbits. This fact, studied with others developed by the investigation, points strongly to impure water as the probable origin of the epidemic.

The biological test affords us the possibility of detecting the specific agents of infection, but this result is as yet comparatively restricted. Its special value at present is based upon the fact that the pathogenic bacteria belong to the class of microorganisms which are recognizable, and, as Welch remarks, from the behavior of these forms conclusions may be drawn with regard to the behavior of those of pathogenic origin.

AT a meeting of the Executive Committee of the Congress of American Physicians and Surgeons held in Philadelphia last Saturday, Dr. S. Weir Mitchell was elected President of the next Congress, which will be held in Washington in September, 1891, and Dr. W. H. Carmalt, of New Haven, was elected Secretary, Dr. J. S. Billings, of Washington, Treasurer, Dr. William Pepper, of Philadelphia, Chairman of the Executive Committee, and Dr. S. C. Busey, of Washington, Chairman of the Local Committee of Arrangements.

AT the late meeting of the American Gynecological Society, Dr. Robert P. Harris, of Philadelphia, was elected an Honorary Member of the Society.

AT the Annual Meeting of the American Pediatric Association, held last week, the following were elected officers for the ensuing year: *President*, J. Lewis Smith, of New York; *Vice Presidents*, Arthur V. Meigs, of Philadelphia, and F. Forchheimer, of Cincinnati; *Secretary*, W. D. Booker, of Baltimore; *Recorder*, W. P. Watson, of Jersey City; *Treasurer*,

Charles Warrington Earle, of Chicago; *Member of Council*, L. Emmet Holt, of New York.

THE corner-stone of the new building for the New York Academy of Medicine on West Forty-third Street will be laid next Wednesday, at 4 P.M. The order of exercises includes an invocation by Bishop Potter, an address by Dr. A. Jacobi, remarks by ex-President Cleveland, and the formal laying of the corner-stone by the President of the Academy. Dr. Alfred L. Loomis.

THE first general meeting of the Continental Anglo-American Society will be held at the Grand Hôtel, Paris, on Monday, September 30th. The first annual dinner will take place the same evening at the Grand Hotel. The Honorary Presidents of the Society include the following gentlemen: Sir Spencer Wells, Sir Joseph Lister, Dr. Richard Quain, Prof. Ball, Prof. Brown-Séquard, Dr. Ricord, Dr. J. S. Billings, Dr. Fordyce Barker, and Dr. Weir Mitchell.

THE annual meeting of the American Academy of Medicine will be held at Chicago, Ill., November 13th and 14th.

SCARCELY any heroism of modern times has called forth such universal admiration as the voluntary sacrifice of Father Damien. It is now stated that his follower and successor, Father Conrady, has been stricken with the dread disease.

THE Fifth International Veterinary Congress was held in Paris from the 5th to the 8th of September. Tuberculosis in animals was the principal subject for discussion.

BERLIN has an active Society of Railway Surgeons. At their last meeting, among the subjects discussed were: Practical tests for color-blindness; traumatic neuroses and railway-spine, and others.

REVIEWS.

DISEASES OF WOMEN: A MANUAL OF NON-SURGICAL GYNECOLOGY. By F. H. DAVENPORT, A.B., M.D., Assistant in Gynecology, Harvard Medical School, etc. 12mo., pp. 311. Philadelphia: Lea Brothers & Co., 1889.

THIS manual, its author states, is intended to instruct students in the principles and details of gynecological examinations and treatment, and to help the general practitioner in treating average cases of women's diseases. We believe that this intention has been fulfilled; the indiscriminate laparotomist and extirpator will find little to attract in the volume, but the general practitioner may well avail himself of its lucid and rational modes of treatment, while the student will not find elsewhere more practical instruction in those details of scientific gynecology which are so essential in diagnosis and treatment.

"Methods of examination" are treated and illustrated with most satisfactory fulness. In the treatment of disordered menstruation, the author's mode of using leeches is very efficient; the leech is grasped gently behind the neck by dressing forceps, and held against the cervix, to which it rarely fails to adhere promptly. These valuable agents are neglected because of their inefficient application as generally practised. In fibrous stricture of the os internum, discission under antiseptic precautions is very properly preferred to divulsion, the latter being reserved for more elastic conditions of the tissues.

The chapter upon uterine displacements is especially full and satisfactory; the author is an intelligent and rational advocate of the use of pessaries, and gives an interesting exposition of his methods, including the safe and efficient, but not brilliant, treatment of displacements with adhesions by repeated vaginal tamponade. Purging with salines is not with our author a specific cure for peritonitis, he is quite out of fashion in this, but believes from experience that morphia and quinine, with rest and external applications, limit this disease in the pelvis and result in recovery. The value of electricity in promoting ovulation, in curing ovarian and pelvic neuralgias and promoting absorption, is fully recognized, and will not be disputed.

A useful list of instruments necessary for gynecological practice is appended, and scattered through the book are various instrumental devices of practical value.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS.

Fourth Annual Meeting, held at Washington, D. C., September 18, 19, and 20, 1889.

WEDNESDAY, SEPTEMBER 18TH.—MORNING SESSION.

THE Association was called to order at 10 A. M.

THE PRESIDENT, DR. FRANCIS MINOT, of Boston, read an address on

THE PROGRESS OF MEDICINE DURING THE LAST FIFTY YEARS.

The immediate causes of the great advancement of medicine were the growth of physiology and pathology, including bacteriology, and the improvements in clinical and laboratory teaching of the present day, which have led to a better acquaintance with the nature and causes of disease, to a more rational and successful thereapeutics, and to the prevention by means of hygiene of a large number of diseases, including some of the most fatal. These means have been greatly aided by the progress of science in general, and by the conveniences of modern civilization which enable observers from different countries to assemble together for interchange of knowledge and experience. A large share of medical progress is also due

to the dissemination of knowledge by means of well-conducted journals which enable thousands of practitioners who cannot leave their homes to be constantly supplied with the most recent discoveries relating to pathology and the diagnosis and treatment of disease. The organization of this Association is peculiarly adapted to the progress of medical science, representing no one section of our country, but including practitioners from all parts of the United States and Canada, whose experience, knowledge, observation, and ability are brought together for comparison and for mutual instruction.

The President reported the deaths of the following members, Drs. H. D. Schmidt, of New Orleans; John C. Dalton, of New York (honorary member); Robert Palmer Howard, of Montreal, and Edward T. Bruen, of Philadelphia.

DR. C. F. FOLSOM, of Boston, then read a paper on

THE EARLY STAGE OF GENERAL PARALYSIS.

He reported a number of cases illustrating the early stage of the disease in which the motor disturbances were very slight, and might readily be overlooked and escape detection. The striking loss of muscular control or power, generally considered a part of the disease, was not found until a late period of the disease. The mental symptoms consist in impairment of a peculiar quality, often so slight as to be made out with difficulty.

The disease arises most commonly under prolonged strain, particularly when associated with unaccustomed excesses. At least two-thirds of the general paralytics have had syphilis, and the relation of the disease with syphilis is too frequent to be accidental. The disease is, however, not a stage of syphilis, and is not benefited by specific treatment. The prognosis is probably not so hopeless as it is generally considered to be.

The common early treatment is harmful. Foreign travel is injurious. The only hope of at least partial cure or marked amelioration is in entire mental and physical rest.

DR. ROBERT T. EDES, of Washington, reported the case of a man suffering now from pronounced general paralysis, in whom the first symptoms of the disease made their appearance some twenty years ago. If the anatomical view of general paralysis is accepted he did not consider it strange that mental symptoms might precede the motor, depending upon the seat of the lesions.

DR. S. WEIR MITCHELL, of Philadelphia, was sure that certain cases of general paralysis began most markedly with motor trouble, while others began most decisively with mental conditions. In regard to syphilis he agreed with the author, except that he had seen cases due to syphilitic disease in which cure followed specific treatment. He had also seen cure follow in a small number of cases where the treatment was begun in the early stages, but where the motor disturbances and the mental incapacity were sufficiently marked to render the diagnosis reasonably certain. In all of these cases there had been a total abandonment of all previous pursuits, with absolute mental and physical rest. He agreed with the author that foreign travel was often injurious.

DR. JAMES J. PUTNAM, of Boston, remarked that the fact that syphilis acts in this disease not by producing a direct lesion, but in an indirect manner, justifies us in looking for other causes of degeneration which might act in a similar manner. He asked if the reader had seen any cases in which chronic lead poisoning was the apparent cause of the general paralysis, and related a case in which the imperfect and slow speech, the imperfect handwriting, and the expression of apathy and indifference, suggested a diagnosis of general paralysis. In this case there was, however, a history of drinking of water contaminated with lead, and there were certain local symptoms indicating lead-poisoning.

DR. WILLIAM PEPPER, of Philadelphia, believed that he saw these cases from a different standpoint than that of Dr. Folsom; they came to him as cases of dyspepsia, lithæmic disturbance, and the like, and were under his care for some time before symptoms leading to recognition were developed—sometimes for years before the paretic symptoms appeared. He could not regard syphilis as in any way essential in the causation of general paralysis.

In regard to the early stage of the disease, there was one symptom mentioned by Dr. Folsom, or described by others, as indicating the early stage, which he did not often find in cases of nervous lithæmia. There may be a grouping of these symptoms or a delicacy on the part of the diagnostician which will enable a finer and finer shade of these differences to be recognized, which does constitute a basis of diagnosis.

He thought that general paralysis could be initiated by many disturbing, depressing, or irritating causes, and that in its early stages and slight degrees it was capable not rarely of being entirely cured. If these cases are permitted to go on with neglect of hygiene, and with excesses, sexual, alcoholic, or business, a notable proportion will end with symptoms of general paralysis.

DR. FOLSOM said in regard to lead, that while he had seen cases in which this agent had produced symptoms similar to the initial symptoms of general paralysis, he had not seen a case in which the terminal symptoms of general paralysis had been produced. As illustrating apparent cure after specific treatment, he referred to a case in which the use of large doses of iodide of potassium apparently produced complete recovery, and the patient returned to his previous business. The symptoms after several months reappeared, and have continued steadily to progress. Whether this is the result in all such cases he was unable to say.

DR. JAMES STEWART, of Montreal, then read a paper on

TETANY.

The details of the following case were referred to: The patient, a male, aged forty, has been troubled during the past eight years with regularly recurring attacks of tetany. He served as a soldier during the American civil war. Suffered at that time and subsequently from chronic dysentery and malarial attacks. For upwards of ten years he has been troubled with diarrhœa. Patient is tall, emaciated, and anæmic. The first subjective symptom of his tetany is usually double vision, which is quickly followed by the characteristic contractions of the flexor muscles of the hands. Occasionally the flexors of the forearms and adductors of the arms become spastic, muscles of the face almost constantly suffer, muscles of the lower extremities rarely. The affected muscles are the seat during the attacks of fibrillary twitching. The attacks often last several days (seven to twelve), unless terminated by the very free use of morphia.

The galvanic irritability of the nerves is found to be greatly increased, also the mechanical irritability of both nerve and muscle. Knee-jerks exaggerated during attack, absent in intervals. Œdema of the hands and arms, with herpetic eruptions frequently to be seen after particularly severe attacks. The quantity of urine excreted during attacks is usually normal in amount, and contains urea and indican in great excess. Patient has been under observation for more than three years, and it has been noticed during the past two years that he has been getting gradually dull and apathetic. It takes him a long time to answer questions; he complains of general numbness, his face and lips are swollen; symptoms closely resembling those seen in myxœdema.

Tetany, he said, may be divided into three varieties: 1. Epidemic or "rheumatic" tetany, common in Europe, but extremely rare in America. The course is acute and favorable. 2. Tetany from exhausting causes, as lactation, diarrhœa, etc. Course is chronic and favorable. 3. Tetany from removal of the thyroid glands. Course generally is usually either quickly fatal or chronic and incurable. 4. A form of tetany occurring in cases of dilatation of the stomach. Very fatal. Infantile tetany is excluded from this division, as what is so frequently called tetany in infants is not that disease. No doubt, true tetany may occur in childhood.

Experimental Tetany.—When the thyroid gland is removed from cats, dogs, or monkeys, a condition very similar to the typical tetany of the human subject is observed, viz., fibrillary tremors and intermittent spasmodic contractions. Death usually follows in a week, and no changes can be found to account adequately for it.

The fact that there is a great increase in the electric irritability of the nerves after the removal of the thyroid glands is strong evidence of the similarity of the tetany of man and animals. Of the many forms of muscular contractions seen in man, in none, with perhaps the exception of cholera, do we find any marked increase of the electric irritability of the nerves and muscles.

No pathological changes that in any way can be considered characteristic have been described. All recent observers tend to confirm the conclusion of Schiff, that the tetany following removal of the thyroid gland is directly due to the loss of the gland, and that the thyroid gland in some way has a direct influence over the nutrition of the nervous system. It is difficult to explain how causes so diverse in their operation, as "rheumatic" influences, diarrhœa, pregnancy, lactation, and removal of the thyroid, can induce similar symptoms. It appears probable that impoverishment of the nerve centres is one of the main factors in its production.

DR. JOHN T. CARPENTER, of Pottsville, Pa., then read a paper on

TETANY, AND A NEW THEORY OF ITS PATHOLOGY.

He defined tetany as a nervous disorder, accompanied by tetanic spasm of an intermittent character, which may extend from the extremities to the jaw, and be reproduced during the periods of intermission at will, by pressure on the track of the affected nerve-trunk or over the blood-vessel obstructing the circulation. A historical *résumé* of the disease was given; tetany was regarded not as a special disease, but as a sequel of precedent phenomena only. The affection was regarded as the result of septic absorption. The diminution of cases of tetany coincident with the successful treatment and the prevention of septic poisoning was regarded as an argument in favor of the connection between septicæmia and tetany. Cases illustrating this view were cited. The views previously held in regard to the pathology of tetany were discussed and considered untenable.

DR. FRANCIS P. KINNICUTT, of New York, had seen but two cases of intermittent tetany, both occurring in patients with dilatation of the stomach. In one the dilatation was due to pyloric stricture resulting from cancer. In the other there was non-malignant stricture. In both of these cases the conditions were favorable for absorption of poisonous matter.

DR. F. T. MILES, of Baltimore, reported the case of a woman, aged twenty-two years. She had suffered for six to eight years, from dilatation of the stomach. She had vomited acid matter, but never offensive. She several times had numbness of fingers and toes. She suffered from her first attack of tetany twenty-four hours before her death. In this case the stomach had never been washed out.

DR. A. JACOBI, of New York, had been struck with the stress laid by the readers upon sepsis as the cause of tetany. In one of the cases reported by Dr. Stewart, which he thought was due to absorption of putrid material, the stomach was twisted, and Dr. Jacobi suggested that the intermittent contracture was due to nervous influences resulting from the twisting rather than to absorption. He did not doubt that there were cases in which septic absorption produced such symptoms; but when we recall the fact that the contracture is temporary, we must conclude that the influences giving rise to that attack were also temporary. Many of these cases are, he thought, the result of nervous irritation. In some of the cases reported, he should attribute the condition to anæmia.

DR. JAMES J. PUTNAM, of Boston, remarked that the reported cases of tetany showed such a variety of infectious sources that it seemed hardly probable that they should act in such a similar manner, unless there was something else behind. Two or three things are to be considered: first, the influence of habit. The disease set up by a variety of causes may continue as a result of habit. Secondly, the suggestion that in such cases of disordered action we have to deal with an over-sensitiveness of physiological arrangement is important. In these conditions we have the disordered manifestation of what is really a function, but one which ordinarily we do not recognize, as it has no independent existence. It would seem that in the absence of further knowledge with regard to infection and the manner this infection, arising from various sources, may act, we should insist upon the possibilities of explanation which are presented to us by what we know of the physiology and disordered physiology of the nervous system, in attempting to explain conditions met with in this and similar diseases.

DR. STEWART said, in connection with the influence of peripheral irritation, that in the cases of the dilatation of the stomach where tetany had caused death, the symptoms came on a few minutes after the stomach had been washed out. This would point to irritation rather than decomposition as the active cause in this class of cases. There are many other cases in which infection could not enter.

DR. CARPENTER said, in regard to anæmia as the

cause of tetany, that we should have to go back of the anæmia to the cause that produced it. He knew of no cause that would produce anæmia so surely as septic absorption.

AFTERNOON SESSION.

DR. A. BRAYTON BALL, of New York, read a paper on

THROMBOSIS OF CEREBRAL SINUSES AND VEINS.

He first referred to the influence of the following factors in the production of thrombosis: 1, blood stasis; 2, vessel lesions; and 3, blood changes. The anatomical conditions in the sinuses that best favor thrombosis were described at length. A number of cases of marantic thrombosis of cerebral veins and sinuses in chlorotic girls were reported.

The symptoms were next considered. Much importance has been attached to distention of external veins collateral to the internal veins supposed to be affected, giving rise to hemorrhage and œdema. These signs are frequently absent, and may be due to other conditions. The mobility of the symptoms has been considered of value. In these cases the cerebral symptoms undergo strange alternations not seen usually in other affections. Active delirium is exceptional. The depression continues, but alternates with a certain amount of improvement. Fever is absent at first; and, if present, is to be attributed to complicating conditions. Paralytic symptoms of varying extent are usually present. With the exception of the variation in degree, the paralysis does not differ from paralysis from other causes.

DR. WILLIAM OSLER, of Baltimore, exhibited two specimens illustrating the conditions described by Dr. Ball. The first specimen was one of extensive thrombosis of the lateral sinus, occurring in a man who died from phlegmonous erysipelas of the cheek. There were no special symptoms in that case. The second specimen was from a woman dying of consumption. It was thought that gradually increasing coma and the onset of cerebral symptoms were supposed to be due to basilar meningitis.

DR. A. JACOBI enumerated certain additional aiding causes. The first was a disproportion between the white and red blood-corpuscles. The second cause was the relative absence of muscular tissue in a number of the veins. A third cause was absence of water in the blood, often due to the withholding of sufficient fluid in the diet of patients. The last cause referred to was weakness of the heart. When, in exhaustive diseases, the heart is allowed to become feeble, thrombosis, with all its bad results, must be expected. It is certainly a good therapeutic measure to stimulate and strengthen the heart in every disease that will last long or tends to terminate in exhaustion.

DR. WM. H. WELCH, of Baltimore, said that there is one point of great force in explaining the production of thrombosis; that is, the possibility that there is some form of intoxication analogous to that produced experimentally by various substances, such as the fibrin ferment. Under such circumstances, there is almost instantaneously extensive thrombosis wherever the ferment reaches. Pathologists are aware of the frequency with which thrombi, usually of a mixed character, are found in the cerebral sinuses, particularly the superior longitudinal sinus, in cases that have presented no symptoms during life.

DR. SAMUEL C. BUSEY, of Washington, then read a paper on

THE EFFUSION OF CHYLE AND OF CHYLE-LIKE, MILKY, FATTY FLUIDS INTO SEROUS CAVITIES.

The reported cases of effusion of chyle and milk-like fluids into the pleural and peritoneal cavities, including the doubtful cases, do not exceed 43, and these cases cover a period of one hundred and ninety years. Nevertheless 23 of the cases of effusion of chyle and chyle-like fluid into the abdominal cavity have been observed during the present century, 15 since 1850, and 13 during the last and present decades. The increasing frequency of the occurrence is thus clearly shown.

Effusion into the pleural cavities; chylothorax. Of this, including the doubtful cases, there have been 10 cases reported. In 5 of these the chyle poured directly from the thoracic duct. The diagnosis in these cases can only be made by evacuation and examination of the fluid. The prominent symptoms are dyspnœa and accumulation of fluid in one or both cavities. The prognosis is unfavorable and the treatment expectant.

Effusion into the tunica vaginalis testis. The case of galactocele reported by Vidal (de Cassis) seems to have been the first observation of this class of effusions. In two of the reported cases the patulous orifices of the vessels from which the lymph exuded were found. Since 1885 there have been reported in this country 13 cases in which filaria were found, and 2 of these were cases of lymphocele. It has not been shown, however, that filaria are present in every case of lymphocele. It is conceivable that adenitis, gonorrhœal lymphangitis, or other conditions which obliterate the permeability of neighboring and connecting glands, might cause stasis of lymph and dilatation and rupture of lymph capillaries and plexuses with which the serous membranes are so richly supplied. The opinion of those who have had the best opportunity to study the relation of filaria to disease in general, seems to be that of Sir Joseph Fayrer, that it has been shown that disorders of the lymphatic system are most frequently associated with, if not caused by, the filaria. The recent invaded portions of the subtropical belt of this country by the filaria, and the reports of cases of disease with which the parasite has been so uniformly associated, together with the fact that the mosquito has been proven to be its intermediate host, present considerations of the highest importance to the profession and general public. Some of the cases have been cured by injection of iodine, others have been cured by dissecting back the vessels and tying the bundle *en masse* with a silk ligature.

Chylous and oily ascites. A tabulated statement, arranged chronologically, presenting a condensed summary of the reports of cases of chylous and oily ascites, was given. The number of cases reported was 33. Primary rupture occurred in but 5 cases. Chylous ascites may be the secondary result of a variety of morbid conditions, which directly or remotely obstruct the flow of the chyle through the lacteals, receptaculum, or thoracic duct, impede its exit into the left subclavian vein, or retard the current of blood in the left subclavian vein, right side of the heart, or lesser circulation. The relation of puerperal conditions to the effusion of chyle,

is not susceptible of explanation. In five cases the fluid found in the peritoneal cavity was associated with tuberculosis, and in four it is stated that the peritoneum was more or less studded with tubercle. No perforation or rupture of chyle-conveying vessels was found in any of these cases.

The symptomatology of effusion of chyle into the peritoneal cavity is not sufficiently distinctive to differentiate such cases from ordinary ascites, and a diagnosis is only possible after examination of the evacuated fluid. Of the 33 cases, 19 died, 9 recovered; and in 5 the result is not stated. Of the 22 cases of chylous ascites proper, 12 died, 5 recovered; and in 5 the result is not stated. Meagre and unsatisfactory as are the clinical details of these cases, they point to two conclusions: 1, that a free and unobstructed channel of communication between the venous system and the chyle-conveying vessels is essential to the proper nutrition of the body and preservation of life; 2, that death following partial or complete obliteration of this communication is the result of inanition.

In 17 of the 33 tabulated cases, tapping was practised, and in most of the cases repeated several times. Six of these recovered. In 2 laparotomy was resorted to, with recovery of both patients. One was a case of intact retention cyst, and the other was probably a ruptured cyst. As a medical resource, paracentesis is of questionable value. The treatment is mainly directed to the prolongation of life. The causative condition may in some cases be amenable to medicinal treatment, but in most cases some surgical procedure might offer a prospect of cure. In filarial cases, the treatment applicable to such would be admissible. Sonsina thinks that astringents, such as gallic acid and tincture of the chloride of iron, with rest, tonics, and proper alimentation, are useful. Lancereaux thinks that the parasitic forms of lymphatic disease are curable. He has found mercurial inunction in the region of the affected gland in connection with hydropathy of service. He suggests the injection of a parasiticide into the affected glands for the purpose of destroying the female adult worm,

DR. OSLER said that in ordinary post-mortem work it was not infrequent to meet with varices of the chyle vessels of the mesentery covering the walls of the intestine. Sometimes there are extravasations which may form large chylous cysts.

With reference to chyluria, he was positive that there was a non-parasitic form. He had made thorough examinations in one such case and failed to find filaria. On post-mortem examination, nothing was discovered. Also in a case of lymph scrotum, he had examined the fluid and the blood and had found no embryo. He laid a great deal of stress upon these cases, as it is generally stated that these conditions are always parasitic.

DR. WELCH exhibited a specimen of chyle removed from the abdominal cavity of a boy, twelve years of age. He described the chemical and microscopical characters of the fluid, and dwelt upon the importance of distinguishing between chylous and fatty hydrops.

DR. J. F. A. ADAMS, of Pittsfield, Mass., then spoke of the

SUBSTITUTES FOR OPIUM IN CHRONIC DISEASES.

The disadvantages attending the use of opium are: 1. In an overdose it is a poison 2. In ordinary doses its benefits are largely offset by various functional derangements. Its use involves the danger of the opium-habit.

Of remedies that may be substituted for opium for the relief of pain, the antipyretics—antipyrine, acetanilide, phenacetine, and exalgine—have well-grounded claims to be regarded as rivals of opium. They are, however, less certain and less prompt, particularly when pain is very violent. Antipyrine in five- to ten grain doses has been found valuable as an analgesic, particularly in headache, neuralgia, and rheumatism.

Acetanilide he had found less active than antipyrine. He used it in doses of seven or eight grains. He had found it particularly serviceable in lumbago and dysmenorrhœa. In the latter condition, one or two doses have afforded prompt relief.

Salicylic acid and its sodium salt should be included on account of their marked effect in the relief of pain in rheumatism, particularly its acute form.

Substitutes for opium to induce sleep. Paraldehyde is an excellent hypnotic, although rather uncertain. Hydrate of amyl is generally preferable to paraldehyde, being more reliable as well as more agreeable. Sulphonal is more extensively employed than either of the above, and is applicable to all forms of insomnia.

Chronic diarrhœa. It is probable that no remedy has been used in this affection so largely as opium. The effects of this mode of treatment have been far from satisfactory. Recently the author had treated these cases antiseptically with far better results. The remedy chiefly used has been sodium salicylate in five- to ten-grain doses, three or four times a day. He had also used salol with success.

We now have remedies which may be used in place of opium in all chronic affections where formerly this remedy was our chief reliance. For producing sleep and for the treatment of chronic diarrhœa, we have certain hypnotics and antiseptics which are not only as efficient, but so much more satisfactory that we may practically lay aside opium, to be used only on rare occasions. As an analgesic, opium still stands at the head of the list for promptness and certainty, but the antipyretics mentioned are probably capable of replacing it in the majority of chronic cases, and the relief afforded by these remedies is attended with less disturbance of the system than that induced by opium.

DR. G. M. GARLAND, of Boston, referred to the value of the fluid extract of gelsemium as a substitute for opium. In frontal headache it has an admirable effect. It is used also with advantage in difficult and painful menstruation, and in certain forms of neuralgia. As a simple hypnotic, gelsemium answers well in cases of temporary congestion with insomnia and headache. In hysterical conditions this agent will often induce sleep in a short time. The drug is given in doses of five to ten drops every half hour until the desired effect is obtained, or its physiological effect is produced in diplopia and ptosis. These appear sufficiently early to serve as a warning.

DR. I. T. DANA, of Portland, reported two cases of opium-habit occurring in a man and wife. The husband was a young man who had for some time given hypodermic injections of morphia to a patient dying of cancer. He subsequently broke his leg, and remembering the effect of the injections in the case of cancer, he tried them on himself. The result was so exhilarating, and as he "could not see why his wife should not have a little

of the fun," he began giving her the injections, although she was perfectly healthy. In this way the habit was induced, and when admitted to the hospital each one was taking six grains of morphia daily.

DR. D. W. PRENTISS, of Washington, exhibited

A REMARKABLE CASE OF SLOW PULSE, EXTENDING OVER A PERIOD OF NEARLY TWO YEARS.

G. W. P., white, male, carpenter, aged fifty-four years. Has always been healthy. The only illness he remembers is neuralgia of stomach, fourteen years ago. The only injury he ever received was a fall, a distance of fifteen feet and striking on his feet, when nineteen years old. Ten years ago a brick fell upon his head, cutting the scalp, but causing no serious injury. Never had any form of venereal disease. Always temperate in the use of alcohol, but not in the use of tobacco. He has been under the observation of the writer for sixteen years, but had never been attended professionally until present illness.

December 13, 1887, after working some time in a malarial locality, he began to have "weak spells," and several times fainted on lifting heavy weights. Examination showed no well-defined disease. No fever, mind clear, pulse 36. Urine normal. No organic disease of heart discovered. The systole was full and strong; diastole greatly prolonged. Between December 13, 1887, and January 20, 1888, the pulse ranged from 22 to 76. During this time there were frequent attacks of syncope. During one fainting attack he fell down stairs. At another time fell out of a chair, remaining unconscious about a minute. After January 20th, when pulse had reached 76, he had no more fainting spells. In March he resumed work. October 2, 1888, he had a relapse, with the same symptoms as in previous attacks. From this date to April 15, 1889, the pulse ranged from 15 to 44 per minute. The fainting attacks continued throughout this time, occasionally very severe. He improved to a certain extent, but about August 1, 1889, he began to have a return of the old symptoms. During the fainting spells the pulse fell to 12 or 15. Between August 5th and September 18th the pulse ranged between 12 and 88 per minute, and between August 10th and August 15th it did not rise above 14 per minute.

The temperature during this time was between 94.5° and 97°. The patient improved somewhat after August 15th, and September 18th was well enough to present himself for examination before the Association.

The "spells" referred to were described. They come on without warning, often without apparent cause, sometimes after exhaustion. He faints, losing consciousness. They last from a few seconds to half an hour. Breathing gasping and slow. Face and hands first pale, then dark and purplish. There is no pain. He has great confidence in the bromide of ammonium, which he thinks controls the attacks. The treatment of the case from the first has been rest in bed, tonics, stimulants, electricity, and bromide of ammonium, together with supporting diet. The tonics used, strychnine, quinine, and iron, with belladonna. Digitalis was tried, but made him worse. Nitroglycerine seemed to help for five doses, but later caused distress. Convallaria and strophanthus were tried, with like result. The drug which appeared to give the most relief was bromide of ammonium, given in doses of one gramme (fifteen grains) three times a day, and extra doses when paroxysms threatened.

The most interesting question in this case turns upon the pathology. What is the cause of the retarded action of the heart? The causes which may produce slow pulse may be classified as follows:

1. Disease or injury to the nerve centres, producing either irritation of the pneumogastric or paralysis of the sympathetic (accelerator) nerve of the heart.
2. Disease or injury of the pneumogastric nerve increasing its irritability.
3. Disease or injury of the sympathetic nerve of the heart, paralyzing it.
4. Disease of the cardiac ganglia, by which the influence of the pneumogastric preponderates.
5. Diseases of the heart muscle (degeneration) whereby it fails to respond to the normal stimulus.
6. Action of poisons as of lead or tobacco either on nerve endings or on nerve centres.

In this case it is difficult to say to which of these divisions it belongs. There are no symptoms to indicate any form of disease of the nerve centres. There is no evidence of disease of the nerves themselves, nor has any organic disease of the heart been discovered. There is left only the action of certain poisons and the question arises whether or not in some obscure way the conditions may not be due to tobacco poisoning from excessive smoking. Another possibility is malarial poisoning. The attacks first appeared while he was working in a malarial district and in the summer of 1888, he had intermittent fever. These considerations make it probable that there is paralysis of the accelerator nerves and not an irritation of the vagus. The symptoms are due solely to defective circulation.

In many of the cases collected in connection with this report, the pathological appearances were a result of the slow pulse rather than a cause.

Abstracts were given of 55 cases of slow pulse of which the following is a brief analysis as to causes: fracture or dislocation of cervical vertebra, 9 cases; disease of brain, 9 cases; cerebral syphilis, 2 cases; sunstroke, 1 case; ossification of aortic valve and coronary arteries, 2 cases; starvation, exhaustion, loss of rest, convalescence, 3 cases; epilepsy and epileptoid disease, 9 cases; heart disease, 6 cases; lead-poisoning, poisoning by salt fish, pernicious fever, 3 cases; nervous shock, cholera morbus, 2 cases, and not stated, 9 cases.

SEPTEMBER 19TH—MORNING SESSION.

DR. FREDERICK P. HENRY, of Philadelphia, opened a discussion on the

RELATION BETWEEN CHLOROSIS, SIMPLE ANÆMIA, AND PERNICIOUS ANÆMIA.

He said the subject might be treated under three heads:

1. Are they separate diseases?
2. Are they of kindred nature?
3. Are they different stages of one affection?

Pernicious anæmia was first considered, because the determination of its status is of fundamental importance. It is admitted by all that the clinical features of this disease are common to a number of affections, especially cancer and atrophy of gastric glands; but those who argue most forcibly in favor of its independent nature

exclude from the category of pernicious anæmia all cases in which an anatomical lesion of any organ is found. This appears to him unscientific, for an independent disease is one which rests upon a constant anatomical basis or is invariably produced by the same specific agent. Hunter has endeavored to establish pernicious anæmia as an independent disease by the demonstration of an excess of iron in the liver in cases of that affection. He regards this as the essential anatomical feature of pernicious anæmia. The work of Hunter is of great value, and certainly demonstrates the existence of an excessive hemolysis in that disease. In the speaker's opinion, however, this excessive hemolysis is a consequence of defective hemogenesis, for certain facts show the red corpuscles of pernicious anæmia to be abnormally weak and perishable. Chlorosis is universally admitted to be due to defective hemogenesis, and, therefore, he regards it and pernicious anæmia as closely related affections. Transitions from the one affection to the other have also been observed by himself and others.

His conclusions were: (1) That pernicious anæmia is a process, not a disease; (2) that it is closely related to chlorosis; (3) that it may be the terminal stage of other diseases, and especially of cancer of the stomach and atrophy of the gastric glands.

Leucocythemia and Hodgkin's disease, in that they are always associated with lesions of the blood-making organs—spleen, lymph-glands, bone-marrow, etc.—are independent diseases, or, rather, different stages of the same disease, for several cases are recorded in which an undoubted transition from one to the other has been observed.

DR. F. FORCHHEIMER, of Cincinnati, then spoke as co-referee on the same subject. He first referred to the confusion which existed in regard to the definition of the two diseases. Immermann states that we are justified in regarding anæmia as that condition in which there is a diminution of red corpuscles as well as the albumins of the plasma in the blood (hypalbuminosis). Strümpell considers that "the essential element in anæmia is, therefore, a diminution in the number of red corpuscles or so-called oligocythæmia," and states further, that oligocythæmia is not invariably accompanied by a diminution in the amount of serum-albumin (by which he means plasma-hypalbuminosis)." Going on it is found that anæmia or oligæmia vera really means a diminution of the whole quantity of the blood and that this condition can be divided into hydræmia, oligocythæmia, oligæmia sicca and oligæmia hypalbuminosa. We have three representative definitions: the one broad and general, including a diminution of any one or all of the constituents of the blood; a second, in which hypalbuminosis and oligocythæmia are the principal if not the only factors; and a third, which makes oligocythæmia alone the characteristic feature. From a purely practical standpoint the latter seems the best.

The same confusion in regard to definition is met with in a consideration of chlorosis. Duncan (1867) was, however, probably the first to make the distinctive feature, oligochromæmia characteristic for chlorosis—that is, in chlorosis we find the individual red corpuscle deficient in hæmoglobin. Unfortunately for this definition, the term chlorosis is to be looked upon as an essentially clinical one; it is not going too far to state that by far the great majority of reported cases of chlorosis are not chlorosis at all. Another difficulty is that both oligocythæmia and oligochromæmia may occur in the same individual, so that the term chloranæmia is justified by observation of existing conditions. It is more than probable that anæmia is a forerunner of chlorosis in a great many instances, and possibly a number of cases occur in which there is a combination of both conditions.

Almost every cause put down for anæmia will hold good for chlorosis. Sex, age, a peculiar composition of the blood, and certain vascular anomalies are held to be especially characteristic for chlorosis. The two latter are the only ones to be found in chlorosis. The process of sexual development is looked to as the time of most common occurrence of chlorosis. This age also produces a great number of cases of anæmia; but children and old people are subject to anæmia and practically excluded from chlorosis. The greater number of cases occur between the ages of fifteen and twenty-five years, decidedly after the time of first menstruation. Furthermore, an anæmic constitution is a strong predisposing cause for chlorosis.

The clinical characteristic of chlorosis lies in the peculiar changes in the blood. In anæmia the red corpuscles as well as the albumins of the plasma are reduced in quantity and frequently there is production of a greater number of smaller corpuscles (microcytes). As a result of the reduction of the number of red corpuscles the hæmoglobin is correspondingly reduced in quantity. In pure chlorosis the number of red corpuscles is not diminished and a tendency to the production of larger red corpuscles (megalocytes) is especially well marked. These changes are, however, not sufficiently characteristic to establish a diagnosis. It is also found that the amount of hæmoglobin in each corpuscle is diminished. It has been said that in anæmia there is always hypalbuminosis, while in chlorosis this is absent, but this has not yet been positively proven.

One respect in which chlorosis is said to differ materially, if not absolutely, from anæmia, consists in the pathological changes, first described by Virchow. These are narrowing of the lumen of the cortex and larger arteries as well as thinning of their walls. The heart is sometimes small, sometimes hypertrophied. This view would permit us to state that chlorosis is always congenital, in some cases latent for years, while anæmia in most cases is acquired. Many objections have been urged against this view.

The relation of the symptoms of anæmia to chlorosis depends upon the condition of the blood and the anatomical sub-strata. Given a case of anæmia in which there is only a reduction of hæmoglobin as a result of oligocythæmia and a case of chlorosis in which there is a reduction of hæmoglobin as a result of oligochromæmia, and metabolism in both these cases will be approximately the same; but if in anæmia we have oligocythæmia as well as hypalbuminosis, which is said to coëxist in the majority of cases, the metabolism must be different from that of a pure case of oligocythæmia. As a result of reduction of hæmoglobin there is simple reduction in the process of oxidation; at the same time the waste products are carried off and sufficient albuminous food is carried to the tissues by the plasma of the blood which is unchanged. Hypalbuminosis and obligocythæmia produce an entirely different result. We have

the same factor, suboxidation, but we have in addition deficiency of supply. In mild cases of anæmia, there is produced a loss of weight; in severe cases the condition called marasmus. In chlorosis very little, if any, loss of weight occurs; very frequently the opposite condition is brought about by too good supply and by the presence of too much CO_2, preventing decomposition of fats. When anæmia is associated with chlorosis, we have a very unfortunate combination, especially if there is a great amount of hypalbuminosis.

Unless we believe that the anatomical lesions of Virchow belong to chlorosis, there exists no difference between the symptoms of chlorosis and anæmia.

The therapeutic relations of the two diseases must be considered. While the indiscriminate use of iron in anæmia must be deprecated, yet, upon the whole, iron is just as much looked upon as a specific in anæmia as in chlorosis. Where, in anæmia, we try to remove the cause and institute causal treatment, we are satisfied in chlorosis in removing that symptom which is the essential of that disease. It has been repeatedly demonstrated that the removal of this essential symptom is followed temporarily by complete recovery. Whereas, in anæmia, treatment is followed by complete recovery or complete failure, iron in chlorosis will always result in amelioration, even if the tendency to relapse cannot be removed. There are few cases of chlorosis, even those with the lesions of Virchow, that are not benefited by the administration of iron in sufficient quantity. In a great many cases of anæmia, the use of iron will be followed by negative results.

DR. OSLER took issue with Dr. Henry in regard to chlorosis. He held that chlorosis is absolutely distinct from pernicious anæmia, and for the following reasons: 1. The sex. He had never seen chlorosis in the male. 2. The pathological conditions. He regarded the hyperplasia of the heart and great vessels as a specific anatomical distinction in a certain number of cases. 3. The character of the blood. He considered the diminution of the percentage of hæmaglobin a distinctive feature of chlorosis. 4. Curability. Although, in chlorosis, there is a tendency to relapse, each given attack can be cured, if sufficiently large doses of iron are employed.

DR. KINNICUTT agreed as to the lack of relation between chlorosis and pernicious anæmia. He had never seen true chlorosis in the male. All his cases of pernicious anæmia, on the other hand, with one or two exceptions, had occurred in males. He agreed with Dr. Henry in regard to the relation between Hodgkin's disease and true leucæmia. He related a case which came under his observation with typical symptoms of Hodgkin's disease. At this time the proportion of white corpuscles to red was normal. The spleen and liver gradually enlarged, and two years later, at the time of the patient's death, there was one white corpuscle to five or six red.

DR. W. W. JOHNSTON, of Washington, thought that a study of certain anæmias, which are met with in women, will throw light upon the association of anæmia with diseases of the intestinal glands and gastric tubules. The explanation of the chronic anæmias of parturition is probably the continued pressure upon the intestinal tube, causing a long starvation, lasting nearly a year. This seems to produce an actual organic change in the intestinal glands. Several illustrative cases were cited.

DR. PEPPER agreed with Dr. Osler in regard to the relation between true anæmia and chlorosis and progressive pernicious anæmia so-called. He was not prepared to admit the analogy between true chlorosis and progressive pernicious anæmia. The conditions of the blood are widely antagonistic in these two affections. The clinical differences are also very marked. In the present state of knowledge it is probably wiser to consider essential anæmia as an independent affection.

DR. HENRY thought that the definition of chlorosis, given by Dr. Osler, could not be maintained—that is, that there is always a diminution of hæmoglobin with a nearly normal number of red corpuscles. The arguments that he had advanced were based entirely upon personal observation. While if chlorosis is readily relieved by treatment in the early stages, yet, if it is neglected, the chlorosis may become more intense, and may present the appearances of pernicious anæmia.

DR. S. WEIR MITCHELL then spoke on the

SUBJECTIVE FALSE SENSATION OF COLD CONSIDERED AS A SYMPTOM.

He had met with many cases where a feeling of cold is complained of in members which do not present any objective changes in temperature. These may be placed in three classes: 1. Those due to a central cause. 2. Those due to neuritis. 3. Those whose origin is at present inexplicable, or due to hysteria. A number of cases exhibiting this symptom to an extreme degree were reported. In the first case, a marked sensation of cold, involving the left side of the body, followed an injury to the head. Three or four cases were referred to, coming in the second class. The sensation of cold involved the posterior part of the legs, the back, or buttocks. In all these cases there was either neuritis at the time, or it developed subsequently. When this symptom is noted neuritis may be expected. Two cases belonging to the third group were described. One was an elderly individual with no signs of hysteria; the other was a case of a young woman with marked hysterical symptoms.

DR. PUTNAM had frequently seen the coldness spoken of in chronic spinal disease and in neuritis; and described such a case in a man with chronic sensory neuritis.

DR. MILES regarded this sensation of coldness as a very impotent symptom of neuritis, and reported a case associated with acute neuritis of the ulnar nerves.

DR. G. M. GARLAND, of Boston, then read a paper on

GASTRIC NEURASTHENIA.

He first reviewed Leube's observation on dyspepsia nervosa, and presented a tabular statement of the gastric neuroses.

A case of anorexia nervosa occurring in a woman, sixty-three years of age, was reported. The woman was of feeble constitution. She digested her food without consciousness of the process, and her bodily functions were practically normal in every way except that she suffered from anorexia.

Three cases of vomitus nervosus were then reported:

Case I.—Miss S. began at the age of two years to have sudden attacks of vomiting. These occurred at irregular intervals until the time of her death. The attacks lasted twenty-four hours, and it required a week for the child to recover her strength. At the age of twenty, she began to have excessive muscular twitchings with the attacks. Two years later she began to have

severe headaches. These gradually merged into one steady ache. January 1, 1885, the author saw the patient suffering from intense headache and slight twitching of arms and legs. Vomiting appeared the next day, causing intense burning of the throat from the intensely acid character of the matters vomited. After four days she gradually improved and entirely recovered. November 12, 1884, the patient was again seized with headache. November 15th, vomiting and twitching began. She gradually improved until December 2d, when all the symptoms returned and continued until her death, December 13th. Urine was normal until a few days before death, when it contained a trace of albumin but no casts. At the autopsy no marked organic change was found in any part of the body.

Case II.—Miss. S., twenty-two years old, first seen September 19, 1888. She was in bed with headache, poor appetite, constipation, and weakness. Pulse, temperature, and urine normal. Some nausea. Vomiting appeared in a few days. She was fed exclusively by the rectum for three weeks, but the vomiting persisted, and there was severe burning along the entire œsophagus. At times the urine was scanty, but never contained albumin. She gradually improved, but is not as strong as before her illness.

Case III.—Miss D., æt. forty-three years, had been subject to bilious headaches. During the summer of 1888, she had a severe attack of vomiting, and she was very ill for several weeks. During the following September, as a result of anxiety, her appetite left her and the nausea returned. She, however, did not vomit.

The conclusions drawn from the above cases were: 1. All the women have been of dark complexion. 2. They have not been of the so-called hysterical temperament. 3. Feeding by the mouth was abandoned in every case, and rectal enemata were necessary. 4. None of the drugs usually potent in soothing a nauseated stomach were of any avail. Morphia subcutaneously was the only remedy that was of benefit. 5. The vomitus caused great discomfort along the throat, and in one case caused severe glossitis. In connection with the hyperacidity, he referred to certain cases of acid vomiting described by Rossbach, and designated nervose gastroxynosis. The acidity of these cases depends upon excessive secretion of hydrochloric acid, and is independent of the presence of food in the stomach.

DR. MITCHELL said that in all cases of neurasthenia where there are great complaints of gastric and intestinal difficulty, the presence of hypochondriacal conditions must constantly be considered. It is rarer for grave cases of neurasthenia to present themselves without some abdominal symptoms. In regard to anorexia nervosa, he thought that in the majority of cases a background of hysteria would be found. It is suspicious that this condition is never seen in men.

DR. PEPPER asked in what respects other than the invariable and extreme acidity of the matters vomited, these cases differ from those that have been described under the head of cyclic, acid, and recurrent vomiting. He had seen many such cases, and some like the fatal case reported. In some of the cases the vomited matters were extremely acid. He had had these matters examined chemically with the hope of finding some leucomaine, but so far with negative results. In regard to treatment, the only remedy that had been of benefit was antipyrine.

AFTERNOON SESSION.

DR. JOHN H. MUSSER, of Philadelphia, read a paper on

PRIMARY CANCER OF THE GALL-BLADDER AND DUCTS.

After describing two cases of this affection that had come under his observation, he reviewed the cases that had been reported, and presented the following conclusions: Primary cancer of the gall-bladder is not so rare as is generally believed. It occurs in the female nearly three times as often as in the male. A large number (57 per cent.) of the cases occur under the age of sixty. Gall-stones are an exciting cause, especially in persons predisposed to the affection. The organ is generally not much enlarged, save as the result of secondary processes. Metastasis is not widespread. By continuity of structure neighboring organs are involved. Adhesions to adjacent organs with ulceration and perforation are not uncommon. Pain, jaundice, and the presence of a tumor are the most common phenomena. With them are associated much cachexia, vomiting, constipation, diarrhœa, and ascites. Pain was present in 62 per cent. of the cases, at first ill-defined, then becoming localized to the right hypochondrium, and lancinating in character. Jaundice was present in 69 per cent., gradually increasing in degree. In some cases, however, it was intermittent. Tumor was noted in 63 per cent. The tumor was hard, firm, painful and generally movable with respiration. The progress of the disease is always continuous. Some extraordinary cases are reported in which there was temporary cessation in the progress of the disease. Death results from exhaustion; frequently from peritonitis; in some cases from metastasis to other organs; in some from biliary obstruction; in eight cases death was due to cholæmia. The duration of the disease is short, the average being six and two-thirds months. The progress is rapid after complete occlusion of the biliary passages or evidence of inflammation of the biliary passages has developed.

DR. HENRY F. FORMAD, of Philadelphia, read a paper on

THE ANATOMICAL AND PHYSIOLOGICAL RELATIONS OF LESIONS OF THE HEART AND KIDNEYS,

which was based upon the post-mortem study of 300 cases observed in public and private practice.

DR. P. G. ROBINSON, of St. Louis, then read a paper on

THE CONTAGIUM OF DIPHTHERIA.

Diphtheria, he said, is an acute infectious disease, doubtless due to a living organism (microbe) the exact identity of which cannot yet be regarded as settled. Primarily a local affection, the system becomes secondarily and generally infected through absorption of a poison generated at the primary and localized seat of inoculation. The modes of infection are numerous, the contagium being directly transferred by contact, in a dry state through the air for limited distances, in foul clothing, in polluted food and drink, milk probably being a prolific source of infection.

While, strictly speaking, diphtheria can hardly be called a filth-disease, since it prevails often to a very limited extent in those localities whose hygienic surroundings are apparently the worst, yet certain kinds of

filthy accumulations, as the manure of animals, notably the refuse from cowsheds and dairies, seems to furnish the most favorable conditions for the culture of this particular germ.

SEPTEMBER 20TH—EXECUTIVE SESSION.

The following were elected

OFFICERS FOR THE ENSUING YEAR.

President.—Samuel C. Busey, of Washington.

Vice-Presidents.—William Pepper, of Philadelphia, and Henry M. Lyman, of Chicago.

Recorder.—I. Minis Hays, of Philadelphia.

Secretary.—Henry Hun, of Albany.

Treasurer.—W. W. Johnston, of Washington.

Member of Council.—G. Baumgarten, of St. Louis.

Representative on Executive Committee of Congress of American Physicians and Surgeons.—William Pepper, of Philadelphia.

The following were

ELECTED TO MEMBERSHIP.

William G. Thompson, William H. Thomson, and J. West Roosevelt, of New York; Charles Carey and Charles G. Stockton, of Buffalo; Victor C. Vaughan and Heneage Gibbes, of Ann Arbor; Charles W. Purdy, of Chicago; Starling Loving, of Columbus, O.; W. H. Geddings, of Aiken, S. C.; William C. Dabney, of Charlottesville, Va.; B. F. Westbrook, of Brooklyn; and Henry P. Walcott, of Cambridge, Mass.

The date of the next meeting was directed to be fixed by the Council, between May 20 and June 15, 1890.

DR. JAMES J. PUTNAM, of Boston, then read

A SUPPLEMENTARY INQUIRY INTO THE FREQUENCY WITH WHICH LEAD IS FOUND IN THE URINE.

The paper embodied further researches as to the frequency with which traces of lead are found in the urine of persons in good health, or not presenting the classical symptoms of lead-poisoning; and discussed the propriety of enlarging our clinical conception of that disease. A table was shown in which the results of the present investigation were combined with those reported two years ago, which may be summarized as follows: The urines of 68 persons, either presenting no symptoms (healthy medical students), or only symptoms of specific or local disease (phthisis, pleurisy, local injuries, etc.), were found by Dr. A. M. Comey and Dr. C. P. Worcester to contain lead in the proportion of about 17 per cent.; while those of another group of 125 persons, presenting various symptoms of disease, such as it was thought might possibly be due in part to lead-poisoning, contained lead in the proportion of 50 per cent. The largest sub-group of this latter class embraced 36 cases, not strictly homogeneous, but made up of chronic or subchronic affections of the spinal cord and peripheral nerves. One (typical) fatal case of this sub-group was analyzed at some length, and the results of the microscopic examination of the spinal cord and nerves were reported upon. The case was that of a carriage-painter, who suffered for some years with progressive anæmia and general emaciation, and for the two years preceding his death with weakness, paræsthesia, and impairment of sensibility with exaggerated tendon reflexes and extensor spasm, increasing, finally, to complete paraplegia. Lead had been found in the urine three times, but the patient had never presented "a blue line, characteristic of paralysis, encephalopathic symptoms, or colic, though the bowels had been obstinately constipated for years. The morbid changes found after death, besides the signs of general anæmia, were those of combined antero-posterior and lateral sclerosis of the cord, on which, at the last, a subacute process of diffuse destructive softening had engrafted itself."

This latter process, which was characterized by the presence of a dense infiltration of granule-cells, and by a breaking down of the nerve tubes, so as to form round or oval cavities, such as have often been described, extended the length of the cord occupying the position of the sclerosed system tracts and the adjoining tissues. The nerve-roots were affected, though to a less degree than the cord; the posterior much more than the anterior. The acute process was at its height in the dorsal region. The gray matter was also affected, apparently in proportion to the severity of the secondary acute change—*i. e.*, most severely in the dorsal region—the smaller arteries were here and there thickened, the peripheral nerves were degenerated, but only to a moderate degree.

It was not assumed that these changes in the cord were due to lead as a specific poison, though, at the same time, the evidence is that such myelitic changes as lead does set up are diffuse in character, and not coördinated with the typical peripheral nerve degeneration.

It was, however, thought more probable, in view of the circumstances under which such pathological processes had been seen in other cases, that the lead acted, if at all, by inducing a general and—through the thickening of the vessels—a local anæmia, thus intensifying the effects of other influences, of which one might be an hereditary tendency.

Another case was cited to show that lead in drinking-water may cause outbreaks of acute indigestion in children, while other children, exposed to the same influences, may be wholly unaffected.

A number of observations made on Boston drinking-water by Dr. E. M. Greene were reported, showing the frequency with which lead is present, and the length of time required to rid a pipe wholly of its presence.

DR. HAROLD C. ERNST, of Jamaica Plain, Mass., then read a paper, entitled

HOW FAR MAY A COW BE TUBERCULOUS BEFORE THE MILK BECOMES DANGEROUS AS A FOOD SUPPLY.

The observations which he reported were made at the instance of the Massachusetts Society for the Promotion of Agriculture. The surroundings of the animals used were prepared in the most careful manner; 114 samples of milk were examined for the bacillus. These were obtained from 36 cows suffering with tuberculosis of some organ other than the udder; 17 samples were found to contain tubercle bacilli. These 17 specimens came from 10 cows. The cream was found to contain bacilli as often as the milk. The bacilli were present with a fair degree of constancy.

Well animals were then inoculated with the result of inducing the disease in 50 per cent. of the cases treated. Feeding experiments were also made, with the result of inducing the disease in a number of calves and young pigs. The following conclusions were presented: 1, and emphatically, that milk from cows affected with tubercu-

losis in any part of the body may contain the virus of the disease; 2, that the virus is present, whether there is disease of the udder or not; 3, that there is no ground for the assertion that there must be a lesion of the udder before the milk can contain the infection of tuberculosis; 4, that, on the contrary, the bacilli of tuberculosis are present and active in a very large proportion of cases in the milk of cows affected with tuberculosis, but with no discoverable lesion of the udder.

DR. E. L. TRUDEAU, of Saranac Lake, New York, then read a paper on

HOT-AIR INHALATIONS IN PULMONARY TUBERCULOSIS.

(See page 337.)

Adjourned.

CORRESPONDENCE.

"OIL OF CEDAR."

To the Editor of THE MEDICAL NEWS,

SIR: My attention has been accidentally called to "oil of cedar" by a death in the practice of a professional friend. He tells me that about an ounce was taken with suicidal intent. Text-books are almost silent on the subject, and I find but few articles in the journals. The articles seen are conflicting. A partial explanation of the conflicting accounts I find in the fact that two or three entirely different articles are sold under the same name. Two of these are manufactured, the one from the tops and the other from the wood of the *Juniperus Virginiana* or red cedar. The other is made from the *Thuja occidentalis*, sometimes called the white cedar or arbor vitæ.

"Oil of cedar" is to be found in almost every drug-store, and is frequently used as a vermifuge. It is also used in liniments, as an abortifacient and as an emmenagogue. I find here that the Thuja oil is the one most commonly kept. In one store there were two specimens. The one was labelled "Oil of Cedar, Red, Pure," which, I was informed, was the oil of red cedar, and when first received was red in color, but had become white. This was clearly *not* the oil of red cedar, but the Thuja article, judging from the odor. The other bottle was marked "Oil of Cedar, Pure," and I was told that this was the white cedar oil. I could in that detect not the slightest odor of the Thuja.

It is my purpose to make some investigations as to the oils to determine their physiological action. I will, therefore, be greatly obliged to any members of the profession who may aid me by giving me therapeutical or toxicological notes of cases. Such writers will receive due credit; they will please let me know which of the oils was used, so far as possible.

HENRY BIXBY HEMENWAY.

524 S. PARK ST., KALAMAZOO, MICH.,
September 21, 1889.

NEWS ITEMS.

The Mortality of Foreign Cities.—The annual death-rate per 1,000 in the principal foreign cities, according to the last weekly returns communicated to the Registrar-General, is as follows: Calcutta, 26; Madras, 40; Paris, 21; Brussels, 20; Amsterdam, 18; Rotterdam, 18; The Hague, 24; Copenhagen, 24; Stockholm, 17; Christiania, 26; St. Petersburg, 33; Berlin, 20; Hamburg, 23; Dresden, 28; Breslau, 27; Munich, 42; Vienna, 19; Prague, 22; Buda-Pesth, 30; Trieste, 23; Rome, 22; Turin, 30; Venice, 26; Cairo, 67; Alexandria, 44; New York, 28; Brooklyn, 25; Philadelphia, 22, and Baltimore 21.—*Medical Press and Circular*, September 4, 1889.

A New Hospital for Denver.—We learn, through the *Boston Medical and Surgical Journal*, that Denver, Colorado, has just completed a $30,000 hospital.

Death of Dr. Maurice Perrin.—The death is announced in Paris of Dr. Maurice Perrin, President of the Académie de Médecine, Inspector of the Service de Santé, formerly Director of the School at Val-de-Grâce, Physician-in-Chief of the Army of Marshal MacMahon in 1870, Commander of the Legion of Honor. Dr. Perrin commenced his career by teaching military medicine and ophthalmology at the Military School of Medicine. He was the author of several well-known works; among them may be cited, *Du Rôle de l'Alcool et des Anesthétiques dans l'Organisme*, a treatise on Surgical Anæsthesia (jointly with M. Lallemand), and a treatise on Ophthalmoscopy and Optometry.—*British Medical Journal*, September 14, 1889.

The University of Berlin and Poor Students.—It is reported that the Senate of the University of Berlin deprecates the substitution of free study for poor students in place of the present system of allowing such to obtain instruction and attend lectures on credit. The Senate believes that such an innovation might make it impossible for the poorer men to matriculate, as they might have too much pride to accept as a gift what they now merely get on credit.

NOTES AND QUERIES.

CONIUM OINTMENT IN PAINFUL RECTAL TROUBLES.

To the Editor of THE MEDICAL NEWS,

SIR: The conium ointment recommended by Whitla for painful rectal troubles can be much simplified and made of more general use by substituting for the *succus conii* of his formula the *alkaloid coniine*. I have used an ointment made according to the formula given below in a number of cases, and the success is all that is claimed by Whitla for the original combination. This is the formula:

℞.—Coniine	gr. ij.
Sol. ferri persulph.	ʒss.
Vaseline	℥j.

M. ft. ung.

Very respectfully yours,

O. T. SCHULTZ.

MT. VERNON, IND., September 21, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE TWO WEEKS ENDING SEPTEMBER 21, 1889.

BEARDSLEY, G. S., *Medical Inspector*.—Granted six months' leave, with permission to go abroad.

RUTH, M. L., *Surgeon*.—Order granting furlough revoked, and placed on waiting orders.

Medical Director HUDSON, *Medical Inspector* WOODS, and *Surgeon* DICKINSON will continue as President and members of an Examining Board for examination of applicants for the position of Assistant Surgeon in the Navy, at San Francisco, California, until June 30, 1890.

THE RELATIONS BETWEEN CHLOROSIS, SIMPLE ANÆMIA, AND PERNICIOUS ANÆMIA, INCLUDING LEUCOCYTHÆMIA AND HODGKIN'S DISEASE.[1]

BY FREDERICK P. HENRY, M.D.,
PHYSICIAN TO THE PHILADELPHIA HOSPITAL.

THE title of the subject which I have the honor to discuss before this Association, viz., the Relations between Anæmia, Chlorosis, Pernicious Anæmia, etc., might be criticised on the ground that it assumes certain relations to exist between these various affections of the blood. To such criticism it might be replied that the selection of such a title is the expression of the universal medical belief that these affections are allied, and that it is in the highest degree improbable that such a practically unanimous verdict can be erroneous.

Without stopping to mention any of the numerous historical instances in which the prevailing medical belief has been erroneous, I will begin by pointing out that in the discussion of this subject everything depends upon what is understood by the term Relation.

While we are justified in speaking of kindred diseases, there are no facts to warrant the belief that one affection can be converted into another, or that the cause of one disease can be so modified by its habitat and general environment as to excite another which is, by common consent, entirely different.

The best example of kinship is afforded by the infectious diseases, which originate, not in the same, but in a similar manner. No nearer relation than this has yet been recognized in disease. In the remotest past there may have been one pathogenic organism, the source of all the ills to which flesh is heir, but at the present time there are many such, and their differentiation is complete and permanent.

There are, therefore, three questions to be discussed:

1. Are chlorosis, simple anæmia, pernicious anæmia, etc., separate diseases?
2. Are they of kindred nature?
3. Are they different stages of one disease?

I will first consider pernicious anæmia, because the determination of its status is of fundamental importance. It is admitted by those who argue most forcibly in favor of the independent nature of this disease, that its clinical features are common to a number of affections, particularly cancer and atrophy of gastric glands. They have also been repeatedly associated with the presence of parasites in the intestinal canal, such as anchylostomum duodenale and bothriocephalus latus. In these and other affections the blood has presented the characteristics of pernicious anæmia, viz.: 1. Great diminution of volume. 2. Enormous reduction of the number of the red corpuscles, sometimes to ten per cent. of the normal—*i. e.*, the blood may contain 500,000, instead of 5,000,000, of these bodies to the cubic millimetre. 3. Poikilocytosis—*i. e.*, remarkable alterations in the size and shape of the red corpuscles. 4. Microcytosis, by which is meant the presence in the blood of numerous minute spherical, yellowish-red corpuscles, resembling oil-drops; these are not constantly present. 5, and most diagnostic, a relative richness in hæmoglobin. The percentage of hæmoglobin may equal, exceed, even double, that of the red corpuscles. 6. No absolute increase in the number of the white cells.

By one set of writers it is argued that when, in the course of cancer, atrophy of the stomach, or other disease, the above-mentioned striking changes in the blood are observed, the case is not one of pernicious or idiopathic anæmia, as they term it, because a well-marked lesion is present. If, however, the same alterations of the blood are present, and at the autopsy no lesions can be found except those that are manifestly secondary to the blood-change, such as fatty degeneration of the heart and intima of blood-vessels, then the case is one of pernicious or idiopathic anæmia. For example, in 1886,[1] I reported, in conjunction with Prof. Osler, a case of atrophy of the secreting structures of the stomach with every clinical feature of pernicious anæmia. About the same time I had under observation another patient, a woman, whose symptoms and blood-changes were identical with those of the above-mentioned case.

"After an illness of more than a year she died, and at the autopsy, at which I was present, no lesion was found to explain the profound alteration of the blood. According to most authorities, the first of these cases, in which a lesion was found, to which the symptoms might be reasonably attributed, is, for that very reason, not a case of pernicious anæmia. The second case, on the other hand, is one of pernicious or 'idiopathic' anæmia, because a lesion, to which the symptoms might be attributed, was not found."[2]

[1] Read before the Association of American Physicians, September, 1889.

[2] Anæmia. By F. P. Henry, M.D. Philadelphia, 1887.

This kind of reasoning appears to me very unscientific. In both cases there were the same blood-changes, viz., those universally recognized as pathognomonic of pernicious anæmia. In one, the cause of these changes was manifest, or, rather, became so after a careful microscopical examination of the stomach. In the other, it eluded the minutest investigation. The pernicious blood-change was a process common to a known and an unknown cause, and not a separate or independent disease.

An independent disease is one which rests upon a constant anatomical basis, or is invariably produced by the same specific agent. Processes of disease, on the other hand, are common to a number of distinct and independent affections, the most widely distributed of these processes being fever, inflammation, and anæmia. Anæmia may be either a disease or a process—a disease where directly dependent upon a lesion of one of the hæmatopoietic organs; a process when not so dependent. From this point of view, the uniform blood-changes of pernicious anæmia are due to a disturbance of nutrition of the profoundest character, which may arise from a number of causes, some known and others unknown. It is, therefore, nothing more than a disease-process, and as such related both to anæmia and chlorosis.

Let us now inquire more particularly as to the mode in which this profound anæmia is produced, whether by a defect of hæmogenesis, an excess of hæmolysis, or by a combination of both.

The causes of anæmia have been divided by Coupland into two classes: "deficiency of income and excess of expenditure," and, according to most writers on diseases of the blood, chlorosis is a typical example of the former. In that affection there is a deficient assimilation of iron, which is accounted for in a more or less satisfactory manner by various theories. The most prevalent is that of Bunge, which has been practically adopted by Sir Andrew Clark. Until quite recently, no satisfactory explanation could be given of the efficacy of iron in chlorosis, and especially of the necessity of administering it in large doses, for it was well known that very little of this drug was absorbed. It was also known that our food, which, when in proper amount and variety, contains more iron than we need, does not contain this metal in inorganic form, but in an exceedingly complex organic union. Human milk, which contains the merest trace of iron, supplies all that is needed for the wants of the rapidly growing infant. Nearly all our food-substances contain iron, and there is probably no drinking-water in which traces of it cannot be found. Zander[1] examined the water from three hundred springs, and found iron in every specimen. The same observer examined the feces of chlorotic patients before they had been placed upon any treatment, and found iron in them in considerable quantity—a sure proof that there was no want of this metal in the food. The conclusion, therefore, must be that there is, as already stated, something which interferes with the digestion and assimilation of the superabundant iron contained in the food; and this something is believed by Bunge to be sulphur.

In chlorosis, as is so emphatically insisted upon by Sir Andrew Clark, digestive disturbances are exceedingly common. Abnormal fermentations and decompositions take place in the gastro-intestinal tract, and give rise to the formation of quantities of sulphides which decompose the iron contained in the food, and completely unfit it for the purpose of nutrition. By administering an inorganic preparation of iron we simply offer a bait to these sulphides, which they seize upon and so allow the organic combinations in the food to escape and to be absorbed. This theory explains also why it is often necessary to administer large quantities of iron, for in such cases the sulphides are supposed to be formed in large amount, and to need corresponding quantities of iron to saturate them.

The blood of a healthy adult contains only about forty-five grains of iron (three grammes), and, therefore, in severe cases of chlorosis there is only a deficit of about one scruple of this metal. Why then is it so often necessary to administer colossal doses of iron in order to cure a case of chlorosis? Evidently because the iron plays some other *rôle* than that of a food. The theory of Bunge, to which I have just alluded, offers the most satisfactory explanation of its mode of action.[1]

There are other theories of chlorosis supported with equal ingenuity, such as those of Zander[2] and Landwehr,[3] which, in accordance with the division of labor agreed upon between us, I leave to the consideration of the co-referee in this discussion. Suffice it to say that they all unite in referring the cause of chlorosis to a defect in hæmogenesis.

I have entered into these details concerning chlorosis because it is universally conceded to be a typical example of defective hæmogenesis, and because I wish to compare it with another disease—pernicious anæmia, which is now generally attributed to excessive hæmolysis. This opinion, now prevalent, of the nature of pernicious anæmia, is largely due to the elaborate investigations of Dr. William Hunter.[4] This observer not only believes that the blood-changes of pernicious anæmia are essentially hæmolytic, but that "hæmogenesis is so little interfered with that it is generally in excess of the normal." The arguments of Hunter in favor of the

[4] Lancet, Sept. 22 and 29, Oct. 6, 1888.

independent nature of pernicious anæmia are the most powerful that have yet been advanced. They may be summed up in the concluding paragraph of his valuable paper:

"In pernicious anæmia the seat of disintegration [of the red corpuscles] is chiefly the portal circulation, more especially that portion of it contained within the spleen and the liver, and the destruction is effected by the action of certain poisonous agents, probably of a cadaveric nature, absorbed from the intestinal tract."

Hunter admits that the clinical features of pernicious anæmia are often associated with various gastro-intestinal lesions, especially cancer of the stomach and atrophy of the gastric glands, and with intestinal parasites, but believes such association to be accidental:

"This conclusion is based chiefly on two considerations: (1) that similar anatomical changes, sometimes even more marked, are constantly to be met with in cases presenting none of the features of pernicious anæmia; and (2) that cases of pernicious anæmia are constantly met with in which no such gross anatomical changes are to be found."

Atrophy of gastric glands has often been observed in association with the clinical features of pernicious anæmia, and it is believed by some, myself among the number, to be a cause of that disease-process. The same gastric lesion has existed without the clinical features of pernicious anæmia, and this is one of the reasons why Hunter regards the latter as representing a distinct and independent disease superadded to the former. When closely looked into, this argument loses much, if not all, of its force. The function of the stomach is very complex, and may be largely supplemented by that of the intestine. In fact, in the opinion of some of the best authorities, gastric is merely preparatory to the more perfect intestinal digestion, the office of the stomach being chiefly to coagulate milk and liquefy albuminous bodies. It has been found that a dog whose stomach has been excised may be nourished for an indefinite period by placing food in its duodenum, and there would, I think, be little difficulty in proving that of the various functions of the stomach, the motor is of paramount importance.[1] As I have remarked elsewhere:

"The important part assigned by nature to intestinal digestion, coupled with the fact that it may entirely supplement the action of the stomach, has led Jaworski to attribute a subordinate *rôle* to the stomach, which he regards as a species of warm chamber, in which the food is detained for a time prior to its delivery to the intestine. This view reminds one of the Hippocratic theory of the coction of food by animal heat."[2]

These well-known facts offer one explanation why atrophy of the gastric glands is sometimes associated with the symptoms of pernicious anæmia; at others not so associated. The difference depends upon the preservation or impairment of the motor function of the stomach. The fact that "cases of pernicious anæmia are constantly met with in which no such gross anatomical changes" (as those of cancer and atrophy) "are to be found" affords no proof whatever, as Hunter seems to think it does, of the independent nature of pernicious anæmia. On the contrary, it rather tends to prove that there are two kinds of pernicious anæmia, a structural and a functional.

I have just shown that a motor insufficiency of the stomach may be one of the causes of pernicious anæmia. This is generally associated with gross anatomical lesions, such as cancer, atrophy, fibroid thickening, etc. A pernicious anæmia arising under such circumstances may be called structural or organic. There is good reason to believe that a chemical insufficiency of the stomach, long continued, especially if associated with intestinal indigestion, may also give rise to the symptoms of pernicious anæmia. Under these circumstances it would be of the functional variety.

Recent observations have shown that the gastric juice has other functions besides those of curdling milk and liquefying albuminous substances.[1] Although proved by Spallanzani, more than a hundred years ago, to be possessed of antiseptic properties, it is only quite recently that its destructive action upon various microörganisms has been rigorously demonstrated. The facts thus established have an important bearing upon Hunter's theory that the blood-corpuscles in pernicious anæmia are destroyed in excessive numbers by a cadaveric poison absorbed from the gastro-intestinal tract. In cancer and atrophy of gastric tubules the gastric juice is notoriously of defective composition, and a deficit of hydrochloric acid has also been observed in certain neuroses of the stomach. With the two first-mentioned conditions the clinical features of pernicious anæmia are often associated, and they have also in a number of instances been clearly of neurotic origin. Several typical cases of pernicious anæmia have been reported by Stephen Mackenzie, of London; R. G. Curtin, of Philadelphia, and others, which had their origin in a profound shock to the nervous system. Probably in all these cases, certainly in the two first-mentioned classes, the antiseptic influence of the gastric juice has been withdrawn from the gastro-intestinal tract and the formation of ptomaines has proceeded therein to an abnormal extent. In this manner the origin of the supposititious cadaveric poison of Hunter may be accounted for.

[2] American Journal of the Medical Sciences, Nov. 1888, p. 498.

[1] De l'Action du Suc gastrique sur quelques Microbes pathogènes. Par MM. J. Straus et R. Wurtz. Arch. de Méd. Exp. et d'Anat. Path., 1 Mai, 1889.

I will now point to what seems to me another imperfect link in Hunter's chain of reasoning. In his article in the *Practitioner*,[1] in which he discusses, and answers in the affirmative, the question whether pernicious anæmia is a special disease, he acknowledges his adherence to the general opinion that chlorosis is caused by defective hæmogenesis, and attributes this defect to a cadaveric poison which destroys the iron contained in the food we eat. This, as is well known, is the theory of Bunge. Now it seems to me illogical to attribute to one hypothetical ptomaine, that of chlorosis, a power of interfering with hæmogenesis, and to another, that of pernicious anæmia, a power of increasing hæmolysis.

Hæmolysis is increased in pernicious anæmia. This is proved beyond doubt by the able researches of Hunter; but it is, in my opinion, *because of defective hæmogenesis*. The red corpuscles in this affection are abnormally weak and perishable, as is proved by the fact observed by Copeman[2] that their hæmoglobin crystallizes out of them with great readiness. I am not alone in this opinion. In a recent discussion of a case of hæmoglobinuria in the London Medical Society,[3] Dr. Stephen Mackenzie "insisted upon the fact that in essential or pernicious anæmia there appeared to be some defect in the formation of the corpuscles, in addition to their rapid destruction."

I trust that I have made it plain that, in my opinion—1. Pernicious anæmia is not an independent disease. 2. It is closely related to chlorosis. 3. It may be the terminal stage of other diseases, and especially of cancer of the stomach and atrophy of the gastric tubules.

The grounds on which I believe pernicious anæmia and chlorosis to be related are not merely theoretical, for I have seen several cases and published one[4] in which a transition between the two affections was, in my opinion, plainly evident, and Trechsel[5] has observed two similar cases. The transition from pernicious anæmia to chlorosis may be observed in any case of the former disease in which marked improvement occurs. Under such circumstances the red corpuscles lose their irregular contours and become circular in outline; they increase in number, and, most important of all, their percentage of hæmoglobin, which may have been equal, or superior, to that of the number of the corpuscles, is now much below the latter. The change is so marked that the case which, seen at its worst stage, would have been unhesitatingly set down as pernicious anæmia, would now, with equal certainty, be regarded as one of chlorosis.

The constant presence of fever in pernicious anæmia can no longer be regarded as a point of distinction between that affection and chlorosis, for hyperpyrexia has been frequently observed in the latter, and would, according to Jaccoud,[1] be more often found if looked for. In fact, Trazit[3] devotes his thesis to the consideration of febrile chlorosis.

The origin of pernicious anæmia has been attributed to microörganisms by Frankenhauser,[3] Planchard,[4] and others. The former describes certain minute bodies supposed to be micrococci which he has observed in the blood of several cases of pernicious anæmia. In the liver cells of the same cases he detected threads resembling those of leptothrix buccalis. All of Frankenhauser's patients had carious teeth, and these he believed to be the source of the microörganism of pernicious anæmia.

This theory has found very few adherents, and it is worthy of remark that the latest work on pathological histology,[5] by a countryman of Frankenhauser, makes no mention of it.

(To be concluded.)

WHITE LEAD IN THE TREATMENT OF ERYSIPELAS.

BY E. STUVER, M.S., M.D.,
OF RAWLINS, WYOMING TERRITORY.

DURING the last four or five years I have treated a number of cases of erysipelas with ordinary white lead ground in oil, thinned to a proper consistency with Japan dryer, and so prompt and efficient has been its action that I desire to call attention to its merits.

I have tried quite a number of the most highly lauded remedies, including the combination of sulphichthyolate of ammonium and lanolin, which is claimed by many to be a specific in this disease, but in my hands white-lead paint has exerted a more favorable influence than anything else; it very promptly relieves the burning pain and feeling of tension which are so marked in severe cases; it limits the spread of the disease process, and forms an impermeable covering over the affected parts, thereby preventing the dissemination of diseased particles. If this disease, as is now generally admitted, be caused by pathogenic microörganisms, this power of the treatment to limit the spread of the disease germs should lead to its more general adoption.

The following cases will illustrate the advantages above indicated:

Case I.—I was called to see Mrs. M., who was approaching full time with her eighth child, and found a clearly defined erysipelatous inflammation on the right side of the nose, which I treated by painting the swollen parts with a mixture of equal parts of collodion and castor oil, and giving internally a mixture composed of quinine, iron, and simple syrup. Under this treatment the pain and swelling continued to increase until the disease had extended over both cheeks and around the eyes, which were nearly closed, and involved both ears, which were greatly swollen. A blister about one-half inch in diameter had formed on the right cheek bone. This having been covered with absorbent cotton and the parts thoroughly cleaned, I applied a thick coat of the white lead paint over the whole surface, extending slightly beyond the margin of the inflamed parts, and ordered it to be repeated three or four times a day. The first application almost immediately relieved the pain and discomfort, and while the swelling did not begin to subside for about twelve hours, the disease extended no further, and she obtained a good night's rest.

Three days after the onset of the attack, I was called to the case and found her in active labor, which terminated without any trouble in a couple of hours. Recognizing the danger of the situation, rigid antiseptic precautions were taken to avoid septic infection. A supply of sanitary towels (absorbent cotton enclosed in a light cheese-cloth material) were immersed in a 1 to 500 bichloride of mercury solution, squeezed out, dried, and kept constantly applied to the vulva; the patient was instructed under no circumstances whatever to touch the genitals or make applications to same; the nurse who changed the cloths and washed the parts each time used a strong solution of the bichloride to render the hands aseptic; the genitals were washed twice a day with a 1 to 1000 bichloride solution, and the nurse was not allowed to paint or in any way touch the diseased face; the husband attended to this part of the treatment. Under this management the case progressed rapidly to recovery, the temperature and pulse respectively falling from 101⅗° and 120 per minute on the 14th, to 98° and 88 per minute on the 17th. The inflammation rapidly subsided, and on the 20th the exfoliative process was well under way, leaving the skin smooth, soft, and white. In this case I am convinced that the impermeable coating formed by the lead paint did much to lessen the danger of infection.

Case II.—Mrs. N. was taken sick with chills and fever; was treated by another physician for several days, but continued to grow worse. Five days later I was requested by the husband to see the case, and found the ears, cheeks, and nose largely swollen and of a purplish color; quite a number of vesicles were on the swollen parts; there had been considerable diarrhœa, but this was now subsiding. The pulse was 116 in the morning and afternoon. The temperature varied from 103° to 104¾°. Applied white paint freely to inflamed area, and gave internally quinine and large doses of the tincture of chloride of iron. The pain and soreness, which were very marked, soon diminished. On the next day by 2 P. M. the pulse was still 115, and the temperature 104⅕°; the ears were not so much swollen, but the inflammation had extended to the scalp. The hair was, therefore, clipped off short, exposing a surface covered by an eczematous eruption with small, yellowish scabs; this was worst on top of the head, but existed to a certain extent over the whole scalp; the erysipelas was found to extend over the parietal and temporal regions to the vertex and posteriorly to the lambdoidal suture—this whole region was found to be swollen, infiltrated, and painful on pressure; the head was thoroughly washed with a mild soap and warm water, carefully dried, and then completely covered with the lead paint.

The next day the pulse and temperature remained unchanged, but the head was feeling better, though the eyes and frontal region were badly swollen. The lips were dry and sordes were on the teeth. Six additional grains of quinine night and morning were now added to the treatment. Twenty-four hours later the pulse and temperature had fallen very much. the latter from 103° to 101⅖°.

She had passed a restless night. The nostrils were occluded and secretion collected in the trachea; the appetite, however, was better, and she took a considerable quantity of milk and a soft boiled egg. I gave her the following:

℞.—Pepsini puris in lamellis (P. D. & Co.) ℈j.
Aquæ . . . . . f℥j.
Ext. cascaræ sagradæ fl. . . f℥ij.
Spts. frumenti . . . . f℥iij.
Vini ferri et carnis . q. s. ad. f℥viij.—M.
Sig.—Large tablespoonful three or four times a day:

On the tenth day the pulse in the sitting position was 103; temp. 99⅘°; and she was looking and feeling much better.

The disease rapidly subsided, and under a tonic treatment she made a prompt and satisfactory recovery. In this case the disease assumed a very severe type, and at one time I had very serious doubts whether it would end in recovery. The lead paint acted very nicely, promptly relieved the pain and checked the spread of the morbid process.

In two other cases, one a boy of about thirteen, the other a man, I first used sulphichthyolate of ammonium and lanolin in equal parts, but this only produced moderate relief; in both cases the white-lead paint was substituted with markedly advantageous results.

Other cases might be cited, but the above are sufficient to justify the following conclusions, viz.:

1st. White-lead paint promptly relieves local pain and tenderness.

2d. It limits the spread of the disease.

3d. By forming an impermeable coating it prevents dissemination of the disease germs, and consequent infection of abraded or wound surfaces.

ACUTE INTESTINAL OBSTRUCTION COMPLICATING STRANGULATED HERNIA; HERNIOTOMY, WITH SUBSEQUENT LAPAROTOMY; RECOVERY.

BY J. HOWELL WAY, M.D.,
OF WAYNESVILLE, N. C.

AT 12 P. M., on April 11th, I was called to the neighboring town of Clyde in consultation on the case of J. M., a farmer, æt. thirty-one, of small, slender build, and weighing only about one hundred and twenty-five pounds, but a man who, as his neighbors expressed it, "did twice as much lifting at the log-rollings as any man of his size." On my arrival I obtained from the attending physician the following history of his patient's illness:

Early on the morning of the 9th, feeling about as well as usual, save a sensation of being rather tired from his having been engaged in building a barn on the day previous, he shouldered a very heavy bag of corn, and, putting it on his horse, mounted and rode away to the mill, a little more than a mile distant from his home. While on the way he felt nauseated and experienced an uneasy sensation in his bowels, which continued to increase until soon after reaching the mill, when he felt chilly, experienced a considerable degree of abdominal pain, and vomited freely the contents of his stomach. Returning home, half an hour later, his sufferings were so augmented that it was deemed expedient to summon a physician. When he came, an hour later, the patient was frequently vomiting matter of a bilious character and suffering the most acute pain, which ranged from the umbilicus down to the right inguinal region. His bowels were constipated.

The diagnosis, as made at that time, was "bilious colic with constipation," and for the relief of which morphia *per os* was given, and a number of small doses of calomel were left to be taken during the day; also additional doses of morphia to be used if necessary to relieve pain. Both were given, and during the following night, on the recommendation of friends, three compound cathartic pills and two ounces of castor oil were also administered. Late in the night enemata were resorted to several times; at first a small amount of fecal matter was passed, but later the fluid returned unchanged and presenting the same appearances as when injected.

When seen by his physician on the following day, the patient's condition was much worse. Despite the free use of opiates *per os*, he had been unable to procure the least degree of comfort, or even momentary freedom from pain. His abdomen was very tympanitic, and also quite tender over almost its entire surface. He was extremely thirsty, and vomiting of a fecal nature now took place occasionally. He had still been unable to produce a movement of the bowels. Copious enemata were again administered, but with results as before.

The patient now, for the first time, observed a slight swelling in the right inguinal region, extending down over the spermatic cord into the scrotum just above the testicle. The attention of the physician was directed to this, and, though not fully able to satisfy himself that it was a hernial protrusion of the bowel, he practised taxis for some little time, with the result (as he thought) of almost entirely reducing the enlargement. A temporary truss was improvised and applied, and a messenger dispatched to procure a proper one. The liberal use of the cathartic agents mentioned above, to which was also added Epsom salts in full doses, was continued during the day, but no motion followed; the patient's sufferings were increased, and his general condition grew worse up to the time when I first saw him, on the evening of the 11th.

Having obtained this history of the patient from his physician, I proceeded to examine him, and elicited the following facts relative to his condition at that time.

On entering the room, an offensive odor, as of fecal matter, was noticeable. This, it was found a few moments later, was caused by the exhalations of the patient's breath, which was very offensive from his having vomited fecal matter several times during the few preceding hours. His face was wan and pallid, wearing a pinched expression suggestive of the intense pain he had endured so patiently during the two days past. His tongue was heavily coated, red at the tip and edges, very dry and glazed in appearance, and very tremulous when protruded. He was exceedingly thirsty, and constantly desiring water, of which he drank large quantities with much avidity. Decided anorexia was present, the mere mention of food being very repulsive to him. His respirations were forty per minute, and quite shallow, owing to the great abdominal distention present and the pain induced by the downward expansion of the lungs. Singultus was present, and had been for a few hours. The patient's abdomen was greatly distended and tender over its entire surface, being markedly so at a point about two inches above and slightly to the left of the right internal abdominal ring. Upon removing the truss, which did not fit very accurately, I observed a slight enlargement extending from the external ring down to a short distance above the right testicle. It was slightly tender, and communicated a doughy sensation to the fingers when manipulated. No impulse was visible in the swelling on the patient's coughing. Gentle but sufficiently prolonged manipulation failed to effect any reduction in its size. His pulse was 130 per minute, small and weak; his skin dry and parched; his temperature 102.8°.

Arriving at the conclusion, as I soon did, that we had to deal with a case of acute intestinal obstruction, and deprecating the use of cathartic agents, I advised the bringing of the patient profoundly under the influence of hypodermatics of morphia for a few hours, and in the event of that failing to relieve him an operation should be performed without further delay. One-half grain of morphine was given subcutaneously and repeated twice at intervals of half an hour, when the patient became more tranquil and slept for a few hours. Professional engagements necessitating, I was compelled to leave and did not return until noon on the 12th, when I found the general condition of my patient apparently much better, the pain having been so slight as

not to require a repetition of the morphia. But this improvement I was convinced, on careful examination, was only apparent, for there were symptoms pointing strongly to the beginning of what I feared would be fatal collapse. Feeling assured that intestinal obstruction was present, though not fully able to convince myself as to whether it existed alone at the abdominal ring or at the site within the abdomen, two inches above the ring, which was so acutely sensitive and painful, or at both, I advised an exploratory incision over the site of the inguinal canal, intending, if necessary, to extend it upward to the sensitive spot.

This being agreed to by my *confrères* in the case, I proceeded to operate. The patient was thoroughly anæsthetized by chloroform, and additional efforts were made to reduce the tumor, but without avail. The abdomen and pubes were then shaved and thoroughly cleansed. Pinching up a fold of integument it was transfixed, and an incision three inches in length, directed upward and outward over the rings, was made. The various hernial coverings were then carefully gone through until the peritoneum was reached. This, presenting a dark appearance, was opened and gave vent to two or three fluidrachms of dark grumous fluid having a putrefactive odor. A fold of omentum was now seen protruding from the external ring. It was of a dark purple color and emitted an offensive odor. The fibres of the external ring were freely divided and the omentum withdrawn until healthy tissue was reached. A silk ligature was then thrown around this *en masse* and the gangrenous portion removed. Examining the internal ring I found its margins torn so that it was quite patulous, but to my surprise the omental pedicle with a small loop of bowel which had come through the internal ring but had not passed out of the external ring, would not return to the abdominal cavity. I also observed that while there was not the slightest constriction of the bowel at the internal ring, it was intensely congested and its tissues swollen. I now continued my incision upward until the point the patient had complained of as being so sensitive was reached. Then by partially withdrawing the loop of bowel with the fingers of one hand and passing the index finger of the other along the course of the bowel deeply into the abdominal cavity I discovered the source of constriction to be a ligamentous fold or band under which the bowel seemed to have been suddenly forced and been unable to return. This was divided partly with a probe-pointed knife and partly by tearing it with my finger, and the bowel released. The site of the operation was thoroughly irrigated with a hot carbolized solution, a rubber drainage tube passed deep into the abdominal cavity, and the edges of the wound brought together by two sets of sutures, a superficial and a deep, each being of silk. The patient reacted from the operation finely. An hour later his bowels began moving. Between fifteen and twenty very loose, watery, feculent discharges took place within the next few hours, when it was deemed advisable to restrain further movements for the time being by hypodermatics of morphine.

From this time on the patient's progress toward recovery was rapid and not a single bad symptom occurred in the case; for only one or two days was the temperature as high as 101°. His appetite was excellent from the morning after the operation, though for a fortnight I restrained him to a fluid diet. On the eighth day the stitches were removed. A few days later he was out in the full enjoyment of his usual health and vigor.

LAPAROTOMY IN A CASE OF DERMOID CYST.

BY J. HERBERT DAREY, M.A., M.D.,
OF GRANGER, MINNESOTA.

ON the 8th of July I was called to see F. B., a girl of eleven years of age, whose parents had accidentally discovered that morning a protuberance in her abdomen. On examination a large symmetrical tumor was discovered extending from the hypogastrium two inches above the umbilicus. It was dull on percussion and had a firm elastic feel to the touch. It seemed to contain fluid. The abdomen measured twenty-eight inches at the umbilicus. The little girl had been growing rapidly, and was decidedly thin. She had had no symptoms of any kind, except that she had complained of not feeling very well in the spring. Next day I took her into Cresco, Iowa, and examined her there with Dr. Kessel. The tumor was not nearly so firm, and a solid growth was easily made out by deep pressure on both sides. We came to the conclusion that it was probably a dermoid cyst, and advised an early operation.

The patient was put on a mixture of ext. cascara sagrada fl. ℥v, and syr. rhei. aromat. f℥ss, twice a day, which caused her to have four or five loose passages daily, till the operation was performed. She was also given potass. acetat. gr. vijss, and ext. buchu fl. ℥xv, four times a day, For three days preceding the operation the urine had a sp. gr. of 1026, 1024, 1028, respectively, but contained no albumin or sugar. I secured a large, airy room for the operation, and had all the furniture removed and the floor and all the woodwork thoroughly scrubbed. I had several gallons of boiled water prepared for use if necessary.

On July 13th Drs. Kessel and Connolly, of Cresco, Iowa, came over to take part in the operation. The patient had been given a warm bath the night before and felt in good spirits. Dr. Connolly administered the ether; Dr. Kessel operated, I assisting him. Instruments were all put in boiled water, and ligatures, needles, etc., in a five per cent. carbolic acid solution. The belly was, first of all, scrubbed with soap and water, and was then washed with an ethereal solution of iodoform. The ether was not well taken at first, as it caused a copious mucous secretion in the throat and larynx, so chloroform was substituted for a few minutes, one-fourth grain morphine given hypodermatically, and after that she took the ether all right. The tumor was aspirated in the lower part but no fluid was obtained. Then an incision four inches long was made in the linea alba, and a careful dissection was made down to the peritoneum, which was opened, and a solid tumor came into view attached to the omentum for about six inches. Two

hypodermatic injections of 20 minims of whiskey were now given. A solid steel sound was introduced into the abdomen and swept around freely in all directions, showing that there were no other adhesions. The pedicle was found to be deep down in the pelvis on the right side. The adherent omentum was ligated with silk in sections, and cut off, and the upper part of the tumor aspirated, and about half a pint of bloody serum obtained. The incision was enlarged upward to about an inch above the umbilicus, and the tumor delivered outside of the body. The pedicle was ligated with stout silk in three pieces and the tumor removed. After satisfying ourselves that there was no oozing from the stump, it was allowed to drop back into the pelvis. It seemed to be attached to the broad ligament. The peritoneal cavity was now swabbed out with sponges dipped in a hot five per cent. boracic acid solution, till it was perfectly clean from blood-clots. The wound was closed by means of six deep and six superficial silk sutures. Iodoform was freely dusted over the wound and a dressing of carbolized gauze, padded with absorbent cotton, applied and a roller bandage outside of that. The time consumed during the operation was about an hour and a half. The tumor was as large as a fœtal head at term. On dissection it was found to contain a number of cartilaginous plates and alveolar processes in which teeth were found imbedded. The patient's pulse was 100 after the operation; no shock, and general condition good. She rallied well from the ether. The temperature, which had been 98.6° F. before the operation, rose to 100.2° F. in the evening after the operation. The pulse rose from 72 in the morning to 108 in the evening.

July 14. Patient rested well. Morning temperature 100.5°, pulse 120; afternoon temperature 101.2°, pulse 120; evening temperature 100.8°, pulse 116. No food of any kind was allowed for twenty-four hours, only a little water and cracked ice to suck when thirsty. Then a few teaspoonfuls of milk every hour were given.

15th. Morning temperature 99°, pulse 86; evening temperature 100.4°, pulse 90. Feels well; rested quietly.

16th. Morning temperature 100.3°, pulse 100; evening temperature 101.2°, pulse 92. This was the highest point the temperature reached. Next day it fell to 99.5°, and after that it remained about normal.

20th. All the superficial sutures and one deep suture removed. Wound looks nicely. No suppuration, except a drop about the deep suture, which was removed. Nothing but small quantities of milk every hour was allowed for the first week. Bowels moved for the first time to-day since operation by means of ʒj glycerin injections and the cascara mixture.

24th. Three deep sutures removed; wound healing nicely. Bowels keep open without much trouble.

26th. The two remaining deep sutures were removed. The wound has all healed by first intention, except about one and a half inches at the centre, where it gaped a little. Adhesive plaster was applied to draw the edges together. The patient was fed more liberally after this. She was kept in bed for four weeks, then allowed to sit up in an easy chair for a week, and after that was permitted to walk. Now she walks about wherever she wants and is gaining in flesh. She wears an abdominal bandage and will do so for a year.

REPORT OF A CASE OF RUPTURE OF THE BICEPS MUSCLE OF BOTH ARMS.

BY RICHARD WILSON,
STUDENT OF MEDICINE, UNIVERSITY OF PENNSYLVANIA.

THE following case of muscular rupture is believed to be unique and worthy of publication.

I would mention here that it was Dr. Walter F. Atlee who kindly furnished me the opportunity of examining this patient, and who urged me to publish the case.

John S. McCarthy, æt. fifty-four, white, weighing one hundred and eighty pounds, a baker by profession, of splendid physique, the muscles of his arms being particularly well developed—owing, no doubt, to his occupation, was returning home from his work on Christmas evening, 1888, when he was attacked in the street by three half-drunken young men. In the fight which ensued he knocked down two of them, and in attempting to give the third one a "left-hander," he missed his antagonist, heard a loud sound like the cracking of a whip, and his arm fell to his side almost paralyzed. The pain was intense. He presented himself at the Jefferson Medical College and was seen by the late Dr. S. W. Gross, who bandaged his arm, advised perfect rest, and said that nothing else could be done for him. A few weeks afterward he saw Dr. Pancoast, who wanted to operate on his arm, and suture together the two ends of the muscle. To this the patient objected, as he had to work to support his family. It was then he went to see Dr. Atlee, who agreed with Dr. Gross, that no operation was desirable. The patient did not give up his occupation, but continued working with his right arm. He could move his left arm, but could not make any effort with it. Six weeks after this accident he was again attacked, probably by the same persons, and having only one arm (the right one) to defend himself with, he struck out with it vigorously, and during the fight the biceps of that side gave way in precisely the same manner as the first one had done. The biceps broke as he struck a blow. He did not hear the sound like the cracking of a whip; for, he said, he was too busy fighting to be on the lookout for it. The right biceps does not seem as badly ruptured as the left one, but the rupture is almost complete. In April, 1889, he called to see Dr. Atlee. He then had both biceps muscles ruptured. It was after this that I saw him.

On examining the patient's arms, the deformity is at once apparent. Where the rupture took place (at the lower third), there is an unnatural depression, wide enough to admit readily three or four fingers, which terminates abruptly by an irregular elevation. Both muscles seem to have been torn in bulk; their tendons are intact and in their natural places. On pressing in the depression one can feel the aponeurotic sheath of the muscle standing out like a cord. The man can flex both forearms, and in this position the deformity is much more marked, due to the contraction of the two ends of the muscle. Undoubtedly the brachialis anticus muscle helps him a great deal in flexing the forearm. He did not stop working even after the rupture of the second muscle, having full power of moving his arms, but not being able to lift anything heavy. This was his condition when I saw him last, on August 1st.

Such is the history of this interesting case. A few remarks on the subject will, I think, not be amiss. The symptoms of this case are typical. As the diagnosis is made by the history, inspection, and palpation, I will recapitulate the symptoms: (1) A noise like the cracking of a whip; (2) a sharp, sudden pain, feeling like a blow from a stick or whip. The pain is constant, fixed, and intense, from the moment the rupture occurs; it diminishes with rest and position. The patient will get in a position that will put the muscle at rest. In two or three weeks there is left only a dull pain over the seat of the lesion. (3) The pain disappears when the muscle is at rest and returns when the muscle contracts. (4) A depression easily perceived which varies from a few millimetres to four or five centimetres; the space also varies with the position. (5) Ecchymosis appearing on the second or third day; this, however, is not constant, but often is absent. On the other hand, the hemorrhage may be quite considerable, reaching even half a litre (Charvot et Coullault), in which case it forms a tumor of variable size, doughy, and afterward becoming hard.

Muscular ruptures are very rare, and whether partial or complete, are usually not serious if early recognized and properly treated. But if not recognized, or neglected, a partial rupture may prove serious, especially if the patient continues the violent exercises which caused the first rupture of the muscular fibres. Where the muscular fibres are long and the tendons short, the body of the muscle breaks, while where the muscular fibres are short and numerous and the tendons long, the tendons break. Thus the rectus abdominis, the sartorius, the psoas, the iliac, the sterno-cleido-mastoid, and the biceps, though rarely ruptured, break the muscular fibres almost invariably. The extensors of the leg on the thigh, and of the foot on the leg, that are the opposite anatomically, rupture their tendons. Usually, the flexors rupture in their fleshy parts, and the extensors in their tendinous part. Ruptures are almost always complete when they affect the flexors, and incomplete or partial when they affect the extensors. The muscles which are known to rupture most commonly are, in the trunk, the rectus abdominis, psoas, and iliacus; in the neck, the sterno-cleido-mastoid; in the upper extremity, the biceps flexor cubiti; in the lower extremity, the sartorius and the rectus femoris. The extensors are ruptured much more rarely. Among other muscles, ruptures of which are on record, might be mentioned the gastrocnemius, the sphincter ani, of each of which Dr. D. Hayes Agnew reports a case, the rectus femoris, the deltoid, the longissimus dorsi. Ruptures of the muscles of the perineum during parturition are by no means an uncommon accident, in some cases extending completely through the sphincter ani. Partial ruptures are much more commonly met with than complete. Only a few fibres of a muscle give way, and they can be felt as a hard mass over the seat of the lesion. The accident is well known among tennis and foot-ball players. In England it has received the name of "poop" or "pope." It happens only to men who are not in training.

The accident always happens in the same manner; a man is running and suddenly feels a sharp pain in his leg and falls. He has to be helped off the field and in two or three weeks is well enough to go about.

Charvot and Couillault, in *La Revue de Chirurgie*, give an account of twenty cases of muscular rupture that they observed in some new recruits in a regiment of light cavalry. Eighteen of the cases were rupture of the rectus abdominis, occurring in the act of jumping on horseback from behind. From this account we see that: (1) Muscular ruptures are observed almost exclusively in young soldiers, at the time when they first begin to take violent exercise to which they are not accustomed. (2) The accident happens preferably to men not trained to gymnastic exercises. (3) Ordinarily the wounded man has received no previous injury that weakens the muscle. (4) Muscular ruptures are seldom complete; they are usually partial. (5) The same muscle is almost always ruptured at the same point by the same forced movement. (6) Muscular ruptures are indirect. The whole or part of the muscle is broken simply by a great effort, without external violence.

The mechanism of the rupture may be explained as follows: The anatomical muscle is made up of bundles of fibres, sometimes having different directions, and in some cases supplied with nervous filaments coming from different sources. In the daily movements all the muscular fasciculi, trained by habit, contract together under the influence of the will or of reflexes, to execute the movements with which they are familiar. Thus by a synchronous effort the muscle will overcome the resistance, even if very great. This is not the case when the muscle is forced to make a sudden violent movement to which it is not accustomed. There is a lack of unity in the muscular fibres, and they contract separately. At a given time at the moment of action, one group of fibres will have to support the whole effort. It is not astonishing, therefore, that it should break, if the resistance it has to overcome is considerable. This is the theory of Sédillot.

Another theory, that of Nélaton, is as follows: The nerves supplying the muscles give them a certain sense (called muscular sense), by means of which we are conscious of their degree of contraction, and thus we can exert our efforts in proportion

to the resistance we want to overcome. At the moment of a misstep, or a fall, etc., the muscle, stimulated by the instinct of preservation, contracts violently and instantly. The nervous impulse comes from the brain through the motor nerves, but the sensory nerve no longer carries the state of contraction of the muscle to the brain. The brain, therefore, loses the muscular sense, and continues sending contracting impulses to the muscle. If the muscle, under the influence of an excessive impulse to contract, finds an invincible obstacle to its contraction, it stretches beyond its physiological limit and breaks. The muscle may also break if, after having contracted, a mechanical force superior to that which controls it counterbalances suddenly its contraction. In voluntary movements the muscles sometimes may contract instantly and violently; their contraction may be excessive, and the rupture may then take place without the brain having time to become conscious of their state of contraction and moderate its motor impulses to prevent the accident. Therefore, whenever a rupture follows an instinctive contraction, or a quick violent voluntary movement, it is the result of the temporary suspension of the relations established by the sensory nerves between the brain and the muscle.

A post-mortem examination of a ruptured muscle shows that all the fibres are cut across at the same level. At this point there is an interval between the fragments of the muscle proportionate to their length, and always greater in complete ruptures. A little blood has extravasated between the two ends, and also in the surrounding connective tissue. It is not known whether the aponeurotic tissue of a muscle is ruptured or not. The wound heals in the usual manner by the exudation of plastic lymph, which undergoes contraction, vascularization, and organization, forming fibrous connective tissue. True muscular tissue is not formed again, the two ends of the muscle unite by a fibrous band which gradually thickens.

The prognosis varies with the severity of the rupture. The prognosis of a partial rupture is very favorable. If the rupture is very slight, it may get well in twenty days. Other degrees of rupture take longer time. When the rupture is complete, it takes from eight to twelve months before the muscle is as strong as before. For one year the patient must not make any violent effort with the ruptured muscle. As a rule, a rupture does no harm except to disable a man for several months. Excess of hemorrhagic extravasation is a complication which may prove serious, terminating in an abscess. Boyer gives an account of the only fatal case on record. It happened to a youth, seventeen years old, in attempting to lift a bucket full of water. Fever and insomnia set in; a fluctuating tumor appeared in front in the upper part of the thigh and the lower part of the groin, on the right side. He died on the tenth or eleventh day after the accident, and a post-mortem showed a rupture of the psoas muscle.

The treatment of this affection is very simple; usually perfect rest and relaxation will suffice. If necessary, poultices and anodynes may be applied locally. When the pain has passed away apply a tight bandage in such a manner as to bring the two ends of the muscle as near together as possible. This is best done by using three roller bandages. Apply each of the first two by beginning at one extremity of the limb and bandaging toward the rupture. If the ruptured muscle is in the trunk or neck, as the rectus abdominis and the sterno-cleido-mastoid, then the treatment consists only of rest and position, as a bandage cannot be applied. It is always prudent after a rupture of the abdominal muscles to recommend the patient to wear a belt to support the abdominal muscles, and not to engage in any violent exercise for several weeks after he is going about. By this means you prevent new muscular ruptures, or a secondary hernia from forming—fortunately, a rare accident. Dr. D. Hayes Agnew and others recommend suturing the two ends of the muscle together subcutaneously, when the muscle is of superior importance; and when the ends cannot be included thus by deep sutures, Dr. Agnew thinks it is a necessary and advisable procedure to open the wound and suture together the two ends.

Muscular ruptures for a long time have been unrecognized, and have been described as tears of the aponeurosis, luxations, sprains, and hernias of muscle (Nélaton). In 1781, Rousille Chamseru read before the Société Royale de Médecine several observations on the subject. The next year the elder Fagner also reported several cases. But of all the authors, J. Sédillot is the one who has contributed most from the surgical point of view. He first mentioned the subject in an inaugural dissertation in 1786, and in 1817 he presented a memoir on the subject to the Académie des Sciences.

CLINICAL MEMORANDA.

SURGICAL.

A Simple Method of Treating Umbilical Hernia in Infants.—If the treatment of umbilical hernia in the earlier weeks of infant life has proved as troublesome and annoying to others as to the writer, this description of a simple and effective method of treatment will not be out of place.

Agnew and others use a button of cork covered with chamois skin, and held in place by a broad strap of porous or rubber adhesive plaster encircling the trunk. Elastic bands, pads fastened to the binder, hard-rubber spring trusses, and various more complicated devices are also recommended. Most of these methods I have used, all with discomfort to the child, and unsatisfactory re-

sults. Porous plaster invariably irritates the skin, as does rubber adhesive plaster, and their removal causes a paroxysm of crying when the consequent straining is most undesirable. All absorbent pads become malodorous from retained perspiration, and are constantly moist from the daily bath. Bands extending around the waist interfere with respiration, peristalsis, and the development of the abdominal and lumbar muscles. Elastic bands are by far the worst in this respect. Pads fastened to the binder are constantly slipping out of place. The same may be said of trusses, which have the additional disadvantage of hurting a child that is not handled carefully.

An apparatus for successful treatment should be non-absorbent, non-irritating, and of such material that it will remain in place for at least a week, nothwithstanding daily bathing. It should not interfere with peristalsis, respiration, or development, and must be free from the possibility of hurting a carelessly handled child. Such requisites are combined in the following device, which differs slightly, but in important particulars, from others.

It consists of a hard-rubber, slightly oval, plano-convex lens, with a greater diameter of 3 cm., and thickness of 6 or 7 mm.; on the plane surface are two small wire loops facing each other at a distance of 2 cm. This is attached to the centre of an adhesive plaster strap, 2 cm. wide, and long enough to embrace three-fourths of the child's body, by thrusting the wire loop through the plaster and a small safety-pin through the loop. No plaster other than a reliable emplast. resin. of the Pharmacopœia should be used. In using, the hernia is reduced by the pressure of the button, and the warmed plaster quickly applied while the child is quiet. This will retain its position for from one to three weeks, unless considerable soap is used in the bath. When removal is desired, a few moments' soaking with soap and water will loosen it unnoticed by the child. If redness of the skin is produced, the cause will be found in the adulteration of the plaster with turpentine or Burgundy pitch.

Walter Chrystie, M.D.,
Physician to the Children's Dispensary,
University Hospital.

TOXICOLOGICAL.

Peculiar Case of Idiosyncrasy to Quinine.—The following case of idiosyncrasy appears worthy of being reported:

M. F. H., male, aged thirty-five, healthy; about five years ago became exhausted while working at a fire. For a stimulant he took some whiskey and quinine (how much he does not know). A short time afterward (one or two hours), intense itching of the dorsal and outer aspect of the middle phalanx of the right little finger set in, soon followed by the appearance of a large wheal. At the same time the glans penis, under the foreskin, was similarly affected. This latter became irritated and inflamed under wrong treatment (for gonorrhœa), and discharged pus for about a week; the finger getting well in about twenty-four hours. Six months later he took quinine again, followed by the same result. And again, in about a year, he had a similar experience.

About two years ago, being ill, the doctor prescribed quinine, but, remembering his former experience with it, he refused, until assured the dose was very small. But he suffered exactly the same as on former occasions. This time, however, the swelling and intense irritation of the glans were much relieved by application of a solution of lead and opium.

La Crosse, Wis. Edward Evans, M.D.

A Case of Chloroform Narcosis.—On December 10, 1888, Mrs. C., aged twenty-four, primipara, a remarkably robust and healthy young woman, was confined, and after a tedious labor of twenty-four hours, delivered of a large male child.

In the later stages of the labor chloroform was given during each pain. A right occipito-posterior position was diagnosed, and with the patient in a semi-conscious condition from the chloroform, three trials were made to deliver with Hodge's forceps; in each attempt the instruments slipped.

Dr. Randolph Winslow was at once sent for, with the request that he bring his instruments. He came promptly, and kindly administered the anæsthetic, when, with Simpson's forceps, the labor was terminated about 10 P. M., December 11th, with complete rupture of the perineum and also two lateral tears of the vagina.

Owing to the exhausted condition of the patient and bad light, operation on the torn parts was deferred until the next morning, when Dr. Winslow sewed up the lacerations; chloroform being administered by Dr. F. M. Latham, which the patient took nicely with no trouble whatever. When the stitches were removed in about ten days, it was found that the operation was only partially successful, the deep lateral vaginal tears having healed, but the perineal rent still remaining.

February 14, 1889, Mrs. C. was again put under chloroform by Dr. Latham; Dr. Winslow operating assisted by Dr. John Winslow and the reporter of this case. One ounce of whiskey was given beforehand. She again took the anæsthetic nicely and Dr. Winslow had completed part of the operation, when Dr. Latham stated that the patient had stopped breathing, while no movement of the heart could be detected.

She was immediately held up by her limbs with her head as low as possible, artificial respiration was resorted to, and hypodermatic injections of whiskey given in different parts of the body. After some five or ten minutes signs of renewed animation appeared, which were very materially hastened by nitrite of amyl applied to the nostrils.

The operation was completed later on with ether.

Squibb's chloroform was used in this case—in fact, that remaining in the bottle from the previous operation, about two ounces. Thinking perhaps some deterioration might have taken place in the interval of the two operations, I wrote to Dr. E. R. Squibb. In his reply he states: "Chloroform in a corked vial does not deteriorate in quality until the cork becomes shrunken by the action of the chloroform vapor, so as to open it to the air. In your case, however, I think there could hardly have been any doubt in regard to the perfectly good condition of the chloroform used, and that it could hardly have possibly been the cause of the accident. That is to say: two ounces of chloroform in an eight-ounce vial, even if exposed to light during the whole time of two months, could not, under any ordinary circumstances, have undergone a sufficient amount of decomposition to be injurious; besides, had the decomposition been considerable, the odor of hypochlorous acid would have been such as to make all bystanders sensible of its presence and to make them cough."

The odor of this chloroform was pure.

In looking over a number of medical journals it is found, in many of the reported deaths from this drug, the deceased had, just as in this case, taken the anæs-

thetic once or twice before, with no trouble whatever. Might it not be a subject worthy of investigation as to whether a patient is more liable to extreme narcosis or death when he has taken the drug on several previous occasions?

BALTIMORE, 1889. JAMES M. CRAIGHILL, M.D.

MEDICAL PROGRESS.

Thalline and Thallium.—These two substances, which have not a trace of similarity in their natures, are, in consequence of the similarity of their names, very frequently confounded by both druggists and physicians;—thallium sulphate, especially, being erroneously ordered or prescribed in many cases where thalline sulphate is meant. In the pharmaceutical Latin nomenclature used in several European continental countries—where thalline is called thalli*num* instead of thalli*na*, the similarity is, unfortunately, still more apparent.

Numerous inquiries and communications from professional circles show, indeed, that the confusion referred to is widespread, and has taken such firm root that many medical men to-day actually believe both these names, thalline and thallium, to signify but one substance; whereas, in truth, they signify two substances about as different as they can be—thalline being a highly complex organic compound, an artificially grouped combination of coal-tar derivatives,—while thallium is a mineral and elementary substance—a metal!

But this is not all—confusion, more dangerous as to its results than the above, has taken hold of the minds of some persons who have indeed become informed as to the chemical difference just noted, but have somehow been led to consider these two substances, thalline and thallium, as having identical therapeutic properties. This second error—the offspring of the one above exposed—is still held by a number of pharmacists and others, who have been disabused of the former misapprehension but have substituted this one in its stead.

Such error has even been induced or supported by the editorial inadvertence of professional journals of high standing, as the following instance proves:

The researches made by Kreis on the therapeutic properties of thalline were correctly reproduced in the *Medical Record*, of London; but were thence copied into *Nouveaux Remèdes* (1888, p. 42) under the mischievously misleading title of "Effets des sels de thallium sur les gonococcus."—*Merck's Bulletin*, May, 1889.

Abdominal Compression in the Treatment of Dyspepsia.—WETTENDORFER, in the *Deutsche med. Wochenschrift*, speaks highly of the treatment of dyspepsia, flatulency, torpid digestion, etc., by the application of abdominal compression, in the shape of an elastic bandage about twelve inches wide. Wettendorfer struck upon the plan merely by accident. While treating a patient for chronic eczema of the trunk with a Martin's rubber bandage, he observed a rapid and complete disappearance of all symptoms of indigestion, from which the patient had been a great sufferer. Since then the treatment has been used in a large number of cases of dyspepsia and flatulency with great success.

Another Elixir of Youth.—It is stated by a Pesth newspaper that DR. SZIKSZAY, a Hungarian physician, has been making experiments in the State Prison at Engelsfeld by injecting a liquid, the composition of which is not revealed, into aged persons. The results are said to be remarkable. The strength of the "subjects" was tested with a dynamometer before and after the injections. In the case of a man aged seventy-five, the strength was found to be increased after the seventh injection from 14 to 19 kilogrammes, and after the thirteenth to 35 kilogrammes. Experiments on men and women of different ages showed, as might be expected, marked individual differences.—*The British Medical Journal*, September 14, 1889.

Glycerine Tampons in Ozæna.—At a recent meeting of the Society of Military Surgeons in Vienna, DR. SIDLO strongly recommended the treatment of ozæna with glycerine. His method consists in daily washing out the nasal cavity with a two per cent. solution of chloride of potassium, to which ten per cent. of glycerine has been added. This is followed up with the insertion of rolls of cotton soaked with a mixture of one part of glycerine and three parts of water, the tampons being allowed to remain in place for an hour at a time. Dr. Sidlo claims good success in the management of ozæna by using this method, which requires some weeks to effect a cure.—*The Medical Chronicle*, September, 1889.

Local Treatment of Laryngeal Phthisis.—PROFESSOR S. KRAUSE has lately published an article in the *Therap. Monatschrift*, in which he pleads for an extended employment of local methods of treatment of laryngeal phthisis. The method most in favor by him is that of first scraping the diseased portion by the curette, and afterward applying lactic acid. He curettes out not only the ulcerations and granulations in order to obtain a sound base, but also excises portions from the infected tissues to make them more accessible to the lactic acid. In this way he has treated 71 cases, 43 of which have been discharged cured and freed from trouble. Of these, 23 are still living, 7 are dead—but none in consequence of the laryngeal tuberculosis, 8 have withdrawn from treatment, and 12 are still under it.—*Med. Press and Circular*, September 11, 1889.

The Bacilli of Alopecia —DR. SAYMONNE, says the *Medical Record* of September 28th, claims to have isolated a bacillus, called by him "bacillus crinivorax," which is the cause of alopecia. It is, he says, found only on the scalp of man, other hirsute parts of the body and also the fur of animals being free from it. The bacilli invade the hair follicles and make the hair very brittle, so that they break off to the skin. Then the roots themselves are attacked. If the microbes can be destroyed early in the disease, the vitality of the hairs may be preserved, but after the follicles are invaded and all their structures injured the baldness is incurable. The following is Dr. Saymonne's remedy to prevent baldness: Ten parts crude cod-liver oil, ten parts of the expressed juice of onions, and five parts of mucilage or the yolk of an egg, are thoroughly shaken together and the mixture applied to the scalp, and well rubbed in, once a week. This, he asserts, will certainly bring back the hair if the roots are not already destroyed, but the application of the remedy must be very distressing to the patient's friends and neighbors.

Idiopathic Enlargement of the Heart.—Science, from time to time, halts for a moment in her onward career to review past work, in order to substantiate and purify her labors and free them from useless theories and unfruitful hypotheses. Then, relieved from unnecessary incumbrances she is again able to step forward with increased vigor and energy.

In the various branches of internal medicine the value of such a review and correction of past work is most ably shown by Dr. O. Fraentzel in his lectures on diseases of the heart. His first lecture, referred to in the *Deutsche med. Wochenschr.* of September 5th, deals exclusively with idiopathic cardiac enlargements, under which head he includes all enlargements of the heart which are not dependent upon valvular failure.

The term "enlargement" is capable of two different meanings; on the one hand it may refer to a hypertrophy of the cardiac muscles, or on the other hand the enlargement may be due to a dilatation of the heart cavities. These conditions are not only anatomically different, but have also a different clinical meaning, and different symptomatology, and the line between them must be drawn clearly. Idiopathic enlargements of the heart may be divided into three groups: first, abnormal obstructions in the arterial system (aorta or pulmonary) may cause hypertrophy or dilatation of the otherwise normal heart; second, enlargements due to disease of the cardiac muscle; and third, those due to a primary affection of the cardiac nervous system. Abnormal obstructions in the pulmonary circulation may arise from various lung troubles. Of greater practical and theoretical interest, however, are the abnormal obstructions of the aorta, which cause increased pressure of blood. Cardiac enlargement may also be directly dependent upon renal diseases, chronic contraction of the kidney being a well-known factor, as well as parenchymatous nephritis and pyelonephritis. Until quite recently great weight was placed upon the influence of arterial sclerosis upon cardiac enlargement, but autopsies frequently failed to reveal any sclerosis, and often, also, sclerosis was found where no enlargement existed. Fraentzel says neither is dependent upon the other, although both may be traced to the same causes, viz., over-indulgence in eating and also overwork, bodily.

The cases are few where enlargement of the aortic system with simultaneous decrease of vascular elasticity causes enlargement of the heart.

Regarding fatty heart, Fraentzel is of the opinion that it cannot be regarded in the light of a separate disease, since many autopsies have proved the existence of a fatty heart in cases where any symptoms indicating such a condition had been clinically absent. Molecular changes of the cardiac muscle, however, result from several infectious diseases and a weakness of the muscle frequently permanently remains. A like weakness of the cardiac muscle may be occasioned by long confinement in bed, especially in old persons; also by excesses with Bacchus and Venus. Adhesion of the pericardium can only give rise to enlargement when accompanied by myocarditis. Of true affections of the cardiac nervous system little is known. Probably Basedow's disease, cardiac affections due to the misuse of tobacco, and paroxysmal tachycardia belong to this group. Brachycardia, Fraentzel considers not due to a nervous origin, but to a sclerosis of the coronary arteries with subsequent injury to the heart muscle.

Iodoform in Malignant Pustule.—Dr. E. Rinonapoli (*Bolletino della R. Acad. Med.-Ch. di Napoli*, No. 3, 1889) gives particulars of several cases of malignant pustule treated by the subcutaneous injection of a solution of iodoform in ether. Dr. Rinonapoli began this method in 1886, some thirteen months before Senger's work on the antiparasitic action of iodoform appeared. The method employed is that of several injections into and around the seat of the pustule of a ten per cent. solution of iodoform in ether. The pain attending the injections is of severe burning character, but soon passes off. The beneficial effects are rapid in appearance. In three or four hours after the injections, even in advanced cases, the fever lessens, the swelling around the pustule disappears, the tongue becomes clean, and the patient is able to sleep and to take food. The treatment appears to be of distinctly specific character, and to arrest at once the growth and multiplication of the charbon bacillus. If applied at the outset of the attack, the effect is said to be almost magical.—*The Lancet*, September 21, 1889.

Prophylactic Hair Tonic.—The *Bolletino farmaceutico* for September, 1889, gives the following hair tonic, which it claims will stimulate the hair, prevent alopecia and dandruff, as well as act as an agreeable dressing:

℞.—Carbolic acid . . .	2	parts.
Tincture of nux vomica .	8	"
Tincture of red cinchona .	30	"
Tincture of cantharides .	2	"
Eau de Cologne . . .	120	"
Cocoa oil	120	" —M.

The tonic should be applied to the hair daily, with the aid of a small sponge.

Massage as a Therapeutic Agent.—At the last meeting of the British Medical Association (*British Med. Journal*, September 21) the subject of the therapeutic value of massage in nervous ailments was brought up for discussion:

Dr. G. H. Savage said that of late there had been too great a tendency to treat all cases of neurosis by massage. This treatment was not only of no use, but was really harmful in some such cases. It might be taken for granted that it was rarely if ever useful in ordinary cases of insanity; in cases of emotional self-consciousness it was bad, both the solitude and the bed being contraindicated. In hypochondriacal states it was generally harmful, and in most cases of active melancholia it was not useful. He had hardly ever seen it do good in cases in which, with the emotional depression, there were well-marked delusions, such as those of unworthiness or ruin. Its chief use was in those cases in which the mental depression was associated with physical weakness, loss of flesh, and deficient action of the gastro-intestinal tract. In such cases bed and feeding did well enough, as a rule, but in some massage acted more rapidly. For such cases the massage treatment should differ somewhat from that in use ordinarily. He preferred an ordinary medical nurse, lady if possible, to take the whole charge of the case. The masseur should be looked upon as an important aid, but not as the chief person or means of treatment; the massage should be associated with cheerful companionship and some occupation however simple. The massage should be continued as long as the general

health was feeble, and as long as the appetite was bad. The object was like putting salt in the food given by the stomach-tube to create a desire for food, and then to supply it in a suitable form and quantity. He related a specially interesting case of melancholia cured after four years of profound depression.

DR. WARNER had employed massage in many cases of chorea, with low nutrition and loss of body weight, in conjunction with forced over-feeding and rest in bed; the results had encouraged him rather to trust to rest and feeding than to massage.

DR. NEEDHAM had employed massage in some cases of melancholia, and in two or three had seen excellent results from it. Its chief value in these cases seemed to be due to its influence in stimulating the muscular apparatus in the circulation, and so supplementing active exercise, improving digestion, and relieving constipation.

DR. WILBERFORCE made some remarks on the need for distinguishing with more precision than had usually been adopted the cases for which massage was appropriate, especially in nervous cases as distinguished from voluntary muscular exercise.

DR. PERCY SMITH referred to three cases in Bethlem Hospital, in two of which the treatment was quite unsuccessful in curing the mental disease, though there was great physical improvement. They were both cases of stupor, and in one the effect of the physical improvement appeared to be that the depression passed into excitement, another a case of melancholia with malnutrition.

THE PRESIDENT said he had been disappointed with the results of massage in what appeared likely cases for its employment; in others, however, it had been of use. It improved the appetite often when the mental symptoms were not much ameliorated. Massage, like hypnotism, had suffered from quacks, and if care was not taken it would get into bad odor, and whatever use there was to be obtained from it would be lost sight of.

Arsenical Paralysis.—DR. R. KREHL, in the *Deutsch. Archiv. für klin. Med.*, describes the following case of arsenical paralysis: A man, twenty-three years of age, who had always enjoyed good health, was affected with a skin eruption, for which he used an ointment containing arsenic. At first the dose was small, equal to two drops of Fowler's solution, three times a day; afterward the dose was increased. In about four months after commencing the arsenical treatment, the patient suddenly felt tingling and trembling in the hands and feet, with shivering over the whole body. He could not stand, and felt dizzy; there was great pain in the calves of the legs and excessive feeling of depression. During the whole of this time the use of arsenic was continued, the entire amount used being calculated as equal to about twenty grains of solid arsenious acid. At this period the case came under the observation of Dr. Krehl, who found the condition as follows: Much emaciation of the whole body, but especially of the extremities; no fever, weakness in the limbs, and pains in the calves of the legs. The skin over the whole body was dark brown and very dry. There was slight horizontal nystagmus, some appearance of flashes of light, but otherwise the eyes were normal. The internal organs were normal; the muscles of the trunk responded to both currents, and the sensibility of the trunk was unimpaired. The arms were much atrophied, especially the forearms—the thenar, hypothenar, and interossei suffering most. The voluntary movements of the arm were feebly accomplished, the extensor muscles being weaker than the flexors. The fingers were almost entirely paralyzed. Tendon reflexes diminished. Tingling and numbness in both hands. Feeling of touch and localization unaffected, also the perception of painful impressions. In the legs the condition was very similar. In hands, forearms, and thighs, there was partial reaction of degeneration, below the knee it was complete. With the eyes closed the patient could not recognize the position of fingers or toes. If passive movement of the fingers was made, he was aware that a change of position had taken place, but could not describe it. He could distinguish by feel, between smooth and rough objects, but could not determine their shape. The position of head and trunk was recognized without difficulty. The perception of weight was impaired. Four months after, the general condition of the patient was much better; he could stand, but the peronei muscles remained paralyzed. The peroneal and tibial nerve on both sides did not respond to electrical stimulus.

Arsenical paralysis is characterized by very speedy atrophy of the affected muscles, which is often perceptible within a fortnight after the commencement of the first symptoms. In severe forms the atrophy is degenerative, as is proved by the electrical reactions. Sometimes the electrical reactions are merely diminished, the atrophy in such cases being simple atrophy. In the case above reported both kinds of atrophy were present. The tendon reflexes are always absent in severe cases; the skin reflexes demand more careful investigation. In all cases of arsenical disorders of the nervous system there is considerable disturbance of the sensory nerves, even when motor symptoms are absent.—*Medical Chronicle*, September, 1889.

The Use of Pessaries.—In these days, when gynecology has contributed so much to the therapy of uterine displacements, the once vaunted efficacy of pessaries seems to be decidedly on the wane.

DR. J. B. W. NOWLIN, of Nashville, Tenn., sums up the principal objections to the use of pessaries, in the *Southern Practitioner*, for September, 1889, in the following terms:

1. They can only act as palliatives. If too small, they are expelled or cannot sustain the womb, and if too large they exert injurious pressure.

2. They keep up a continual irritation in the vagina, acting as a foreign substance, producing mucous, purulent, and leucorrhœal discharges, thus laying the foundation for fungous or cancerous diseases.

3. Many forms of these instruments are liable to produce septic results.

4. They produce undue and permanent dilatation of the vaginal walls by destroying the tonicity of the parts.

5. If not frequently removed, they become filthy and irritating.

6. They are liable to cause irritation of the bladder and constipation.

7. Their application is often left to the laity.

8. By the obstruction which they offer to the circulation, they produce engorgement, and it may be ulceration of the surrounding parts, extending even to the production of a vesico-vaginal or rectal fistula.

SATURDAY, OCTOBER 5, 1889.

TONSILLITIS.

THE discussion on tonsillitis, its varieties and relations to rheumatism, in the Section on Laryngology, at the recent meeting of the British Medical Association, emphasizes, aside from its intrinsic importance, two facts which during recent years have urged themselves with increasing insistence upon the attention of the profession. These are, first, the advantage of the formal discussion of vexed questions in open meeting by members of the profession qualified by experience and special study; and, second, the fact that the force of the revolution in medicine wrought by the science of bacteriology is exerting itself not alone in the domain of pathology and therapeutics, but that it is steadily and progressively compelling a rearrangement of our established views of diseases in their clinical relations, and corresponding modifications of nosological lines.

Clearer notions of the nature of infection have done away to a large extent with the boundary lines between simple and specific inflammations, and are not only step by step increasing the category of constitutional maladies at the expense of local diseases, but are also bringing into light relations and analogies formerly wholly unsuspected.

The discussion referred to, *British Medical Journal*, September 14, 1889, in which Haig-Brown, Archibald E. Garrod, R. Hingston Fox, Lennox Browne, and others took part, was inconclusive as regards the etiology of tonsillitis. It perhaps served a useful purpose in indicating the obscurity in which the cause of this disease is still enveloped, thus pointing out a promising field for future work. It is of importance as marking the termination of that period in the history of clinical medicine in which tonsillitis has been regarded as a local affection, an event foreshadowed in the writings of Ball, Lasègue, Lennox Browne, and others, and already for some little time regarded as overdue by observant practitioners far and wide.

Henceforth follicular or lacunar tonsillitis will be regarded as an acute infectious disease, and in this sense will naturally fall into the group of the fevers, a position sustained by the sudden onset, marked constitutional disturbance, high fever, critical fall of temperature irrespective of the action of drugs, the occurrence of local epidemics, and the spread by contagion, which are established phenomena of the disease. The frequent association of tonsillitis with rheumatism rather helps than impairs this analogy with the specific fevers, seeing that scarlatina and enteric fever, though usually uncomplicated by rheumatism, occasionally present acute arthritic manifestations precisely similar to those met with in tonsillitis. What the essential relationship between the form of tonsillitis under consideration and rheumatic fever may be, has not as yet been satisfactorily established. The frequency of the association is remarkable, and has been observed by all writers upon the subject in recent years. In one hundred and twenty-seven cases studied by Dr. Haig-Brown in the Charter House School, *Tonsillitis in Adolescents*, 1886, seventy-six gave a history of rheumatism. In forty-three cases observed by Boucsein, *American Journal of the Medical Sciences*, October, 1889, nineteen revealed a history of rheumatism, six personal, and the rest in members of the immediate family.

Whether, as suggested by Lennox Browne, the rheumatic or gouty diathesis, or some combination of the two, is an underlying factor of importance in the majority of patients subject to recurrent tonsillitis or not, remains to be determined. Our own experience is decidedly against this view, which is not, as was at one time thought, sustained by the usefulness of the salicylates in the treatment of the disease; these remedies having been found useful rather on account of their sedative properties than by reason of any great influence upon the course of the disease. Nor does the occasional occurrence of endocarditis in the course of tonsillitis establish the identity of the latter disease with rheumatism, since

implication of the serous membranes of the heart is of occasional occurrence in several of the acute infections. The weight of opinion among those engaged in the discussion seems, however, to have been in favor of the view that tonsillitis is, in a majority of cases, of rheumatic origin.

The form of tonsillitis referred to, is that called follicular, the familiar characters of which require no special description. It would appear from the drift of the discussion that true quinsy, or suppurative tonsillitis, is regarded in England as an essentially different affection. This view does not appear to us to be sustained by the facts. On the contrary, we hold that the boundary line between these affections is not in all cases absolute.

HOSPITALS OF THE ORIENT.

THERE has been a news item that has thoroughly gone the rounds of medical journals, to the effect that the Empress of Japan has contributed during the last year $7,500 out of her "pin-money," to assist the Tōkyō Female Hospital in its good work. The scant knowledge possessed by the profession in this country in regard to the nature of hospitals in the Orient, makes this brief item a suggestive one.

In China hospital work presents grave difficulties, cleanliness being almost impossible. The Chinese patient loathes mattresses, nay, frequently refuses to sleep on them, but clings lovingly to the luxury of a piece of matting thrown across boards, and a wooden, earthenware, or pig-skin pillow. They often insist upon bringing their own bedding, which consists of a few wadded quilts of great age, and, as a rule, alive with vermin. Washing has to be enforced, and many adult patients, incredible though it may seem, take their first bath, as far as they can remember, after entering the hospital. That, with such hygienic surroundings, grave operations—such as laparotomies, resections, lithotomies, etc.—can be performed, and result successfully, seems truly marvellous. Under such difficulties does DR. KERR, the well-known medical missionary of Canton, labor. Yet he has performed nearly 500 successful operations for calculus.

The hospital of Dr. Manson, at Amoy, whose name is associated with the discovery of the intermediary host of the filaria sanguinis hominis, is of a slightly better type, and a crude method of asepsis is enforced, yet the same difficulties are also met with by him. In Japan, however, an entirely different state of affairs exists. The Japanese are a preëminently cleanly nation. In the larger cities the principal hospitals are supplied with comfortable beds and foreign bedding—*i. e.*, sheets and blankets. In the Japanese hospitals proper, however, the beds are made upon the floor, and the covering consists of one or more soft *futons* or quilts. The floor is covered with white mats nearly two inches thick, and made of fine rice-straw; the doors are of paper, and in winter great charcoal braziers supply insufficient heat. The nurses are mostly old women, good at heart, but poor in practice. The physician, in order to make physical examination, must, of necessity, kneel on the floor by his patient's side. The Japanese have a profound respect for physical examination, and the average countryman is firmly of opinion that a physician can diagnosticate the most obscure case by a glance at the tongue or a touch of the pulse. A curious idea also exists that the one pulse differs from the other, and both wrists are always gravely offered to the physician. The physicians of the old Chinese school, who were never allowed to enter the presence of a lady in *dêshabillé*, had to content themselves with sitting outside the patient's room and "feeling" a string, the other end of which was tied around the patient's wrist.

Although there are excellent hospitals throughout Japan, the establishment of hospitals for women exclusively has been neglected, until the Tōkyō Woman's Hospital was founded. This institution is one which would be a credit to any country. Connected with it is a most ably conducted training school for nurses, that is now sending competent trained nurses all over the country.

The Empress is indeed doing a good work with her "pin-money," and when we consider that the value of money in Japan is double what it is here, the donation is by no means small. The Empress is noted for her charities and for the personal interest she takes in the advance of medical science in her country. She is also the President of the International Red Cross Association of Japan, and an active worker for the cause.

A WOLF IN SHEEP'S CLOTHING.

THE old fable, having the title given above, seems once more to have found an application in real life.

In another portion of this issue of THE NEWS we give *verbatim* two letters received by ladies in this city from a well-known firm of opticians, which, for impertinence, would be hard to surpass. It is bad enough for the profession nowadays to be surrounded

by a vast throng of patent medicine venders who daily, by their advertisements, take from the hard-working doctor the pittance which he deserves, without having a firm who, heretofore, have had one of the largest trades in the manufacture of prescription glasses, sending broadcast such invitations to the laity to come and be benefited by the skill which they claim to have become possessed of, rather than by the medical learning and scientific resources of the trained physician. We much regret to see the practice of any department of medicine attempted by those possessing no claims other than a spirit of trade, and we trust that their estimate of human gullibility may prove incorrect.

Probably the greatest risk in this over-the-counter prescribing by opticians is the fact that many people, thinking failing sight due to optical errors, are given all manner of useless glasses, when the fault may be changes of the choroid, retina, optic nerve, or crystalline lens. Within the past three months, we have been informed of three cases who were given glasses by this optical company, in one of whom there was beginning cataract, with much gray degeneration of the optic nerve, due probably to spinal trouble; in another albuminuric retinitis; and in the third, chronic glaucoma in which the central vision was still good, but the field of vision greatly contracted and operative interference urgently demanded.

It is time that the profession should let those persons with whom they are accustomed to deal, or to whom they are accustomed to recommend their patients, understand, so far as the medical branch of their business is concerned, that dignity and honor require them to extend their trade only by giving such skilful mechanical satisfaction to their customers as to make the large body of persons who are so unfortunate to have to wear glasses, look to them for assistance after having consulted a regular physician.

REVIEWS.

Syphilis of the Nervous System. By H. C. Wood, M.D., LL.D. 12mo., pp. 135. Detroit: George L. Davis, 1889.

This book is one which forms part of the series of the Physician's Leisure Library for 1889, and it is above the average standing of its peers. Dr. Wood, while drawing attention, in his preface, to the experience reached by him in a large practice, nevertheless has looked into the contemporaneous literature of the subject to a very great extent, and the book teems with references to the writings of others.

The extreme frequency of "nervous syphilis" is so well known that any words are useless in this respect, and yet we doubt whether many physicians are not in ignorance as to the wayward manifestations of a disease whose presence may be all unlooked for or denied. Dr. Wood has put all the practical points for diagnosis and treatment so clearly that one feels, after reading his brochure, as if he were well equipped to defy all such cases which may fall into his hands. To those who have heard the lectures of the author on this subject, the book at hand will act as a valuable remembrancer, while to those who have not been so fortunate it will prove, we think, a help and in daily practice a useful guide.

Lectures on Obstetric Nursing. By Theophilus Parvin, M.D. 12mo., pp. 104. Philadelphia: P. Blakiston & Co., 1889.

No one who has had the pleasure of listening to one of Dr. Parvin's learned and able lectures can fail to mark that he has carried even to nurses the tales of the early days of medicine and learning in which he delights to revel. The little book of one hundred and odd pages, as it lies before us, teems with matter touching upon the staid subject of obstetric nursing in a way that turns its somewhat sombre edges with a glow of interest, and makes one read it not only to gain the knowledge of the subject in hand, but for its constant quotation of historical fact or mythological fancy. While it has been held by some that all matter outside of the "core" of the subject is extraneous, we cannot help thinking that every one who teaches largely must have noticed that "seasoning" an intellectual meal has much the same effect as a similar treatment of ordinary food, and that the absorption of nutriment is in direct relation to the activity of the digestive function. Both doctor and nurse can read this brochure with advantage and with the ease that comes of ready assimilation. The nurses of the Philadelphia Training School have been favored by many opportunities of learning that in this, as in many other branches of medicine, even the most trying cases may be lightened if the proper means be found.

Transactions of the Thirty-ninth Annual Meeting of the Illinois State Medical Society. Chicago: Jameson & Morse, 1889.

These transactions comprise the usual amount of society business, address of the president, memorials and portraits of deceased members, and a number of papers in the form of reports of the chairmen of various committees.

Most of the reports are of interest and up to date in medical progress, though few show much originality. In the report of the Committee on Practice of Medicine, diphtheria is ably discussed and a well-timed blow is aimed at "those physicians who diagnose all forms of tonsillitis and pharyngitis with deposits as diphtheria, and tell us they have treated hundreds of cases with some particular formula without a failure." We fear such physicians are far from rare and have led many astray in the treatment of this disease. Kerosene oil is lauded as the best local application, quinine, iron, and chlorate of potash the best internal medicaments.

Much of the report on Obstetrics is devoted to the use of antiseptics in midwifery, which are rightly considered

of as much importance in this department as in general surgery.

On Diseases of Children the report is unsatisfactory, being largely devoted to a vain attempt at proving the causation of "summer complaints" to be extreme heat acting upon the sympathetic nervous system. No consideration is given to the effects of heat upon food, and in treatment sterilization of milk is ignored.

The binding, printing, and portraits are good, and as a whole the volume is a credit to the Society.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

Fourteenth Annual Meeting held at the Institute of Technology, Boston, Mass., September 17, 18, 19, 1889.

TUESDAY, SEPTEMBER 17TH—MORNING SESSION.

THE Society was called to order by the PRESIDENT DR. H. P. C. WILSON, of Baltimore, and the Address of Welcome was delivered by DR. J. P. REYNOLDS, of Boston.

DR. H. J. GARRIGUES, of New York, read a paper upon the

USE AND ABUSE OF ANTISEPTIC INJECTIONS IN OBSTETRICAL PRACTICE.

When it is known that puerperal fever is due to infection the use of antiseptic injections is indicated, but this has sometimes been carried to extremes, as was illustrated in a St. Petersburg hospital by the constant use of uterine injections of a solution of chloride of lime after parturition. The other extreme is reached by those who discard injections after labor altogether.

At the Maternity Hospital at Blackwell's Island the mortality from 1875 to 1884 was four and seventeen-hundredths per cent. During the period from 1884 to 1888, in which the author's method of treatment has been observed at the same institution, there have been but two fatal cases, or a fraction of one per cent.

Vaginal injections before delivery were believed by the author to be useful, though objected to by many writers on the ground that they were dangerous because the lubricating mucus was removed, etc. In answer to the objections that the bacteria on the surface of the vaginal mucous membrane were harmless, it must be remembered that they would not be harmless should they penetrate the subjacent tissues. They would also be an element of danger when carried from the vagina into the womb. If vaginal injections were used prior to labor, the vagina would be dilated and the microbes removed or destroyed.

Preliminary disinfections of the vagina are useful. If frequent examinations are required during labor, vaginal injections should be made once in three hours, and during the intervals a pad of absorbent cotton should be placed over the vulva. Injections after normal labor are not indicated, and there is no danger of infection if the labor has been antiseptic. If the labor has been abnormal, vaginal or uterine injections will be required *pro re nata*. If the lochial discharge is fetid, intra-uterine injections are usually required, likewise for the removal of débris in cases in which there has been sloughing and in cases in which the fœtus is macerated. Should peritonitis occur, the intrauterine douche should at once be given, likewise after abortion, the uterine contents having first been removed.

Solutions of bichloride of mercury should be used for these injections, but must be employed with care. Since 1884, twenty-two fatal cases following the use of these injections have been reported, but this loss is small in comparison with the benefits which have been obtained. Of these twenty-two cases, four should be left out, and in most of the others the solutions were too strong, or too frequently administered, or were improper in some other way. The strength of the mercurial solution should not exceed 1 : 5000, and it should be stopped as soon as toxic symptoms appear. Contraindications to injections are anæmia, kidney disease, and diarrhœa. The use of carbolic acid as an injection is objectionable because it benumbs the hands of the accoucheur, and sometimes affects the entire nervous system of the patient. Hydronaphthol is objectionable because it is a proprietary preparation and also because it has low germicidal powers. Creolin is highly approved by the author, as it makes the surface of the mucous membrane slippery; it is also a powerful hæmostatic. It is objectionable because, being used as an emulsion, it may obscure objects with which it is brought in contact. Its odor is pleasant, and used in a two per cent. solution it is, in the author's opinion, the best means which we now have for intrauterine injections. If vaginal injections alone are to be used, a six-inch glass tube is preferable for introreduction into the vagina; and if uterine injections are required, a single tube is preferable to a double one. Great care is necessary to avoid injecting the fluid into the Fallopian tubes. In hospital practice the author uses a glass intrauterine tube, but in private practice prefers an English catheter. The injections should be given with the patient lying upon the back, upon a bedpan, or upon a rubber sheet so folded as to carry off the fluid. The tube is to be guided into the uterus with the fingers and carefully carried to the fundus. If resistance is met, the tube should be withdrawn and reintroduced. Failure to observe these details has resulted in perforation of the uterus and injection of the bichloride solution into the peritoneal cavity. The temperature of the uterine douche should be from 110° to 115° F., the quantity from two to three pints. For a vaginal injection two to three quarts may be used. The return fluid should be examined, then the womb should be compressed, and all fluid should be removed from the vagina. Injections are generally very beneficial.

DR. W. T. LUSK, of New York, agreed entirely with the fundamental principle which related to the prophylactic value of uterine injections. Injections are used most successfully in those cases in which there is putrid infection from débris, blood-clot, etc. In pure septicæmia from round bacteria, injections are of no use and may be harmful after the microbes have passed into the lymphatic circulation. One thorough irrigation followed by the introduction of an iodoform pencil into the vagina is all that will be necessary in most cases. If injections are made as often as once in three hours, they will be very likely to produce harm. The statement that one would depend upon the odor of the discharge, as a guide in giving injections, is erroneous, for the most offensive discharges may be caused by simple puerperal,

catarrhal endometritis. In New York City practice puerperal fever is not infrequently associated with typhoid fever, especially in cases connected with defective sanitation. The method of Doléris of curetting, ecuvillonage, and subsequent irrigation, is very useful for many cases of puerperal fever.

Dr. H. C. Coe, of New York, had followed the method advocated by Dr. Garrigues with success. He believed it a very difficult matter to decide just when uterine douches are indicated and when contraindicated, especially in cases in which septic elements have passed the uterus and gone into the tubes. He was favorably impressed with creolin, but had also found that it masked the offensive odor of the discharges. As had already been said, prophylaxis is the most important consideration.

Dr. W. M. Polk, of New York, uses prophylactic injections, but in a somewhat different manner from that described by the author. He first washes the genitals inside and out with potash soap and hot water, and then uses the 1:5000 solution of bichloride of mercury. If there is suppuration in the cavity of the uterus, it should be treated like suppuration in any other cavity. The patient should be placed on her side and the vagina and uterus swabbed out with cotton, or the curette should be used, being followed by the creolin or bichloride injection. Gauze should then be placed in the uterus for drainage purposes. It is not usually necessary to repeat a douche or, at any rate, not sooner than twenty-four to forty-eight hours.

Dr. P. F. Mundé, of New York, believed it necessary first to ascertain the absolute cause of sepsis—that is, the interior of the uterus should be examined with the finger, in case of chill or high temperature, before irrigation is used. The curette should be used in case anything is found which requires removal, and after this the uterus should be irrigated. Subsequently ergot or an ice-bag should be employed, also the antiseptic pad. One cannot in all cases be guided by the odor, nor even by the finger; for there are cases in which the bacteria have gone beyond the reach of injections, and the patients will die. A chill may follow irrigation with a temperature of 104° to 105° F. Intrauterine injections after a normal confinement are entirely uncalled for. If a puerperal woman becomes septic, as Dr. Lusk has said, it must be through the fault of her physician.

Dr. H. J. Boldt, of New York, showed a modification of the Bozeman-Fritsch double catheter, but admitted that it could only be cleansed by boiling, and this should always be done before it was used.

Dr. A. P. Dudley, of New York, thought there were cases of puerperal fever which were due to infection from single pyosalpinx, and in which the womb became infected after labor had transpired.

Dr. Howard Kelly, of Philadelphia, believed that the vagina should always be washed out when there was any reason for suspecting infection. In tenement-house practice with unhealthy surroundings he had derived much benefit from the use of the obstetric pad, devised by himself, by which means the return fluid from the uterus and vagina was readily carried off.

Dr. E. C. Gehrung, of St. Louis, thought that septicæmia might be developed by uterine injections; débris being sometimes propelled further into the uterus by the current. Suction or aspiration was better than propulsion. A double canula should be filled, carefully introduced to the fundus, and then the stream of water allowed to flow out.

Dr. W. G. Wylie, of New York, believed that in many cases of puerperal fever the source of trouble was in the pelvis, and could not be reached by means of injections. He had been one of the earliest advocates of intrauterine injections, and was in favor of giving them every hour if they were required at all. The proper treatment in cases in which the trouble was located in the broad ligament, was to make an opening through the vagina, remove the septic matter, and drain. Many such cases which are not operated upon develop into general peritonitis, but even such cases may be operated upon successfully.

Dr. Garrigues, in closing the discussion, warned against depending solely upon the temperature as a guide in uterine irrigation. He approved of the use of soap and water, as advised by Dr. Polk, as it was not improbable that infection might take place through the air. He did not believe that a drainage tube or gauze was required, as the natural conditions of the uterus would favor drainage. Irrigation was not usually followed by a chill, but should not be repeated if a chill occur. Laparotomy would seldom be required, and the patients or their friends would rarely consent to it. With regard to frequent uterine irrigations, he thought that as good results could be obtained by the use of powerful vaginal suppositories.

Dr. John Byrne, of Brooklyn, N. Y., read a paper entitled

A DIGEST OF TWENTY YEARS OF TREATMENT OF CANCER OF THE UTERUS BY THE GALVANO-CAUTERY.

The author's paper was composed of facts in connection with his personal experience. The author's first series of publications, which included twenty-four cases of cancer of the uterus, appeared in 1872. In this he tried to demonstrate that the galvano-cautery was a most useful agent in the treatment of uterine cancer, also that it was less dangerous than any form of surgical treatment. He believed that it was a fact that in all cases of malignant disease of the uterus in which there was either induration or ulceration, the operation should extend far beyond the apparent seat of the disease. Prior to 1872 he thought there were few who used and believed in the galvano-cautery. This was partly due to the great difficulty in obtaining suitable apparatus, and there were few beside Jacobi, Noeggerath, and himself who experimented long enough to enable them to overcome the obstacles in this direction. He had finally succeeded in making the battery which he had used for the last fifteen years, which was of high potential, and had been used by him for all uterine operations in which the cautery was indicated. He believed the Paquelin cautery was a much inferior agent on account of the great radiation of heat from it. Whatever instruments were used, cauterization of all parts that were diseased was believed to be superior to any other means. Chloride of zinc had been used as a cauterizing agent for many years and could be employed if the proper galvanic instruments were not attainable. The series of cases which he presented included 367 which had been seen during the past twenty years. Of this number, 121 were lost sight of in the course of one year after they had been operated upon, hence his records

were not complete with reference to recurrence. He divided his cases into four classes: of these there was disease of the portio vaginalis in 59, of the entire cervix in 81, of the corpus in 18, and of both cervix and corpus in 219. In the first class there had been freedom from relapse, from one to fifteen years, in 36, the average period of exemption being 8 years and 6 months. In the second class the average period of exemption in 35 was 5 years and 6 months. In the third class there was an average period of relief from pain, hemorrhage, and discharges for 2 years in 4 cases. In the fourth class 78 cases had been exempt for nearly three years. He believed that all palliative means of treatment of cancer were useful even though relief lasted but a short time. Should hemorrhage occur after such treatment it was usually less profuse, and pain was usually less severe. Great care and thoroughness were necessary in using the galvanocautery. The cautery should not be heated until the knife was fixed upon the tissues to be removed, and great pains should be taken to avoid cauterizing healthy vaginal tissue.

DR. A. REEVES JACKSON, of Chicago, eulogized the author's paper and considered its statements in striking contrast with most of the recent contributions to the surgery of uterine disease. The recent literature of this subject was almost entirely devoted to cutting operations upon the uterus and its adjacent organs. The reports of Pawlik and the author, in which the cautery had been used, showed results which were far more favorable than those in which these organs had been removed by the knife. In comparison with the cautery hysterectomy by the knife had a high death-rate, but as an offset, it has been said that those who recover were less likely to have recurrence. This statement was shown to be fallacious by reference to the latest German statistics.

DR. T. A. REAMY, of Cincinnati, O., thought that the reader of the paper was too sanguine in regard to possible results with the cautery, and referred to a paper of his own in which 22 out of 57 cases of cancer of the cervix which had been operated upon recovered; he did not think that a much larger percentage could have been cured even if the cautery had been used.

DR. BYRNE, in closing the discussion, said that it was impossible to find the limit of cancerous disease with accuracy in any given case, and that when all apparently diseased tissue had been removed by the scissors or knife it was undoubted that the cautery would destroy diseased elements which were beyond their reach. He objected to the term *cure* in any case, and had systematically substituted the term *relief* in its stead. Even after the longest respite the disease might reappear or occur in the ovaries or elsewhere. With regard to hysterectomy, he believed that the actual statistics were even worse than had been reported.

DR. H. C. COE, of New York, read a memorial of the late James B. Hunter, of New York.

AFTERNOON SESSION.

DR. P. F. MUNDÉ, of New York, read a paper entitled

THE NATURE AND TREATMENT OF UTERINE FIBROIDS.

There were many tumors of the uterus which did not require treatment. Of the several varieties of fibroid tumors, the subperitoneal did not usually excite hemorrhage, while the submucous and the intra-mural frequently did. In the subperitoneal variety, operative treatment would consist of the removal of the uterus or of the ovaries. Intra-mural tumors should be removed without removal of the uterus; and the same was true of the submucous variety. The object of long-continued treatment with ergot or electricity was to force the tumor downward, or to restrain hemorrhage. For the removal of sessile fibroid tumors near the fundus of the uterus, he believed it was better to perform laparotomy and remove the uterus, than to attempt to remove them through the undilated utero-vaginal canal. Hemorrhage caused by these tumors might be treated by the curette, or by vaginal electro-puncture. The latter, which was Apostoli's method, resulted in only temporary cessation of the growth of the tumor.

Oöphorectomy for these tumors in the 3 cases in which he had practised it, had been entirely satisfactory. Laparotomy for these growths had been performed by him six times; the pedicle being treated by the extra-peritoneal method, and 4 cases recovered. Tumors which were near the *os internum* could be removed *per vaginam*. Many of them required no treatment. Only a few subperitoneal tumors were benefited by electricity. Interstitial and submucous tumors could sometimes be removed by enucleation; the capsule being first split and traction being then exercised. Tumors which were not influenced by ergot, including large subperitoneal tumors, were sometimes cured symptomatically by oöphorectomy. Laparotomy was not indicated if the tumors caused no trouble. If the patient were near the menopause, an operation was not usually indicated.

DR. W. G. WYLIE, of New York, read a paper entitled

THE NATURE AND TREATMENT OF FIBROID TUMORS.

The growth of the tumors was usually slow. If pain, etc., were present, it was usually due to disease of the endometrium, or of the tubes and ovaries. Tumors which grew rapidly might require operation. In women, who had reached the age of forty or upward, small fibroids were not very significant, but they might delay the menopause. Pain and failing health about the time of the menopause might mean degeneration of the tumor, in which case hysterectomy might be necessary. Fibroids, like all organic matter, have periods of growth and decay. Their average age is two to eight years. If a tumor has ceased growing, and after a time begins to grow again, its removal may be required. In other cases there was cystic degeneration, or internal suppuration, or other septic conditions which indicated removal. If the lining membrane of the uterus alone is diseased, curetting may relieve existing hemorrhage for a year or more. Should this not be efficient, the tubes and ovaries should be removed; and if this were done thoroughly there would probably be no subsequent hemorrhage. The reader's death-rate from hysterectomy had now reached ten per cent., and he believed that it was susceptible of further diminution. For the past two years the reader had been experimenting with Apostoli's method of treatment, and he believed that Apostoli's claims were exaggerated. If it did no harm, it might take away the patient's last chance of hysterectomy by delay. Its effect, in the author's experience, had been variable; and, on the whole, had not been satisfactory. In women, in the childbearing age, strong currents of electricity

were objectionable; for, if they did not cause sepsis, they might result in stenosis and inability to bear children. A strong electric current might relieve hemorrhage from a fungous growth, but it was no better than the curette in this respect.

The author admitted that his opinion concerning the value of electricity was still provisional, on account of insufficient experience.

Dr. Reamy approved of the conservative tone of both of the papers which had been read. A recent statement of Martin was to the effect that in 205 cases in which he had removed fibroid tumors, there were signs of fatty or other degenerative changes in 70. This indicated that in many cases spontaneous recovery would occur. Ergot alone may suffice for a cure without electricity or the knife. He thought there was a prevailing disposition to give insufficient credit to Apostoli for work which he had done. The speaker believed tumors had been cured and had disappeared after electricity had been employed —in fact, he had seen such cases. He believed that curretting was less safe than electricity, and if stenosis of the uterine mucous membrane prevented childbearing, it could not do it more effectually than did removal of the tubes and ovaries. Oöphorectomy would, he believed, usually relieve hemorrhage, and he admitted that in the severest cases hysterectomy was required.

Dr. G. J. Engelmann, of St. Louis, stated that his results in the treatment of uterine fibroids by electricity had been bad, but in chronic inflammatory conditions with indurated masses his results had been excellent. In fibroids accompanied with too much bleeding, as well as in those with scanty menstruation, the symptoms were greatly relieved. Patients were usually made very comfortable by the electrical treatment, and that was a good result from so harmless a method. In some cases puncture and strong currents of electricity were inadvisable, as they might cause an increase in the size of the tumor. If the tumor was growing slowly, electricity in mild currents was urgently advocated.

Dr. J. R. Chadwick, of Boston, was entirely opposed to Apostoli's method. He had had 2 fatal cases from its use, and 2 others which were nearly so. In all his experiments he had followed Apostoli's directions as closely as possible. But it may be that sufficient time was not given in every case. In no instance was there an appreciable diminution in the size of the tumor, though hemorrhage ceased for three years in one case. One who claimed as much as Apostoli must expect the severest and most searching criticism.

Dr. Ely Van de Warker, of Syracuse, N. Y., believed that Apostoli's method had positive scientific value, and objected to such sweeping denunciations of it. He admitted that electrolysis might produce cystic degeneration in a fibroid mass or intensify such a process if it already existed. This was the unfavorable side of the question, but he had also seen results which were positively good; tumors becoming movable, smaller and less troublesome, and hemorrhage ceasing.

Dr. Howard A. Kelly thought we should not ignore the opinions of Keith, Wells, and other eminent men who had experimented with Apostoli's method and believed in it.

Dr. M. D. Mann, of Buffalo, thought that the question as to the value of electricity in these cases was still unsettled. He had used the intrauterine method in many cases, and in all of them the symptoms had been relieved.

Dr. P. F. Mundé, in closing, related three cases in which he had seen tumors disappear after vaginal galvano-puncture. He believed that Apostoli's method was good, but is over-estimated.

Dr. W. G. Wylie, in closing, repeated his statement that Apostoli claimed too much.

Wednesday, September 18th—Morning Session.

Dr. A. Reeves Jackson, of Chicago, Ill., read a paper entitled

A case of abdominal lipoma simulating ovarian tumor.

The case narrated by the reader of the paper had been diagnosticated as a case of ovarian tumor. Laparotomy was performed, and great masses of fat were found attached to the mesentery and posterior portion of the peritoneum. These masses could not safely be removed, and the abdomen was closed. The patient recovered, and had not been materially worse since the operation. The literature of this subject is very meagre. Péan had reported two cases, which were quoted in detail; one resulted fatally, the other recovered; in both cases a diagnosis of ovarian tumor had been made. A case had also been reported by Sir Spencer Wells, which was narrated. The result of the operation was fatal. Dr. Byford, of Chicago, had reported one case, the masses of fat being successfully removed. Dr. Homans, of Boston, had operated on two cases, both resulting fatally. In none of these cases had a correct diagnosis been made, and the results of operation had been bad in a majority of the cases. The reader of the paper, therefore, congratulated himself that he had desisted from attempts at removal of the offending body.

Dr. S. C. Gordon, of Portland, Me., had seen one case of fatty tumor of the abdomen in a male subject. He had been requested to operate, and, having made an abdominal incision, found the condition reported. The patient recovered from the operation, but died soon afterward.

Dr. E. C. Goodell, of Philadelphia, believed that such cases usually occurred in persons who had also large deposits of fat in the abdominal wall. He had seen one such case. A diagnosis of ovarian tumor had been made, with which he had not coincided. The tumor was a mere mass of fat attached mainly to the omentum. It was not considered removable. The patient died soon afterward.

Dr. E. C. Gehrung, of St. Louis, had seen one case. He had considered the case inoperable, but seven years subsequent to his seeing it the patient was still living. The tumor had grown to enormous dimensions, and caused the patient great suffering. An operation was eventually performed, but not by the speaker, and the tumor was found to be a vast mass of fat weighing sixty-eight pounds, the latter fact being determined at the autopsy, which was made a few days after the unsuccessful attempt at removal.

Dr. Fordyce Barker, of New York, had seen one case. It had been removed, but not by him, the patient dying on the third day after the operation.

Dr. H. C. Coe thought that the fatal termination in

the cases reported might be due to the fact that malignant elements were present in the growths.

DR. G. J. ENGELMANN doubted whether all the cases reported were cases of lipoma of the abdomen, to which the subject of the paper was limited.

The President, DR. H. P. C. WILSON, of Baltimore, then delivered

THE ANNUAL ADDRESS,

in which the history of the Society and its satisfactory work were dwelt upon. It also abounded in reminiscences, especially concerning the eminent men who had been connected with it in previous years and had passed away. He also suggested for discussion the question as to the propriety of laparotomy during or just before the menstrual period. Storer had stated, at the first meeting of the Society, that laparotomy would be followed by the best results when performed during the week after menstruation had ceased. The speaker believed, on the contrary, that it was better to operate during the uterine *flood* than during its *ebb*. He believed that at such a time the flow from the uterus was beneficial, and would tend to prevent inflammation. He had acted upon this opinion in several cases in which laparotomy had been performed, and had not had occasion to regret his action.

DR. GOODELL thought the question a very important one. He had operated during menstruation, and was willing at any time to perform ovariotomy during that period. He would not be willing, however, to perform hysterectomy at such a time, or remove a uterine fibroid.

DR. A. P. DUDLEY had observed, as all operators had done, that a flow of blood from the uterus almost always followed laparotomy after a few days, and this had suggested to his mind that a flow from the uterus at any time was not a contra-indication to laparotomy. He had operated several times during the past year while menstruation was in progress. He did not think any one should object to perform hysterectomy at such a time.

DR. R. BATTEY, of Rome, Ga., had performed the original case of Battey's operation while menstruation was in progress without bad result. We should expect metrostaxis in almost all cases within two or three days after performing laparotomy.

DR. KOLLOCK, of Cheraw, S. C., had operated twice during menstruation, and saw no contra-indication in its existence. He was glad to hear the principle advocated by the President.

DR. H. C. COE thought a distinction should be made as to those who were fit subjects for operation while menstruation was in progress. He did not believe it anvisable in women who were susceptible to attacks of pelvic inflammation.

DR. P. F. MUNDÉ had operated during menstruation, and had not observed that the hemorrhage of the operation was more profuse than at other times. He thought it a matter of indifference whether menstruation were present or not in deciding as to the propriety of laparotomy. Proper dressings should, of course, be applied to the vulva, and particular care exercised to prevent sepsis. He did not think it advisable to remove a myomatous uterus during menstruation.

DR. A. J. C. SKENE, of Brooklyn, N. Y., thought no deductions could be drawn from the experience narrated as to the propriety or impropriety of operating during menstruation. In general, it was not well to operate while any function was being performed. If a patient suffered from dysmenorrhœa he would be in favor of operating just before menstruation to economize her vital force.

DR. ELY VAN DE WARKER, of Syracuse, N. Y., read a paper entitled

AN EXPERIENCE WITH SLOUGHING INTRA-UTERINE FIBROIDS.

The paper was based upon four cases.

Case I.—A patient of great obesity, in which attempts at total removal were abandoned, the sloughing layers of the tumor being removed with the curette. Recovery, and death some years subsequently with symptoms of malignant disease of the uterus.

Case II.—Age of patient forty-six, one child, and frequent abortions. Extreme loss of blood, high temperature and œdema of the extremities. Cervix extremely resistant. Rapid dilatation and removal of sloughing fibroid. Recovery, and death a year afterward from chronic nephritis.

Case III.—Age of patient thirty, sterile, fibroid extended from uterus, pedicle low in the cervix, sloughing, hemorrhage and pyrexia. Operation and recovery.

Case IV.—Age of patient forty, three children. Rapid disappearance of pelvic tumor, attended with severe flooding from sloughing intra-uterine fibroid. Extreme high temperature and exhaustion. Operation and recovery complicated with hystero-tetanus without trismus. Neurotic symptoms were relieved by bromides and assa-fœtida.

Case V.—Age of patient fifty-one. Uterine symptoms for fourteen years, which had been ascribed to cancer. Loss of blood almost continuous during that period. Pyrexia for four weeks, exhaustion and anæmia. Operation, and death from shock.

The following summary is based upon the foregoing:

1. The use of the curette to remove the sloughing periphery of an intra-uterine fibroid when non-removable from any cause that renders extirpation extra hazardous is to be recommended.

2. The process of sloughing begins at the outer layers of the tumor, and extends layer by layer to its deeper structure.

3. Rapid dilatation of the cervical canal will afford ample space for the manipulation necessary for removal of a tumor. Sponge-tents and other slow methods of dilatation are unnecessary.

4. Intra-uterine fibroids, when extended and pendulous in the cavity of the cervix, the pedicle being in the cervix, rarely slough.

5. A form of hystero-tetanus, without trismus, may follow certain forms of blood-poisoning, or uterine lesion. In the author's experience this condition was seen only in connection with the puerperal state and was attended with septicæmia.

6. A blanched mucous membrane, with excessive and long-continued loss of blood, accompanying intra-uterine fibroids, indicates that the limits of safety have been reached in the operative treatment of sloughing fibroids, and a doubtful prognosis must be given.

7. Septicæmia, with long-continued pyrexia, is necessarily a fatal condition when due to a sloughing fibroid, unless relieved by the removal of the offending mass.

Complete or partial removal is a life-saving measure, and is comparatively easy and attended with but little danger, except in the cases in which the mucous membrane is blanched.

Dr. M. D. Mann narrated three fatal and one successful case of sloughing fibroid, all illustrative of the danger of the condition and the danger which may attend attempts at its relief.

Dr. Battey narrated several cases, in one of which removal of the ovaries was followed by sloughing of a fibroid tumor. The same result sometimes followed the use of ergot.

Dr. Kollock narrated a peculiar case in which a large sub-peritoneal fibroid tumor was removed. The uterus was also removed, and was found to contain a large collection of fibroids and a macerated fœtus.

Dr. Wylie advised that the sloughing mass be first made as nearly antiseptic as possible, prior to operation, by applications for several hours. After the operation no tampon should be used as it might prevent free drainage. It was a singular fact that intra-uterine tumors in old women, in atrophic conditions, sometimes presented symptoms similar to those which attend sloughing fibroids.

Dr. Goodell believed it better to do several operations for the removal of an intrauterine fibroid than to prolong one operation unduly. He had sometimes been able to deliver a troublesome tumor with a guarded obstetric crotchet,

Dr. Gordon narrated a case. He thought the cause of sloughing in the tumors under consideration was imperfect vascular and nerve supply.

Dr. Van de Warker, in concluding, believed there was a special mechanism which caused sloughing, namely, pressure and constriction, and the impaired vascular and nerve defects were secondary to this. He could not think that antiseptic applications prior to operation would be of much avail, as they would not penetrate deeply enough to affect the entire mass of sloughing tissue.

Dr. H. C. Coe, of New York, read a paper entitled

DEATH FROM VISCERAL LESIONS FOLLOWING OVARIOTOMY.

The great reduction in the death-rate which had attended the improved methods of ovariotomy was a noteworthy fact. In addition, the field of the operation and kindred operations had extended, and many conditions which had once been considered of fatal significance were now regarded as less serious. It was a matter for regret that post-mortem examinations following laparotomies were often performed so superficially that they revealed little concerning the causes of death. His paper was based upon fifty autopsies which had been made with great care and thoroughness.

His first class of fatal lesions were those which involved the heart. Of these, fatty degeneration, dilatation, and mitral diseases were noteworthy. Cardiac disease might not develop for several days after an operation, heart failure then occurring. The heart might also be injuriously affected by the pressure of a distended stomach or intestines notably in those cases in which opium was used. There might also be reflex irritation due to disturbance of the abdominal sympathetic plexus.

Pulmonary affections might be present at the time of operation and be overlooked, the condition not being recognized until after death. The dyspnœa prior to operation might be due to pleurisy rather than to pressure of a tumor. Pulmonary disease after operation might also be a reflex condition, and pulmonary œdema was often one of the final lesions before death. Bronchitis and pneumonia might follow prolonged exposure during an operation, or the prolonged dorsal position after operation. It was important to know whether the disease were intercurrent or preëxisting.

Renal affections were also frequently overlooked. Albuminuria frequently resulted from the pressure of a tumor, and pus in the urine might also be indicative of a renal lesion. A renal lesion did not necessarily contraindicate laparotomy. Complete suppression of the urine after laparotomy was rare, but it might occur with uræmic symptoms. Renal diseases which might occur *de novo* after operation were hydronephrosis, acute pyelitis, and interstitial nephritis. Diseases of the gastro-intestinal tract of an acute or chronic character might precede an operation or follow as its result. Gastric irritation was not necessarily due to pressure; it might be due to venous stasis; and such cases might be fatal from exhaustion following irremediable vomiting. Acute dilatation of the stomach might follow operation.

Gastro-intestinal inflammation of a severe character might follow laparotomy, and a diarrhœa not septic in character might quickly prove fatal. Peritoneal adhesions might also cause intestinal stricture with its serious resulting conditions. Peritonitis after laparotomy was much more common than was usually supposed, and this was frequently demonstrated by those who were called upon to perform several laparotomies upon women.

Other visceral lesions might affect the spleen, the lymphatics, the liver, etc. Sepsis was not the only thing to be avoided, as visceral lesions of an irremediable character might affect the prognosis. All of which taught that too great care could not be taken in examining patients prior to proposed operations. Routine methods were to be avoided, except in so far as they conduced to thoroughness of knowledge of the patient's fitness for an operation.

Dr. G. J. Engelmann, of St. Louis, Mo., read a paper entitled

RENAL DISEASE CAUSED BY DISEASE OF THE PELVIC VISCERA.

Renal disease might be caused by perverted nerve action, disease of the ureters, the pressure of pelvic tumors or of the gravid ureters. The influence of the nervous system in causing this disease was a very important one. Obstructive conditions of the kidneys might exist and yet no lesion be apparent. In connection with parturition, albuminuria might exist as the result of both reflex influence and pressure. Disease of the bladder, caused by the pressure of tumors, was usually detected. Pressure upon the ureters caused a series of morbid conditions, beginning with ureteritis and ending with contracted kidney. The progress of such disease was usually slow and insidious, the more prominent symptoms being backache and lumbar pain. Life was endangered as suppression of urine and coma supervened. The anatomical conditions of the ureter exposed it to pressure during its entire extent. Sometimes it was

pressed against the brim of the pelvis, at others it was involved in the exudate of an inflammation. The right was more exposed, and so more subject to these lesions than the left. Malignant disease of the pelvic organs was also a frequent source of disease of the ureters and kidneys, the condition not being discovered, perhaps, until an autopsy revealed it. It was somewhat singular that cardiac complications seldom occurred in these cases, even though the kidney might be in a condition of hydronephrosis. Ovarian tumors were less likely to be complicated with disease of the ureters and kidneys than were the hard and solid growths; the obvious reason being the yielding character of ovarian cysts, which caused them to develop where the resistance was least. A diagnosis was rarely made when compression of an ureter first occurred, the condition usually progressing to pyelitis before it was discovered; hence there was an indication for active interference as soon as symptoms of moderate intensity appeared. Prolapsus uteri with the traction which accompanied it might cause disease of the ureter and then of the kidney. Renal changes during pregnancy might be reflex, but were usually due to pressure upon the bladder and ureter. Flaischlen had compared the renal phenomena during pregnancy and labor to those which are present in cholera. The pain proceeding from the kidney disease might be obscured by that which proceeded from disease of the uterus or ovaries. It was often described as darting downward apparently along the course of the ureter. Patients frequently complained of vesical tenesmus, scanty and frequent urination, darting, spasmodic pains downward from the brim of the pelvis, and burning and lancinating pains in the back causing lassitude. In some cases the direction of the pain was toward the liver, in others, across the small of the back. As the disease progressed the pain would continue for hours, or even days, with little intermission. These phenomena sometimes appeared after a sudden fall, or a cold, or a sharp attack of cellulitis or cystitis, and should suppression occur, uræmia and œdema of the extremities might supervene. The urine contained pus, phosphates, hyaline, granular, and epithelial casts, and, in the later stages, it was of alkaline reaction. One kidney alone might be involved, complete occlusion existing. The prognosis was usually serious, because the cases were seen too late. If seen early, the condition might be relieved by removing the cause of pressure. This might consist in the removal of a tumor, or in the replacement of the uterus. Medicines were usually of little service, though benefit was sometimes experienced by the use of ergot. Other means which, however, were often inefficient, consisted in the use of heat, iodine, and the galvanic current. Catheterization of the ureter, or Bozeman's operation of kolpo-uretero-cystotomy by enlarging the lumen of the ureter, might give relief. It would also furnish a means of draining the kidney should pyelitis exist.

DR. W. M. POLK thought the papers of Dr. Coe and Dr. Engelmann demonstrated that in connection with pelvic disease there were other organs which called for careful attention. A class of women who were quite subject to coincident renal disease included many who were in the higher walks of life, who indulged freely in the dissipations of society life and the pleasures of the table. With such women ether anæsthesia and operative shock were prone to mar the efficiency of surgical operations. Intestinal complications were common in such cases, and excretion in general was interfered with or suspended.

DR. HOWARD A. KELLY would emphasize the importance of Dr. Engelmann's statements. Literature abounded with cases in which pelvic disease was complicated by renal disorders. The anatomical conditions of the kidney and ureters rendered such complications possible and probable. Such diseases as tuberculosis of the bladder, and cancer of bladder, uterus, and vagina, might extend from the ureter to the kidney; the ureter might also be seriously implicated by retro-peritoneal sarcoma, by adhesive bands in the pelvis, and by vesico-vaginal fistula. In the advanced stage of pregnancy the ureter was liable to become enlarged and displaced by pressure. Inflammation of the extremity of the ureters was a very common condition. It was extremely important to ascertain the exact condition of the ureter, and this could be readily done by palpation and catheterization.

DR. B. B. BROWN, of Baltimore, narrated a case of hydatids of the ureter in which the condition was determined by dilatation of the urethra and exploration of the bladder and ureter with the finger.

DR. COE, in conclusion, referred to several cases of hydronephrosis in which the condition had not been suspected during life. He also disapproved of the operation of kolpo-uretero-cystotomy as inefficient, narrating a case in which it had been performed, and in which an autopsy revealed the presence of renal abscesses which could not be reached by the operation.

DR. ENGELMANN, in concluding, thought that a more careful study of renal disease in its relations with pelvic disease would broaden the field of gynecological work.

DR. S. C. GORDON, of Portland, Maine, read a paper entitled

PELVIC CONGESTION VERSUS PELVIC INFLAMMATION.

Pelvic inflammation as a process and a term had for many years been a surgical opprobrium, especially what was commonly called chronic inflammation, the existence of which had been denied by Peaslee and others. Pelvic inflammation might be repeated an indefinite number of times, the results being resolution, induration, or suppuration. If the result were an indurated exudate, it would cause pressure on surrounding parts, with more or less extensive venous congestion. Prolonged congestion implied hypernutrition with hyperplasia of all the pelvic tissues to a greater or less extent, and an increased tendency to renewed attacks of acute inflammation. This was also one of the sources of the various forms of tubal disease. If there were only a passive congestion, it was evident that the sooner it was relieved by operative measures the better for the patient. Hence the absence of necessity for the prolonged preparatory treatment so often advised in connection with operations upon the pelvic organs. The reader had found such preparatory treatment harmful rather than beneficial, and considered that time and money were saved to the patient by its disuse. If trachelorrhaphy were to be performed, he would at once proceed to the operation after having thoroughly curetted the mucous membrane, and expect reparative changes in the pelvic tissues to be induced thereby. Such operations should always be done under the influ-

ence of an anæsthetic, indeed he preferred to avoid the risk of pelvic inflammations even in making applications to the interior of the uterus by using an anæsthetic for such. His personal experience had demonstrated the soundness of his propositions.

Dr. T. A. Emmet admitted that vaginal douches of hot water were not indicated after an acute inflammation had terminated. A fundamental fact was that inflammation of the connective tissue in all cases meant destruction of that tissue, whether it resulted in resolution or abscess. Localized peritonitis must frequently be the result of such inflammation, and this accounted for the frequent presence of adhesive bands and scars in the peritoneal cavity. With the cellulitis were also associated phlebitis and lymphangitis; then as the cellular tissue was destroyed the veins lacked support, and distention and congestion resulted. Such a condition could frequently be relieved by steady and persistent pressure from the vagina. It was extremely necessary to draw the distinction between acute pelvic inflammation and its results.

Dr. A. P. Johnstone, of Danville, Ky., had found as the result of histological study that a great cause of the susceptibility to pelvic inflammation consisted in the peritoneal bands which, by their tension and pressure, interfered with the growth of epithelium in the tubes and uterus. The lymphoid tissue of the endometrium should develop into epithelium, but faulty conditions, such as the one which had been mentioned, caused instead the development of connective tissue.

Dr. W. M. Polk, of New York, read a paper entitled

THE SURGICAL TREATMENT OF POSTERIOR DISPLACEMENTS OF THE UTERUS.

It must be admitted that there were many cases of backward displacement of the uterus which were not relieved by pessaries. Brandt's method of treating such conditions would not be discussed on account of insufficient experience as to its value. There remained the purely surgical procedures, which were limited to the external or Alexander's operation, the various internal operations, which presupposed laparotomy, and the vaginal operation, in which the vaginal portion of the cervix was stitched to the posterior vaginal wall. Of all these methods a matured experience inclined the reader to prefer Alexander's operation, supplemented, perhaps, by the use, for a time, of an intra-uterine stem pessary, as the one which was least dangerous, and most permanent in its results. This operation, too, was efficient in relieving prolapse of the ovaries when coincident with retro-displacement of the uterus, also many cases of procidentia uteri, for which hysterectomy might otherwise be suggested. With procidentia it was, of course, implied that the pelvic floor was also to be repaired. In those cases in which the round ligaments have undergone fatty degeneration, laparotomy and internal treatment would be required; so, also, would those cases in which the uterus was firmly adherent, or in which there was coexistent disease of the tubes and ovaries. Of the methods of repair which presupposed the opening of the abdomen there were many which were based either upon the utilization of existing supports or the making of new ones. Of the latter, ventro-fixation was believed to be the best, but it had objections which were obvious. Of the former, Tait's and Imlach's implied a reefing of the broad ligaments, especially after removal of the tubes and ovaries; Wylie's, a doubling of the round ligaments upon themselves; and the reader's consisted in bringing the round ligaments in front of the uterus and stitching them together.

Dr. W. H. Baker, of Boston, Mass., preferred ventro-fixation if the abdomen were to be opened, but would avoid such a procedure if Alexander's operation were at all feasible. The question of permanence as to result was also important, and the fact that ventro-fixation frequently required repetition on account of rupture of the uterine attachments to the abdominal wall, was against the operation.

Dr. Howard Kelly thought ventro-fixation better than attachment of the uterus to the pelvis anteriorly, as proposed by Zweifel, as this brought the uterus and its adnexa into a faulty position. He had recently obtained good results in ventro-fixation by passing his sutures behind the uterus and including the utero-ovarian ligaments. He had also tried Schücking's operation in two cases with good results.

(To be concluded.)

NEWS ITEMS.

An Impudent Note.—The following were received in the regular mail, written as private personal notes, without any business heading. To a medical man they condemn themselves; and we understand that many others received similar invitations.

Dear Madam: We should be glad to have you consult us in reference to your eyes. We have been fitting glasses for over thirty years, and after careful study of the subject have adopted a new method of examination which is wonderfully effective.

One visit to our store is all that is required, consequently both a great amount of time and expense are saved.

The glasses we furnish cannot fail to give you a great deal of comfort.

Yours truly, Queen & Co.,
Opticians, Scientific and Artistic Spectacle and Eyeglass Makers

Dear Madam: Do you have trouble with your eyes, or does any of your family? If such is the case, would it not be well to call upon us and we can quickly determine what the difficulty is, and furnish you with glasses if you need them.

We do not frighten you by telling you how serious the difficulty is, nor how much time will be required to correct it, but go sensibly and practically to fitting you with as little expenditure of time and money as possible.

Hoping to receive a call from you, we are,

Yours truly, Queen & Co.,
Opticians, Scientific and Artistic Spectacle and Eyeglass Makers.

The Hyderabad Chloroform Commission.—*The Lancet* of September 21st, states that £1000 have been offered by the Nizam of Hyderabad to that journal to send out a representative to repeat the experiments of the Hyderabad Chloroform Commission, and to make any others that may be suggested. In its editorial columns, *The Lancet* states that Dr. Lauder Brunton has been requested to act as their representative, and also that their request

has been accepted and that Dr. Brunton would sail on the 4th inst. This is confirmed by personal mail received by us.

The Commission is to be at the disposal of and under the directions of Dr. Brunton, who is to be the guest of his Highness the Nizam, and is to be provided with instruments, appliances, and everything which may be required for the experiments.

The subject which the Commission will strive to settle definitely and once for all is, "Whether chloroform exerts any direct action upon the heart or not." Their experiments so far tend toward the negative. The coming experiments will extend over a period of about three months.

Improvement of Jefferson Medical College.—The Jefferson Medlcal College and Hospital will soon add a building to the group already located at Tenth and Sansom Streets, as the needs of the college and hospital have increased to such an extent that the Board of Trustees have found it necessary to have another building.

A Maternity Hospital.—A Maternity Hospital has just been added to the other clinical facilities of the Medical Department of the University of Pennsylvania. Although bnt a single wing of the hospital has been built, equipped, and opened, it will nevertheless have a maximum capacity of fifteen confinements a month. Pregnant women are admitted a month before their expected delivery. To each case two students are assigned, who are required to fill out a complete and elaborate record of the case, under the direction of a demonstrator, from the date of admission till the end of the puerperium. These records are modelled in great part upon those adopted in the large maternity hospilals connected with universities in Germany. The safety of the patients is secured by a thorough system of antisepsis, and they are guarded from unnecessary exposure by giving to each woman a separate room during delivery and the lying-in period.

The Medical Schools of Philadelphia.—The medical sehools of this city began their sessions with the first week of October.

At the Jefferson Medical College no introductory lecture was given, owing to the illness of the lecturer, Dr. W. W. Keen. The number of matriculants up to our going to press is 450.

The course at the University of Pennsylvania was opened by an introductory lecture by Dr. James Tyson, the Dean of the Faculty, on Tuesday, October 1st. The class at this school is unusually large. The new matriculants, up to date, number 175; the second year 155; and the third year 148.

The Medico-Chirurgical College opened its course with a lecture by Dr. J. M. Anders, on Monday, September 30th. We understand that the classes at this school are also larger than heretofore.

New Autopsy Building and Theatre.—A very picturesque building is now going up on the southern side of the grounds of the Hospital of the University of Pennsylvania. The first floor at the north end contains an autopsy theatre, modelled after that of the Johns Hopkins Hospital, with rising steps, so that the autopsy can be comfortably witnessed by all present. This little theatre extends to the roof, from which it is lighted by a skylight. It is provided with a granolithic floor, and the walls are tiled to the height of a man. In addition to the autopsy room on the first floor is a small "laying out" room, where the friends of the dead can collect, and from which a funeral may take place if desired. Between this and the autopsy-room, and communicating with both, is a cold chamber for the accommodation of dead bodies, which are thus preserved, but are not in immediate contact with ice. On the second floor is a photograph- and microscope-room with a developing-room attached.

The exterior is rather quaint and attractive in appearance, with an entrance for students on the north or hospital side by a vestibule, extending part way along the west side of the building, while along the entire east side extends a covered porch or *loggia* in which is also an entrance at its south end. The house is so constructed that it may at any time be enlarged.

Mississippi Valley Medical Society.—This Society held a very successful meeting at Evansville, Indiana, September 10th, 11th, and 12th. The presiding officer, Dr. J. F. Cook, of Indianapolis, did not deliver a formal address at the opening of the session on account of the lengthy programme, amounting to ninety-eight papers.

The Committee on Nominations, through their Chairman, Dr. I. N. Love, reported the names of the following gentlemen as officers for the ensuing year:

President.—Dr. Joseph M. Matthews, of Louisville.

Vice-Presidents.—Drs. C. B. Earley, of Pennsylvania, and T. B. Harvey, of Indianapolis.

Permanent Secretary.—Dr. E. S. McKee, of Cincinnati, O.

Treasurer.—Dr. C. F. McGrahan, of Chattanooga, Tenn.

Chairman of Committee of Arrangements.—Dr. I. N. Bloom, of Louisville.

The place of the next meeting, to be held on September 9, 10, and 11, 1890, will be Louisville.

American Rhinological Association.—The annual meeting of this Association will be held on the 9th, 10th, and 11th of October, at the Palmer House, Chicago. The meeting will be presided over by Dr. John North, of Toledo, and the programme promises to be a most interesting one. Among the titles of papers to be read we notice the following: Brain Abscess emptying into Naso-pharynx; Chronic Rhinitis; Conjunctival Troubles resulting from Nasal Disease; Ocular Reflex in Nasal Disease; Catarrhal Neuralgias, and others. The Association extends a cordial invitation to the profession in general.

Rarity of Christian Charity.—A short time ago the Mayor of New York refused to furnish dogs from the pound to some gentlemen engaged in making certain surgical and bacteriological experiments. The request of one of the experimenters was given considerable newspaper notoriety, and he was recently the astonished recipient of the following letters, written from widely separated localities. The *New York Medical Journal* of September 21st prints these anonymous communications *verbatim et literatim*, leaving all comment to its readers:

"You vile merciless rascally *friend*. I judge from your name you are a nasty Frenchman with no heart, and without a God. If you think you will be permitted to set up a place of Torture in this country for poor animals you are vastly mistaken. You will have to betake yourself to the vile and *Godless* country from which you came or to the Hell to which you are destined, and if you wish to indulge in such fiendish performances when you reach the latter place—which I hope you will soon—unless you *repent* you will have an opportunity with kindred *friends* of torturing yourselves through the endless ages of eternity. I am a woman who despises brutes and all brutal actions."

"When *pain* the most awful sensation of the human frame *exists*—let its alleviation or study prove the sole lawful guide to future cases."

"Only the most *damnable* fiend cloaked in human form ever lifted the knife in *vivisection*. May the *curse* of an all-merciful God rest upon you. Laugh, sneer, such as you do. But may every agony your hellish minds and hands inflicts be trebled upon yourselves in this world and the world to come—and upon all like you. May your death bed be such a scene of horror that all will forsake you."

Possibly some may recall that once Professor Brown-Séquard, while demonstrating to his class certain physiological experiments on a dog, was assailed by a woman armed with a parasol; and we have been informed that Paul Bert once had a similar experience. So the experimenter, who, by the way, is not a Frenchman, may congratulate himself on having had only a verbal castigation.

Changes in the Government of Blockley Hospital.—It has been decided by the Mayor and the Board of Charities and Correction of the city of Philadelphia, that all resident physicians elected to the Philadelphia Hospital shall receive their appointments under a civil service examination. In place of the previously existing examining board, consisting of members of the visiting staff, the Mayor has appointed Dr. Chapman, of the Jefferson Medical College; Dr. Curtin, of the University of Pennsylvania; and Dr. Waugh, of the Medico-Chirurgical College, to carry out the new regulations.

Blockley Hospital Examinations.—The Examining Board will meet at the Civil Service rooms, in the City Hall, on Wednesday, October 9th, at 11 A.M., to examine candidates for the position of Resident Physician, Insane Department, Philadelphia Hospital.

An Ancient Medical Work.—Undoubtedly the oldest medical work extant is the papyrus found recently by George Ebers, the well-known writer and novelist. Dr. Ebers has just translated and published that portion of the manuscript relating to ophthalmology, which must have been written more than one thousand years before Hippocrates was born. The papyrus is said to contain much of interest.

Cholera in Mesopotamia.—Cholera is raging in Mesopotamia. Since August 19th there have been 1285 deaths. The disease first broke out in Bagdad, with great intensity, forty-eight deaths occurring in the first three days. The disease seems to be especially virulent, death occurring in from ten to twenty-four hours. Cholera has also made its appearance in Bombay and Calcutta, fifty-six cases having occurred in both places. These ports are now under quarantine.

Cholera in China.—Cholera is raging in several Chinese cities at present. The disease is worst at Pekin. With the exception of the custom house officials, and some other functionaries, all foreigners have taken refuge in the mountains.

Smallpox in Milan.—The epidemic of smallpox which has been raging in Milan appears to be fast subsiding. 161 cases were reported in January, and 236 in April, against 55 in June, and only 28 in July.

The Physician's Precedence in France.—The French legislature has passed a bill to the effect that the physician's claim on the estate of a deceased patient shall take precedence of all others.

Dartmouth College Hospital.—The plans for the Hitchcock Memorial Hospital, at Hanover, N. H., have been formally accepted. The hospital will be made to accommodate thirty patients, is to be built of stone, and will cost, including the ground, about $50,000.

Tri-State Medical Association.—The following papers have been promised for the meeting of the Tri-State Medical Association:

"Demonstrations with the Microscope," by Prof. James A. Reeves, of Chattanooga.

"Stricture," by Prof. Daniel H. Howell, of Atlanta, Ga.

"A Case of Typhoid Fever with Subnormal Temperature and Subnormal Pulse," by Dr. A. S. Wiltse, of Kismet, Tenn.

"A Plea for the Medical Education of Females," by Dr. Charles P. Gordon, of Dalton, Ga.

"Choleo-cystotomy, with a Case," by Dr. E. E. Kerr, of Chattanooga.

"Report of a Case," by Dr. William T. Blackford, of Graysville, Ga.

"Physiology of the Heart and its Valves," by Dr. W. L. Gahagan, of Chattanooga.

"Relation of the Specialist to the General Practitioner," by Dr. F. W. Skillern, of Pikeville, Tenn.

"Some Points in the Diagnosis of Skin Diseases," by Prof. E. A. Cobleigh, of Chattanooga.

"Imaginary Foreign Bodies in the Throat," by Dr. Max Thorner, of Cincinnati, Ohio.

"Antiseptic Midwifery," by Prof. F. W. McRae, of Atlanta, Ga.

Papers are promised, but their subjects not given, by Dr. F. B. Sloan, of Cowan, Tenn.; Dr. W. C. Maples, of Bellefonte, Ala.; and Dr. J. B. Cowan, of Tullahoma, Tenn. Other papers of interest will be presented.

Prof. Robert Battey, of Rome, Ga., has promised to be present.

This meeting will be held in response to the following call issued by a number of societies in Alabama, Georgia, and Tennessee:

"The members of the medical profession in Alabama, Georgia, and Tennessee are requested to meet in Chattanooga, on the third Tuesday in October, for the pur-

pose of forming a Tri-State Medical Association. All will be admitted to the meeting of the Association, but the membership will be restricted to graduates of regular medical colleges in good standing."

A constitution will be adopted at this meeting which will regulate all matters pertaining to the society.

The meeting will be called to order at 10 A.M. Tuesday, October 15th, at the Chamber of Commerce. The sessions will continue two days.

University of Michigan.—The *Boston Medical and Surgical Journal* states that the regents of the University of Michigan, at Ann Arbor, have received an offer of two acres of land for a hospital site from Mrs. Israel Hall.

An Anti-vivisection Hospital.—The *Zoöphilist* states that there will shortly be established in London an anti-vivisection hospital. A considerable sum of money has been readily obtained from a few friends of the project. One gift amounts to one thousand pounds, and it is confidently expected that other large contributions will flow in as soon as the plan is better known. It has been stated—and this episode bids fair to be a proof of it—that in a large city like London money can be secured for any project, however strange and novel, provided that it shall be fully advertised.

Fraudulent Medical Diplomas.—An enterprise for the sale of medical diplomas has been discovered in New England, having its headquarters at Boston. The diploma that has been discovered to be for sale bears the title of the Trinity University of Medicine and Surgery, at Bennington, Vermont. This high-sounding name, of course, represents an institution which exists on paper only. The managers of this diploma mill have invented other titles of colleges for the deception of the unwary. It is stated that they have blank diplomas, covering a wide range of territory—for example, the Montreal Medical College, University of New Hampshire, New York State Medical College, Trenton Medical College, and University of Cincinnati. These titles are purely fictitious, but some of them are cunningly worded, so as to resemble those of *bona fide* institutions, with intent to deceive. It is further reported that the ringleaders of this fraud are known and will presently be arrested.

The Late Dr. Habershon.—It would appear that the fatal disease in the case of the late Dr. Habershon, of London, was gastric ulcer; this is the reported result of a post-mortem examination, confirmatory of his own ante-mortem opinion. By a strange coincidence, this is the very disease which, of all others perhaps, he had studied the most, and about which the profession was wont, with especial frequency, to consult him.

Responsibility of the Drunkard.—M. MOTEL read a paper on this subject before the International Congress of Psychology recently held at Paris. He said that a man was not responsible for a crime committed during the delirious period of drunkenness, nor when the crime was committed by a man suffering from chronic alcoholism, whose brain has undergone those changes which compromise the regular functions of the organ. The responsibility was attenuated in the cases of those persons naturally of a weak intellect and who take drink badly; it is also extenuated when it has been proved that the man got drunk unintentionally. On the contrary, to those who got drunk with intention, and where alcohol was taken to give courage in order to commit a crime, no extenuation should be allowed. In conclusion, the author proposed that in presence of the great increase of alcoholism in France, and the terrible crimes committed under its influence, the government be invited to take steps to guarantee society against criminal dipsomaniacs, and for that purpose to establish special asylums for the treatment of habitual drunkards. The assembly adopted this proposition unanimously.—*Medical Press and Circular*, September 4, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING SEPTEMBER 28, 1889.

GORGAS, A. C., *Medical Director.*—Detached from Examining Board, and ordered to Hospital, Philadelphia, Pa.

HORD, W. T., *Medical Director.*—Detached from Hospital, Philadelphia, Pa., and wait orders.

BOGERT, E. S., *Medical Inspector.*—Detached from New York Navy Yard, and ordered to Examining Board.

MCMURTRIE, D., *Surgeon.*—Detached from U. S. S. "Vermont," and ordered to Navy Yard, New York.

BABIN, H. J., *Surgeon.*—Ordered to the Receiving-ship "Vermont."

HALL, C. H. H., *Passed Assistant Surgeon.*—Resigned from the Naval Service, to take effect November 1, 1890, and resignation so accepted.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 24 TO SEPTEMBER 30, 1889.

By direction of the Acting Secretary of War, the leave of absence for fourteen days, on surgeon's certificate of disability, is granted ANDREW K. SMITH, *Colonel and Surgeon.*—Par. 1, *S. O. 214, A. G. O.*, September 14, 1889.

By direction of the Acting Secretary of War, GEORGE M. STERNBERG, *Major and Surgeon,* having completed the duties assigned him in War Department S. O. 30, A. G. O., February 5, is reassigned to duty as Attending Surgeon and Examiner of Recruits at Baltimore, Maryland.—Par. 12, *S. O. 218, A. G. O.*, September 19, 1889.

By direction of the Secretary of War, the leave of absence granted BENJAMIN F. POPE, *Major and Surgeon,* in S. O. 54, August 17, 1889, Department of Texas, is extended one month.—Par. 6, *S. O. 224, A. G. O.*, September 26, 1889.

By direction of the Secretary of War, the station of LEONARD Y. LORING, *Major and Surgeon,* is changed from Fort Mojave, Arizona Territory, to Fort Wingate, New Mexico, and he will report for duty at the latter accordingly.—Par. 7, *S. O. 219, A. G. O.*, September 20, 1889.

ADAIR, GEORGE W., *Captain and Assistant Surgeon.*—Leave of absence for one month.—*S. O. 90, Headquarters Department of the Platte*, September 25, 1889.

By direction of the Secretary of War, HENRY G. BURTON, *Captain and Assistant Surgeon,* will report in person, on the expiration of his present sick leave of absence, to the commanding officer David's Island, New York, for temporary duty at that station, and by letter to the superintendent of recruiting service.—Par. 3. *S. O. 223, A. G. O., Washington.* September 25, 1889

With the approval of the Secretary of War, leave of absence for fourteen days is granted ALONZO R. CHAPIN, *Captain and Assistant Surgeon.*—Par. 10, *S. O 223, A. G. O.*, September 25 1889.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

NOTES ON THE FORMATION OF PIGMENT IN THE NEGRO.[1]

BY ROBERT B. MORRISON, M.D.,

SURGEON TO THE OUTDOOR SKIN CLINIC OF JOHNS HOPKINS HOSPITAL, BALTIMORE.

IN the city of Baltimore, whence I come, the proportion of the negro to the white is very large. In round numbers, it may be stated that about twenty-five per cent. of the cases presenting themselves for treatment are of the negro race.

The negro is a happy, easy-going being, with but little care for the past, present, or future. His idea of morals or self-constraint in any way is slight. He eats and drinks gluttonously, and his animal passions pass all bounds when once they are excited. He increases in number rapidly as long as the child-bearing period exists. He lives generally in indifference to his surroundings, whether they be foul or filthy.

With us in America the reason for all this is the sudden enfranchisement of the whole race, whereby they were changed from a dependent, almost unexceptionally well cared for, people, to one which was, without preparation, forced to make its own livelihood and to stand upon its own resources. The condition of the negro race since our civil war has been a serious question for physicians as well as philanthropists and philosophers.

From the abject poverty which they have been thrown into, many diseases have spread among them which were almost unknown when they were necessarily well cared for on plantations. Diseased negroes could not work, nor could they be well sold, hence they were housed, fed, and clothed in a healthy manner. Crowded, as they now are, in narrow back alley-ways or in tenements, with whole families in one room, it is no wonder that skin diseases, due to want of hygiene and nourishment, flourish among them.

Histologically the skin of the black race is more coarse and thick, more tough, than that of the white race. It is composed of more dense fibrous tissue, the glands are larger, as are also the nerves and vessels running into the papillary layer. The epidermis is thicker, and slightly yellowish in color, thereby adding somewhat to the general color of the skin. The pigment which lies in the first layer of the epidermis determines the color of the skin, not so much by its quantity as by its density of shade. That is, in a true black man the pigment is deep black, while in the mulatto it is present in the same quantity, but the color of the granules is lighter. There are fewer elastic fibres in the negro skin, and more subcutaneous adipose tissue than in the white. The nerves, though larger, are less sensitive both to external and internal agencies.

In diseases such as vitiligo and leucoderma, the loss of pigment is often rapid and extensive, so that in some instances the black man turns almost entirely white. In diseases where there is an increase of pigment in the white, there is either no change in the black or else there is loss of pigment. For instance, in eczema, where there is much scratching in the whites, the amount of pigment is increased, but in the negro where the epidermis has been injured, there is frequently a lessening, sometimes even an entire loss of pigment. Almost all eschars in the negro when first found are of a dull yellowish-white color, and generally and gradually take on the color of the surrounding tissues by closing in upon the spot from their periphery. It may be well to state that the negroes spoken of in this paper are the true black men or women, and not that portion of the race which has a mixture of one, two, three, or more per centum of white blood in their vessels.

Another instance where disease causes quite the reverse appearance in the negro to that in the white is psoriasis, for while this disease is rare in the negro, it heals quickly and leaves whitish spots behind, which sometimes never take on color again, so that we might think upon first viewing such a case that we had one of vitiligo before us.

Instead of having a macular syphilide, meaning a roseolar, we have a spotted appearance of the skin, the spots being whitish, and not red or copper colored. Congenital pigmented nævi are not uncommon in the negro, while, as one might expect, port-wine marks do not show even if there should be a condition of the skin similar to that of the white race which produces such a state.

[1] Read before the International Congress of Dermatology and Syphilis held in Paris, August, 1889.

As has been said, the pigment lies in the first layer of the epidermis, and in health does not penetrate higher. In some instances, however, the pigment granules are carried up into and between the epidermic cells almost to their most superficial layer.

In a case of elephantiasis arabum of the vulva[1] in which excision of the tumor was performed, the microscope disclosed that the pigment had been carried from its normal position through the lymph spaces far up into the epidermic layers. It is, of course, easy to understand why this should be, since we know that in elephantiasis arabum all the lymph glands, vessels, and spaces are enlarged. It would seem, also, that as the pigment is carried into what might be called foreign parts, its place is supplied by the formation of more, so that we have, in a case like this one, an increase of pigment, which, although in itself apparently harmless, might in other cases prove a source of malignant disease, the channel by which it spreads being possibly the lymph vessels and spaces. The extra formation of pigment in this particular case, a formation found in proportion to the amount carried into the surrounding tissues, is suggestive. At any rate, there was no loss of pigment in the line which marks its normal position.

The question as to when the formation of pigment takes place in the negro, *i. e.*, at what time of intra- or extra-uterine life, brings me to the principal point of this paper. It is popularly and scientifically stated by many authors that the children (babies) of negro parents are born white or without pigment in their skins.

Kölliker[2] says:

"The pigment of the mucous membrane in the colored races, as in the Europeans, is developed after birth; but in the former—the negro—the margins of the nails, the areola of the nipple, and the genital organs become colored about the third day, and by the fifth or sixth day the color is diffused over the whole body."

This quotation from Kölliker certainly implies that the negro baby is born without pigment and that it takes five or six days for it gradually to appear. This means, apparently, that microscopically there is no pigment in the negro fœtal skin.

Unna[3] says:

"It is very desirable that the origin of the physiological pigment of the skin should be thoroughly investigated. partly because we have no sure basis for the judgment of pathological skin pigment, partly because the origin of skin pigment, as in the history of the development of the hair, is sure to play, from an ethnological standpoint, an important part. For it is known that the colored races at birth are still without pigment (pigmentless), and an exact study of the manner and time of pigmentation in the embryo and newborn would be better able to clear up the relationship of races than the hitherto vain endeavors to draw conclusions from the hair and color of adults."

This quotation from Unna clearly shows that he thinks the negro fœtus and newborn baby is without pigment, which only appears some time after birth. In a personal interview with the author just quoted, the writer of this paper called his (Unna's) attention to the statement made. He said it was from reading and not from personal investigation which had led him to make it. He hoped some one would investigate who had the opportunity and who was brought into contact with the negro race.

Lesser[1] says:

"And I call to mind in this respect the known fact that the children in colored races are also born with entirely white skins and the pigment peculiar to them first develops in the early time of extra-uterine life."

It seems that the highest authorities in histology and dermatology agree that the negro is born white.

A doubt as to the correctness of this idea suggested a cursory investigation to the writer, who has many friends accustomed to deliver negro women. The answers received from many were not satisfactory because they had never thought of noticing the color of the child when born, knowing the mother to be black. Some of them ridiculed the idea of white negro babies, saying they had plenty of color the first moment of birth.

Several had delivered the mothers of negro babies who were themselves white, the mother acknowledging that the father was black. One physician of large experience said the babies of true negroes are born "as black as the ace of spades."

There was but one way of settling the question, viz., by microscopic examination. My assistant at the Johns Hopkins Hospital, Dr. Lord, had delivered a stillborn, eight months fœtus whose father was very black and the mother moderately so. Sections were made from the skin taken from the arm of this child. There was an unmistakable line of pigment granules lying in the lowest layer of the epidermis which could be seen microscopically as well.

In another case which Dr. Neale, of the Maryland University Lying-in Hospital, provided, sections from the prepuce of a negro baby which had died in utero thirty-six hours before birth, also showed pigment under the microscope. It was not as distinct as the specimens from the first case, as the child's parents were not black but mulattoes.

From this investigation, I feel justified in saying that the children of true negroes are not born without pigment however they may appear to the naked

eye. The probability is that the general congestion of the skin, the washing of the vernix caseosa from it, and the thinness of the epidermis which shows the papillary vessels more plainly beneath, cause the pigment to be overlooked when in reality it is there. Negro babies are, therefore, not born white nor do they suddenly grow black. They have pigment in the skin at least a month before birth, which can be plainly seen even with the naked eye.

The embryonic study of normal pigment in the negro will be a matter for future investigation which, as Unna has suggested, may help the pathological study of it.

The investigation must be made, however, entirely independent of the idea that negro babies are born white.

THE RELATIONS BETWEEN CHLOROSIS, SIMPLE ANÆMIA, AND PERNICIOUS ANÆMIA, INCLUDING LEUCOCYTHÆMIA AND HODGKIN'S DISEASE.[1]

By FREDERICK P. HENRY, M.D.,
PHYSICIAN TO THE PHILADELPHIA HOSPITAL.

(Concluded from page 368)

In an earlier part of this article I defined an independent disease to be one which rests upon a constant anatomical basis, or is invariably produced by the same specific agent. If this definition is accepted, pernicious anæmia cannot be regarded as an independent disease. Hunter and others have found, in this affection, a constant and decided increase in the amount of iron in the liver, and regard this as its essential anatomical feature. Without any wish to detract from the value of this observation, it seems to me unquestionable that this increase of iron in the liver is a consequence of defective hæmogenesis, and therefore to be classed with fatty degeneration of heart and other secondary changes. It is, in my opinion, plainly evident that the blood corpuscles of pernicious anæmia have undergone a marked degeneration. As I have elsewhere remarked,[2] the facts with reference to the blood of pernicious anæmia are such as to demonstrate a reversion to the type of the cold-blooded animals. This theory might justly be regarded as fanciful, if it were based upon a resemblance of the blood of pernicious anæmia to that of the lower animals, fishes, and reptiles, in any one particular, but the facts show that the corpuscles of pernicious anæmia resemble those of the said animals in their number, their size, their shape, and their percentage of hæmoglobin. In well-marked cases of pernicious anæmia we observe:

1. A reduction of the number of red corpuscles to a degree that is normal to the cold-blooded animals. It is not at all uncommon, in this disease, to find less than one million red corpuscles per cubic millimetre. Figures such as these are normal in the cold-blooded animals.

2. Many of the corpuscles are much increased in size, so much so that they have received the name of megalocytes. Many of them are quite as large as the corpuscles of the lizard and eel.

3. They often show a tendency to assume an oval outline. The great increase in the size of the diseased corpuscles and their oval shape are very remarkable. The patient from whom the blood was taken was a typical case of pernicious anæmia.

4. To make the resemblance complete, nucleated red corpuscles have often been observed in the blood of pernicious anæmia.

It is a most significant fact, in connection with the relations of the various affections under discussion, that the term "idiopathic" has never been applied to leucocythæmia. This disease was no sooner described by Bennett and Virchow than its association with structural changes in the blood-making organs, especially the spleen, was recognized. It corresponds, therefore, to our definition of an independent disease in being one which rests upon a constant anatomical basis.

The blood-changes of leucocythæmia are so remarkable that they would warrant the separate classification of this disease, even if there were no other constant anatomical lesions associated with it. In the first place, the volume of the blood, which is diminished to such an extraordinary degree in pernicious anæmia, is, in leucocythæmia, not only maintained, but sometimes augmented. In typical cases of this disease there is a condition of plethora, concerning the nature of which there has been some discussion. In the most minutely studied case of leucocythæmia with which I am acquainted—that of Sticker[2]—

> "The increased tension of radial and carotid arteries, the loud aortic-valve sound, and the fulness and tortuousness of retinal arteries and veins, pointed unmistakably to a condition of plethora which Sticker considers hydræmic. On the other hand, von Bamberger,[2] who has often observed dilatation of the heart cavities and abnormal fulness of the vessels in the bodies of those who have died of leukæmia, is doubtful as to the hydræmic nature of this plethora."[3]

He withdrew, by venesection, a small quantity of blood from a leukæmic patient, and analyzed it, with the result of proving that its solid residue was greater

than that of normal blood. He, therefore, proposes for this condition the term *leukæmic plethora*.

The facies of a leukæmic patient is entirely different from that of a case of pernicious anæmia, and of itself shows that the vessels are well filled with blood. Sticker's patient is described as having a bright color—*eine lebhaftere Färbung;* and Delafield[1] reports the case of a man whose lips and skin were of "good color." I, myself, was surprised at the rosy color of the first leukæmic patient whose blood I examined. In addition to this plethoric state of the blood, the increase in the number of the white corpuscles, from which the disease derives its name, the more marked tendency to hemorrhage, and the new formations of lymphadenoid tissue in various parts of the body, all suffice to separate this affection from simple anæmia, chlorosis, and pernicious anæmia.

It remains, therefore, to be considered whether there is any relation between leucocythæmia and Hodgkin's disease. Without pausing to consider the appropriateness of the term, I may say that by Hodgkin's disease we understand an affection of which the most prominent features are an enlargement, more or less general, of the lymphatic glands, enlargement of the spleen chiefly due to hypertrophy of its Malpighian follicles, new formation of adenoid tissue in various parts of the body, and a high, though usually not an extreme, degree of anæmia. From this description it is evident that the lesions of Hodgkin's disease are very similar to, if not identical with, those of lieno-lymphatic leukæmia. In fact, the only material point of distinction between them is the excess of circulating leucocytes in the latter. If, then, we can point to any cases of Hodgkin's disease in which the circulating leucocytes, at first normal or subnormal, subsequently increased in number to an inordinate extent, we are justified in regarding them as instances of transition from the one affection to the other, and in assuming a close relation between them.

Fleischer and Penzoldt[2] hold that there are cases of lymphatic pseudoleukæmia which represent the initial stages (*vorstufen*) of a genuine lymphatic leukæmia, and report one in which the transition from the former to the latter was demonstrated. The patient was a male, æt. forty-two, who presented extensive glandular swellings in the neck on both sides and in the left axilla, which slowly enlarged while the condition of the patient became gradually worse. The blood was repeatedly examined, but it was not until about fourteen days before death—*i. e.*, nearly a year after the first blood examination—that the proportion of white cells to red had increased to such an extent (1 : 9) as to warrant the diagnosis leukæmia.

[1] Philadelphia Medical Times, Feb. 1, 1889.

[2] Deutsche Archiv für klinische Medizin, B. 26, 1880, S. 368.

Mosler[1] reports a case of pseudoleukæmia (Hodgkin's disease) in a boy, fourteen years old, who, when first seen, had enlarged glands in both axillæ, both supra-clavicular regions, and in the cervical and infra-maxillary regions. Neither spleen nor liver was enlarged at first, and there was no increase in the number of white corpuscles. There was moderate fever. The disease, under treatment by arsenical injections into the glands, came to a standstill for sixteen days, the examination of the blood still giving a negative result, so far as concerns the number of the white cells. The patient then returned home. Eight days later severe fever set in; the existing glandular tumors enlarged and new ones made their appearance. It also became evident, on physical examination, that the spleen and liver were decidedly enlarged. On microscopic examination the white corpuscles were now found to be increased in number to such an extent that Mosler estimated them to be equal to the red. The case ran the usual fatal course of leukæmia, but was unusually acute, its whole duration being less than two months. Mosler concludes that too sharp a distinction has been hitherto made between so-called pseudoleukæmia and leukæmia, notwithstanding the fact that this is the first case, in his large experience, in which he had observed a transition from the former to the latter affection.

The rarity of such observations as the above is undoubtedly great, but, according to Fleischer and Penzoldt, may be explained in three ways: 1. The transition is overlooked because the blood is not examined with sufficient frequency. 2. A certain time must elapse before the transition is accomplished, and death generally occurs during the pseudoleukæmic stage. For example, in Fleischer and Penzoldt's case the stage of leukæmia was not reached until eight months after the first examination of the blood, and, therefore, if death had occurred from any accident or complication within that period, the case would have been reported as one of pseudoleukæmia. 3. There may be cases of multiple lymphatic tumors which have no relation whatever to leukæmia, but belong to an entirely different species.

As a rule, there is no absolute increase in the number of circulating leucocytes in Hodgkin's disease, and, as just stated, instances of transition from this affection to leukæmia are rarely observed, but cases are not so uncommon in which the number of the white cells, while greater than under normal circumstances, is scarcely great enough to warrant the diagnosis of leucocythæmia. Laache[2] reports such a case—one in which the blood was repeatedly examined—the proportion of white to red corpus-

[1] Virchow's Archiv, Bd. 114, 1888, S. 461.

[2] Die Anämie, p. 273.

cles varying between 1 : 70, the highest point, and 1 : 339, the lowest.

I am inclined to regard an excess of white cells in the blood as the expression of a form of defective hæmogenesis which may be the terminal stage of any profound anæmia. In Fleischer and Penzoldt's case, leucocythæmia did not set in until fourteen days before death. In a case of pernicious anæmia reported by Litten,[1] the blood, previously without an excess of white cells, was found to be leukæmic (1 : 15) four days before death, and this condition continued to increase until the day before death, when the proportion of white cells to red was as one to four. In a case reported as pernicious anæmia by J. H. Musser,[2] the term leucocythæmia would, at one stage, have been more appropriate, for the white cells were to the red about as one to four. I recently examined the blood of a profoundly anæmic patient at the time of her admission to the Philadelphia Hospital—two days before her death—and found such an enormous increase in the leucocytes that, at the autopsy, which revealed a large perinephritic abscess, I made a careful, though fruitless, search for some communication between the abscess and a venous trunk. The woman had been in the hospital a short time before, in another ward, and had been regarded as a case of pernicious anæmia. The leucocythæmia was undoubtedly a late manifestation of her cachectic condition.

The foregoing facts lead me to accept the first and fourth conclusions of a paper on the "Relations of Leucocythæmia and Pseudoleukæmia," published many years ago by H. C. Wood:[3]

"1. Clinically, the so-called true and false leukæmia are the same, save only in the matter of the white blood-corpuscles. 4. There are cases which, at one period of their course, represent pseudoleukæmia; at another, leukæmia."

I am also inclined to agree with the opinion of Pepper,[4] in so far as it applies to leucocythæmia and Hodgkin's disease, that

"a condition so inconstant and irregular as the increase in the proportion of white corpuscles should not be made a ground of distinction between groups of cases identical in all other respects."

In this paper I have endeavored to confine myself strictly to the question of the relations of these various forms of anæmia, avoiding, as far as possible, any discussion of their nature. All the time at my disposal would have been occupied in the attempt to enumerate and criticise the different views concerning the pathogeny of leucocythæmia alone.

I have tried to impart and illustrate my belief that the circumstances under which chlorosis and pernicious anæmia arise are so numerous and diverse as to forbid our regarding them as independent diseases. They are, in my opinion, neither more nor less than closely related processes of defective hæmogenesis.

Leucocythæmia and Hodgkin's disease, in that they are always associated with lesions of the blood-making organs—spleen, lymph-glands, bone-marrow, etc.—are independent diseases, or, rather, different stages of the same disease, for such cases as those of Fleischer and Penzoldt, and Mosler, prove their relations to be of the most intimate nature. They also show the fallacy of the view that the local glandular affections of leukæmia are secondary to the accumulation of leucocytes in the blood.

ABSCESS OF LIVER; OPERATION; DEATH; AUTOPSY.

By W. W. TOMPKINS, M.D.,
of Charleston, West Virginia.

H. T. W., aged forty years, American. Good family history; always enjoyed good health up to fourteen months ago. May 16, 1888, was injured by a boiler explosion on a steamboat, of which he was captain.

Mr. W. was near the boiler at the time of the explosion, and was blown into the river. He was cut across the forehead, scalded about the face and neck, and received a bruise on the right side just below the ribs. He never lost consciousness, but was carried home, where he remained for several days under medical care, and was then again up and about.

The personal injuries he received, the loss of property, and an apprehension that he would be held indirectly responsible for the mischief resulting from the explosion, all tended to depress him and make him more ready to succumb to disease. After recovering from his injuries he spent a week at home and then felt well enough to attend to business.

A large portion of the subsequent history of this case I have obtained from Dr. J. F. Wilcox, his physician.

After the first week's confinement at home, immediately after being injured, he sought a physician on November 24, 1888, and was confined to the house until December 6, 1888. His symptoms at this time were *malaise*, high temperature, diarrhœa, and pain in right side. He improved after this attack, and gained eighteen pounds in the next month or so; and was about and able to attend to his business, but a diarrhœa kept up all the time which weakened him and reduced him.

He soon showed very great emaciation, loss of strength and flesh, and had a dark olive color.

After this sickness he never engaged in business, but would move about, suffering constantly from diarrhœa and pain in the side, a gradual loss of flesh and strength constantly taking place.

At the time of his first illness he weighed 190 pounds, and at the time of his death, which took

place July 10, 1889, his weight was not over 90 or 100 pounds. His last sickness dates from June 12, 1889, when he took to his bed. At this time a tumor had formed under the ribs of the right side, and continued to grow downward and project forward, the patient constantly growing weaker and more emaciated. Appetite was poor, high fever existed and often chills, also a diarrhœa that was constant and that did not improve under treatment.

I was called by Dr. Wilcox, and saw him June 23, 1889. At this time the tumor extended from the lower border of the fifth rib on the right side to the crest of the ileum, and laterally to the middle axillary line. To the hand it felt hard, and all over this space dulness, or, more correctly, flatness, was found on percussion. At this time his temperature ranged from 101° to 104° F.; sweating was free; tongue furred; considerable dyspnœa; slight headache; and pain in side and over tumor, not acute, but with a sensation of fulness, as if the part was stretched over something.

A red spot as large as a silver quarter was found below the free border of the ribs, the skin was smooth and glossy. Dr. Wilcox had made a puncture in this spot the day before I saw him, and obtained a few drops of pus. On this and the history with the physical characteristics we diagnosed abscess of the liver. An incision about one inch in length was made through this spot and three pints of pus were evacuated. The swelling now in a large measure diminished, the temperature became normal, the pulse reduced in frequency, and the patient spent a comfortable night, the first for a week or ten days.

This abscess cavity was washed out two or three times a day with warm water in which some antiseptic was dissolved. A large quantity of water being used until the water that returned was perfectly clear.

After a period of four days the tumor was observed to grow larger near the median line, and the skin became red and showed indications of pointing as it had before. An incision was made here of an inch or an inch and a quarter. A quart of pus was evacuated, and again the patient became better and spent a good night. This last operation was on June 29th. From the 23d up to this time the first opening had continued to discharge freely, and after the second opening it, as well as the latter, would discharge pus whenever patient coughed or changed his position or would take a deep inspiration.

After this the patient became much troubled with vomiting; would vomit mucus and portions of liquid food; diarrhœa was constant, and did not yield to treatment. July 1st vomited pus, and also passed pus per rectum. The abscesses at first were separate, but, a week before death, water injected into one opening would come out the other. Portions of liver tissue would float into the mouth of the wound or into the drainage-tubes and occlude them, causing the patient to feel worse; they would then be removed and cleansed, and when the pus flowed freely he always felt better. The passing of pus by rectum and the vomiting showed perforation, and when the abscess-cavity was washed out the injected fluid would be passed in the same way.

July 8. Vomited and passed by rectum a quantity of foul-smelling, gangrenous matter. This was very abundant, and the smell was so offensive that the physicians and nurses could not stay in the room without being nauseated. This continued with but slight cessation up to the time of his death.

The patient's mind was never confused or clouded. He always took a cheerful view of the situation, and thought, up to within twenty-four hours of his death, that he would recover.

Autopsy, two hours after his death, conducted by Dr. J. F. Wilcox, assisted by Dr. L. Cox and myself. There were observed great emaciation and an entire absence of *rigor mortis*. A large cavity was found in the right lobe of the liver; this cavity would hold upward of three pints of fluid; it was partially divided by a partition. The liver was soft, and the hand readily broke through into the cavity when the fingers were placed above the liver and slight pressure made. An adhesion was found with an opening into the transverse colon; also an adhesion and opening into the duodenum. The gall-bladder was normal in size, but lower than it should be, and, when cut open, contained thirty-six gall-stones, one of which was larger than a pigeon's egg, and weighed 139 grains; the others were small, and collectively weighed 76 grains. There was an absence of fat in the abdominal wall as well as in the cavity. All the internal viscera looked pale and poorly nourished.

REMARKS.—Whether the explosion caused a bruise of the liver tissue, and an abscess followed, or whether the depressed condition with the diarrhœa and the abscess caused an embolus, we cannot say.

However, it is true he was never well after the injury. A portion of the time he kept up and did not consult a physician, but nevertheless felt depressed and reduced, and had a persistent diarrhœa. The pain over and about the liver was never acute, but there was a feeling of fulness and heaviness there. The thought that gall-stones might exist occurred to us, but we could never find them, although they were sought for.

The temperature was observed to fall to a few degrees below normal at the time of the vomiting of gangrenous matter, and continued so until the death of the patient.

ON RECOVERY IN CIRRHOSIS OF THE LIVER AFTER REPEATED ASPIRATION.

BY RICHARD LEA MACDONALD, B.A., M.D.,
PROFESSOR OF CLINICAL MEDICINE IN MCGILL UNIVERSITY; PHYSICIAN TO THE MONTREAL GENERAL HOSPITAL.

DURING the last few years professional opinion has undergone a change regarding the curability of cases of advanced cirrhosis of the liver, cases where the morbid process had gone so far as to cause obstruction to the course of the circulation in the por-

tal system and ascites. Most text-books give a very gloomy prognosis in this affection, one before me going even so far as to say that it is rare for a patient suffering from cirrhosis of the liver to live longer than a twelve-month after the symptoms have become so pronounced as to allow a diagnosis to be made. I have not been able to find any allusion to the class of cases that are benefited by repeated aspiration, and, so far as I know, no authority on the subject, with the exception of Flint, has laid sufficient emphasis upon the undoubted occurrence of recovery in cirrhosis of the liver, even when in an advanced stage.

Two years ago the Editor of The Medical News drew the attention of his readers to a case which I had brought before the Medico-Chirurgical Society of Montreal, where, after repeated aspirations, the fluid ceased to accumulate in the peritoneum. The patient had been admitted in August, 1885, into the Montreal General Hospital with a history of alcoholic dyspepsia followed by accumulation of fluid in the peritoneum. Sixteen months afterward I was able to report that, after sixty tappings and the removal of about nine thousand ounces, no fresh accumulation had taken place and the restoration to health was complete. Four years have gone by and I am now able to state that the patient's general health still remains good, and that there is no return of the dyspepsia. There is no doubt in my mind that the explanation of the successful result in such cases lies in the fact that the removal of fluid-pressure favors the establishment of a collateral circulation. Our anatomy teaches us that there are more ways than one by which the blood can make its way from the intestines to the liver. In fact, there are many cases on record where these by-paths have been found extensively enlarged.

If the condition of the original disease is stationary, then there is every prospect of a good recovery. Since the publication of my first case, a second one has fallen in my way. Here the result was equally satisfactory. I report the case in somewhat greater detail.

In the beginning of May, 1888, I was asked to visit a man reported to be dying of dropsy. Being unable to go that afternoon, my friend, Dr. H. Lafleur, undertook the visit and found the patient to be a butcher, aged forty-eight, who had been suffering from extreme ascites and was now in a condition of dangerous dyspnœa. A tapping with an ordinary trocar gave temporary relief with the removal of two bucketsful of serum. Two days later the abdomen was as full as ever and I tapped him myself. On the 14th of May, 1888, he was admitted into my wards of the Montreal General Hospital and it was noted in the records that he was suffering from great abdominal enlargement, dyspnœa, pain in the flanks, shooting pain in the abdomen, and a difficulty in passing urine. The patient had been all his life a butcher, and for many years had been intemperate in the daily use of the stronger kinds of spirits. When he was a boy he had had smallpox, but he has not suffered from any other serious illness. In 1886 he had an attack of jaundice with enlargement of the belly, but both disappeared after a few days. Not long afterward he began to suffer from hemorrhoids and has done so more or less ever since. In the summer of 1887 constipation and dyspeptic symptoms were troublesome and he felt very much out of health. The abdominal enlargement made itself perceptible in October, 1887, but he did not abandon his daily work until January, 1888. The first tapping took place on the 30th of March, 1888. Previously to his admission to the hospital the amount of fluid withdrawn was 3840 ounces. At the time that the abdomen first began to become distended there was jaundice which disappeared in a few days. The eyes and face, however, have remained somewhat yellow ever since. The feet have been swollen.

There is a possibility of a syphilitic taint in the family, since a large number of his brothers and sisters died in very early infancy.

On admission there was slight jaundice. Emaciation has been rapid. He weighs 142 pounds with the abdomen empty, whereas formerly he weighed much more. Appetite poor; bowels regular; urine scanty, high colored, loaded with lithates; no albumin or sugar. Abdomen is greatly distended. Girth at the umbilicus is forty-four inches; slight œdema of the feet and legs. Pulse 98, strong, and regular. Complains of the annoyance of hemorrhoids. When the abdomen is relaxed after withdrawal of the fluid, it can be shown that the liver is small, the hepatic dulness measuring but three and a half inches in the right mammary line. The apex of the heart is displaced upward by the accumulated fluid and beats in the fourth space, above the nipple. The extent of cardiac dulness is not readily mapped out. The sounds are normal. Physical signs of the lungs negative.

The patient remained in the wards until the 23d of June, and during that period was tapped six times, 1650 ounces being removed. During the rest of that summer he returned at intervals and was aspirated by members of the resident staff. I found records of three such operations, by which 910 additional ounces were withdrawn. The period between taps was now perceptibly lengthening. There were four taps in June and but two in July. After this period there is no more mention of the case in the hospital case-book. I was obliged myself to be absent from my practice for one year from the 20th of June, 1888. On resuming work in July last, I hunted up this interesting patient, whom I was surprised to find alive. After my absence he returned to his work at the butcher's stall, and put in an appearance at the Montreal General Hospital whenever the fluid became uncomfortably copious. At first it was necessary to have it removed every third week, about 200 ounces being withdrawn. There were six tappings between July 1st and November 1st. In November and December, 1888, and Jan-

uary, 1889, there was no reaccumulation, but in February last 300 ounces were withdrawn. There were but three tappings between February and May, each of about 200 ounces. Since then no fluid has appeared.

August 14, 1889. L. G. sent for me to-day to relieve an attack of vomiting and diarrhœa. For the last thirteen months, in spite of the ascites, he has been able to earn his living. He has wholly given up dram-drinking. He has felt well and strong, eaten ordinary diet, but still suffers from slight nausea and loss of appetite in the morning. According to his own record, aspiration has been performed thirty-one times, and according to my estimate no less than 8600 to 9000 ounces have been removed.

Is the patient cured? It is hard to say that any case is cured, but here was a man on the point of death from a disease well known as being commonly deadly in its effects, who, after submitting to a certain line of treatment, loses sight altogether of a most dangerous symptom, and rapidly recovers health and strength. There is no fluid whatever in the abdomen now. I examined the belly carefully on the 14th of August, 1889, and again on the 11th of September, 1889. It appears to be large, but it measures but thirty-five inches at the umbilicus. The flaccidity depends upon past distention.

In the month of August a curious train of symptoms set in, from which the patient nearly died. He was attended by Dr. W. G. Stewart, of Courville Street, Montreal, who kindly furnished me with the notes. The patient suddenly fell into a semi-unconscious condition. The tongue was thickly coated, and the stomach so irritable that nothing could be retained. There had previously been severe diarrhœa. On the following day the unconsciousness was complete. Pupils dilated. Urine passed involuntarily. On the 18th of August there was improvement, though the patient was still drowsy. In a few days he was up and at his business.

I cannot give any explanation of this attack, except that possibly it may have been caused by opium or some other substance given by mistake for bismuth powders. The symptoms set in immediately after the taking of the powders, and improvement began as soon as they were discontinued.

At the present date the patient is well and can be seen at work every day at an open stall in the St. Lawrence Market.

The conditions necessary to results such as these are the following:

1. The patient must be young, so that the vessels should be in a condition to enlarge under pressure and accommodate themselves to the altered state of the circulation. Both my patients were under fifty—the woman thirty-five and the man forty-eight. But both were younger-looking than their age.

2. There must be no other dangerous symptom present. Ascites must be the one and only morbid manifestation. Heart, lungs, and kidneys must be quite sound, and there must be no other dangerous result of portal obstruction.

3. In all cases where such good results are obtained ascites is a very early symptom, and relief is sought for at an early stage of the morbid process. There is a chance of the disease coming to a stop when the cause is removed. When a patient finds himself getting dropsical, and is told that drink is the cause, he is not likely to keep up his bad habits.

As to the particular method by which paracentesis was carried out, there is nothing to be said beyond that I think it important that the very smallest aspirator needle should be used, and that no attempt should ever be made to empty the peritoneum. Enough should be withdrawn to relieve dyspnœa and to make the patient feel comfortable. No medicinal or dietetic treatment was attempted in either case. The patients lived in the outskirts of the town, and while under treatment were often not seen for months at a time.

NEURECTOMY FOR FACIAL NEURALGIA.

BY E. M. MAGRUDER, M.D.,
INSTRUCTOR IN CLINICAL MEDICINE, UNIVERSITY OF VIRGINIA.

THE following cases in which neurectomy was performed for obstinate facial neuralgia may be of sufficient interest to be worthy of record:

CASE I.—Dr. ——, aged seventy-one; family history good so far as known; personal history also good, except that during the '60's his left foot became inflamed about the tarso-metatarsal junction without apparent cause, suppurated and discharged, preventing much locomotion for several years, with perfect ultimate recovery; no history of dead bone.

In 1875 (fourteen years ago) he began to suffer in the region corresponding to the distribution of the right supra-orbital nerve, but in a few months the seat of trouble was transferred to the infra-orbital and its distribution, and from this time on, the latter nerve and its branches were involved in frightful neuralgia, the former (supra-orbital) being affected only reflexly and during the most violent attacks. These attacks were characterized by paroxysms, with intervals of a few minutes or hours between, and which lasted at first several weeks or months, and would be followed by equal periods of almost entire relief. Gradually, however, the duration of suffering grew longer and time of respite shorter, until latterly not a day, hardly an hour, passed without excruciating torture, the pains being of a shooting, darting, electrical character; the slightest touch to the cheek or motion of the lips and jaws, as in eating, drinking, or talking, was sufficient to cause agony, the patient comparing his sensations to successive red-hot flashes of lightning through the tissues. There were also great tenderness on pressure and considerable swelling between the orbit and margin of the lip.

The patient had had malaria, but not since he was ten years old. No other cause, predisposing or exciting, could ever be traced, all the internal organs being apparently in a normal condition. He had been troubled, however, for some time with a chronic post-nasal and pharyngeal catarrh.

In the absence of any assignable cause, I made the diagnosis of peripheral neuritis, based upon the swelling, tenderness on pressure along the course of the nerve and its branches, and the superficial character of the pain.

The patient first came under my observation and care in the autumn of 1885, after ten years of suffering. Every known anti-neuralgic remedy, both internal and external, had been tried with only occasional relief. During the fall of 1886, I advised a resort to surgery as offering the only hope—though by no means a certain one—of permanent relief. The patient declined, and went to Philadelphia to consult a specialist of that city. The latter discouraged operation on the ground of its being a *dernier ressort* and uncalled for by the case in question. He prescribed iron, rest, and a visit to the seashore. This treatment was carried out, with considerable improvement, for about one year. Then the old enemy returned, reinforced, and waxed stronger and stronger, entirely incapacitating the patient for business, confining him to the house for months at a time, preventing sleep, and interfering with the taking of nourishment. All this, of course, resulted in debility, prostration, depression of spirits, and anæmia. The fluid extract of gelsemium in the dose of from seven to ten drops every three hours gave greater comfort than anything else, except morphine. Finally, even this failed in its action, and tolerance for larger and larger doses of the drug was manifested. This being the case, I again strongly advised neurectomy of the infra-orbital nerve and its branches. Consent was obtained, and I operated on June 11, 1889.

Thorough antiseptis was observed throughout, the solutions used being carbolic acid (1:30) for the instruments and corrosive sublimate (1:2000) for the person of the patient.

The patient having previously received whiskey by the mouth and atropine sulphate (gr. $\frac{1}{100}$) hypodermatically, was placed upon a table before a large window and thoroughly anæsthetized with Squibb's chloroform. The anæsthetic was well borne. I made an incision through the skin, beginning just below the lower orbital margin over the infra-orbital foramen straight downward parallel with the nose toward the lip, and ending on a level with the lower border of the ala nasi, the whole length of incision being about one inch. Then with the handle of the scalpel the fascia and fibres of the levator labii superioris were torn through and the nerve exposed at its exit, lying beneath the latter muscle and dividing into its branches, the *palpebral* running upward into the lower eyelid, the *nasal* turning inward to the nose, and the *labial* continuing downward into the lip. Each branch, spreading into a fan-shape as it neared its destination, was dissected out as far as it could be followed without mutilating the face too much. The main trunk was then seized with forceps at the foramen, drawn out as far as possible without breaking it, and cut off close to the bone, after which the various branches were divided at their farthest point of dissection. Hemorrhage was not troublesome.

The wound was cleansed with bichloride solution (1:2000), and the edges brought together with three fine silk sutures. A dry bichloride dressing was now applied and kept in place by a head-bandage.

At first considerable motor and sensory paralysis was present, but this disappeared in a fortnight, save that the right half of the upper lip still remains without motion and sensation.

The dressings and sutures were removed on the sixth day, at which time the wound was found looking well and entirely healed, without suppuration, and the wound was left uncovered. Five days later, however, distinct fluctuation was perceptible in the cicatrix, and, on a puncture being made at the upper and lower ends of the incision, about one drachm of pus was discharged. A corrosive sublimate solution (1:2000) was then injected through the pus cavity and a second dressing put on. This process was repeated two or three times until, at the end of about a week, the discharge ceased and thorough cicatrization took place.

The result of the operation was and is all that could be desired—that is, *perfect relief* from the neuralgia. The patient is now comfortable and happy, with a good appetite, which can be indulged without difficulty; sleeps well, and has gained twelve pounds in three months. He looks and feels like a new man.

Case II.—Miss ——, aged fifty-eight; father died of Bright's disease; paternal grandparents, three uncles, and two aunts died dropsical; mother died of some spinal affection. Personal history: When three or four years old patient was also dropsical (cause not known), after which health was good until she was eighteen years of age: then she passed through an attack of typhoid fever, which left her dyspeptic; but the dyspepsia has become better in the last few years.

At the age of forty-eight patient felt a slipping at the hinge of the jaw on the left side (left temporo-maxillary articulation), soon changing into *pain and tenderness on pressure*. The pain and tenderness proceeded downward and forward along the ramus and body of the inferior maxilla, corresponding to the course taken by the inferior dental nerve. At first the trouble was entirely confined to the lower jaw, but in the course of time gradually extended to the left half of the tongue, left side of the floor of the mouth, and to the left external ear, left temple, and left side of the head. There was also great tenderness, on pressure, in all of these localities, but no swelling. Attacks would occur in series of paroxysms, lasting for weeks, followed by intervals of freedom from pain, with continual lengthening of the attacks and shortening of the time of comfort. During the last three years not a day, and in the past few months not a half hour, has elapsed without agonizing torture, the most violent paroxysms being excited by the slightest touch or motion of the jaws, as in talking, mastication, swallowing, and also without any exciting cause. I have seen her during a short conversation of fifteen minutes compelled to stop several times, clasp the face with both hands, and almost cry out in the intensity of agony. As a result of her inability to take food she became thin and anæmic.

No positive cause could be discovered. There

was no history of malaria, and all the organs seemed sound. The teeth on the affected side of the lower jaw are intact; the molars have been extracted.

After exhausting the virtues of various medicinal agents, the patient came to Charlottesville to consult me in August of this year. She came prepared to submit to *any* treatment that offered prospect of relief. I kept her under observation for a week, trying different analgesics, such as quinine, antifebrin, phenacetine, and gelsemium, without benefit. Finally, I advised total extirpation of the inferior dental nerve, including its branches, and, with her consent, performed the operation August 10, 1889.

The same technique regarding antiseptic toilet of patient, hands, and instruments was observed as in Case I., the solutions being of the same kind and almost the same strength. Likewise, whiskey and hypodermatics of atropine sulphate gr. $\frac{1}{180}$ were administered beforehand, with chloroform as the anæsthetic, which was well borne.

The parts which may be injured in this operation are: 1. *The facial artery* lying one inch in front of the angle of the lower jaw, at the anterior border of the masseter muscle. 2. *Steno's duct*, which passes from behind forward one finger's-breadth below the zygoma, and corresponding to a straight line drawn from the lower portion of the concha forward to a point midway between the ala nasi and margin of the upper lip.

I began the incision a little in front of the posterior border of the ramus, just below the level of the lobe of the ear and parotid duct, and made a curvilinear incision curving *downward* half an inch in front of the inferior maxillary angle, *forward* a little above the lower border of the jaw, and *upward* just behind and avoiding the facial artery, stopping short of the line of Steno's duct *above*. The two ends of the incision were about one and three-eighths inches apart. This flap was then raised by shoving the masseter muscle from its attachment to the outer surface of the ramus, and the bone laid bare. With a five-eighths inch trephine (half-inch would have been better) a button of bone was cut from the centre of the outer plate of the ramus and raised with a bone elevator, showing the nerve lying in its bony canal. The proximal end of the nerve being seized with forceps, and strong traction made from the direction of its origin, it was cut off with scissors close to the bone as it entered the circular cavity made by the trephine. Then, the wound being stuffed with moist antiseptic cotton and pressure employed to check the hemorrhage, a second incision was made, one inch long, horizontal in direction, over the mental foramen, through skin, fascia, and depressor anguli oris, disclosing the mental nerve (one of the terminal branches of the inferior dental) and its branches lying beneath the last-named muscle. The nerve was grasped with forceps and pulled upon, but broke off at its point of exit. The branches were then dissected out and cut off as far as possible from the foramen.

Returning to the first wound over the ramus, and chiselling away the wall of the dental canal for an eighth of an inch from the circular cavity in the ramus, so as to expose this end of the nerve, which had been divided by the distal side of the trephine, with forceps it was drawn out its entire length from the ramus to the mental foramen. In all, three and three-eighths inches of nerve-structure were removed.

The wounds were thoroughly cleansed with the bichloride douche, the solution passing from one end to the other through the bony canal, the edges brought together with fine silk sutures, six in the larger and two in the smaller, and a dry antiseptic bichloride-cotton dressing applied and held in place by a head bandage.

Hemorrhage gave no trouble, and no arteries were ligated. The inferior dental artery was cut at the same time as the nerve, the two being very close together, but soon ceased bleeding on pressure.

The sutures were removed on the eighth day, at which time the wounds had entirely healed without one drop of pus, nor was there any suppuration afterward. A second light dressing was put on and retained four days longer to give the stitch-holes time to close, infection through them being thus prevented. At the end of this time everything was taken off, and the patient discharged *perfectly relieved*, nor has the neuralgia returned since.

The day after the operation there was a very disagreeable odor about the breath, probably due to irritation and disordered secretion of the parotid gland. This entirely disappeared in three or four days.

Considerable motor paralysis was apparent on the left side of the face and lower lip, the muscles being much relaxed, and the whole face on that side presenting a swollen, expressionless appearance, caused by section of the branches of the facial nerve. This also passed away in about two weeks.

The patient is now able to converse, masticate, swallow, and sleep in perfect comfort, and is prepared to enter upon the enjoyment of life, from which she has been painfully debarred for so long.

OBSERVATIONS.—(*a*) The first operation demonstrated the risk of infection from leaving stitch-holes exposed after withdrawal of the suture; so I consider it best to use antiseptic catgut ligatures and sutures in these operations, as that material, becoming quickly absorbed, will obviate the necessity of the second dressing demanded to protect the needle punctures until their closure after withdrawing the silk.

(*b*) In the second operation the difficulty, probable impossibility, of drawing the inferior dental nerve forward through the mental foramen, even though divided in the ramus, was shown. This is due no doubt to the larger size of the nerve trunk as you follow it backward toward the brain and to the points of attachment formed by the dental and incisor branches, as well as to the fact that the direction of the mental foramen is *backward* and outward from the dental canal, forming thus an *angle* with the latter.

(*c*) In trephining the ramus, it will be found that the trephine very quickly and easily passes through the outer plate of bone, necessitating great care

to avoid dividing the nerve. Should this occur, however, no harm would be done.

(*d*) When neurectomy is performed for facial neuralgia, it may sometimes be possible to remove all the affected portion of nerve, in which case there would probably be no return of the trouble. But more often the disease may be still lurking in the peripheral part left behind; under these circumstances recurrence is possible by a reformation of nerve tissue at the point of removal, so that painful sensations may be transmitted as before; the greater the gap made by excision the less danger of recurrence.

Likewise, there may be a remnant of the malady in the proximal stump, which may act as a focus for the radiation of pain. Hence, I think that in all operations for facial neuralgia the rule should be to remove as much of the troublesome nerve and its branches as the anatomical formation of the parts will possibly allow without rendering the procedure too grave; as there is no infallible means known to science of distinguishing between healthy and unhealthy nerve when lying *in situ*, the surgeon should not be afraid of removing too much tissue.

(*e*) Before the proximal section is effected, strong traction should always be made from the great nervous centre, since the stretching thus imparted exposes more to the knife, and may also be beneficial should the stump, which is beyond reach, be diseased.

(*f*) I do not believe, from my limited experience, that this operation favors the occurrence of neuralgia in other nerves not previously affected. Predisposition to it may exist as before, and the disease may appear elsewhere, but the danger is not increased by the operative process.

Neither of the above cases has had any recurrence, and, indeed, it is difficult to imagine how there could be, considering the large gap left in the sensory tract, unless the proximal stumps are in an abnormal state.

My thanks are due to Dr. H. T. Nelson, of this city, in both of these operations for his skilful administration of the anæsthetic.

THE CONSERVATIVE TREATMENT OF COMPOUND FRACTURES, WITH AN ILLUSTRATIVE CASE.[1]

By W. R. WHITEHEAD, M.D. (Paris),
CONSULTING SURGEON TO THE ARAPAHOE COUNTY HOSPITAL, DENVER, COLORADO.

The question of the conservation of a limb after a badly comminuted compound fracture is of interest to every doctor. Indeed, no general practitioner of medicine and surgery, either in the city or country, can escape responsibility in the management of such cases, when they fall to his lot, even should he summon to his aid those more skilled and experienced in the treatment of fractures.

There is nothing, in my opinion, that so thoroughly tests the practical sense and capability of a surgeon as the manner in which he manages a broken limb in which there are destruction of the soft parts and multiple fractures of the bone, complicated with an extensive external wound.

The recent and improved antiseptic treatment of all wounds gives additional interest to the result of these cases; because, provided certain physiological conditions are maintained, the question of amputation should not be considered.

When the general condition of a patient, after a bad compound fracture, is fairly good, and the main artery, vein, or nerve is not injured, then the question is generally thought to be of easy solution in favor of an attempt to save the limb. But sometimes this is not the case; and it should not be forgotten that, in such cases, the physical condition of the patient, if previously healthy and robust, is not the only factor to be considered in forming a decision as to how to manage a bad compound fracture. The will-power, courage, self-control, and endurance of the individual count for a great deal in aiding the surgeon in proper efforts at treatment.

In timid and apprehensive people, who are irresolute and faint-hearted, a quick amputation, done under ether, and after the most scrupulously exact aseptic rules, will save life, whereas long-continued conservatism, resulting in repeated counter-openings and many painful dressings, is more apt to prove fatal. Such are some of the considerations to influence the question of amputation with a prudent surgeon.

When conservative treatment is decided upon, much depends on the judicious local management and general treatment of a bad compound fracture.

It can be truly said that we cannot establish rigid rules for the treatment of fractures, which will serve as a guide.

As it is my object to be brief in my remarks, and to give practical illustrations, I have selected the following case of railroad injury to present to the Society as an example of a good result, after a very bad compound fracture of the thigh, accompanied with a crushing injury of the foot of the opposite side, and which required amputation after Pirogoff's method.

This patient is present for your inspection, and can answer questions concerning his present condition.

Charles Folkard, aged thirty-one years, on July 10, 1888, sixty or eighty miles from Denver, fell under the wheels of a freight train while in motion and had his right foot crushed close up to the ankle-joint, and his left femur broken in half a dozen or more fragments just above the knee-joint. The

[1] Read before the Colorado State Medical Society, June 18, 1889.

rectus femoris muscle was ruptured, its ruptured ends crushed, the skin covering it was rudely torn and contused, and a fragment of bone projected slightly outward, through the external wound.

Both the wounds of the foot and thigh were covered with dirt and clotted blood, and had been exposed to the air during fifteen or eighteen hours previous to his arrival at Denver at the Arapahoe County Hospital. I saw him soon after his arrival at the request of Dr. McLaughlin, the attending physician of the hospital, who, with others, assisted me in the amputation of the foot and the dressing and splinting of the opposite fractured thigh. This cut, taken from a photograph of him, shows his present condition.

The wounds were thoroughly irrigated with a mercuric chloride solution and wrapped with cloths saturated with the same, before operative interference was attempted, with the hope of lessening the inevitable septic infection which would follow the amputation of the foot.

For the first two or three days the temperature was 101° to 102°; on the third day it ran up to 103.5° F., and the removal of the dressing discovered a superficial gangrene not only of the amputation wound, but also of the wound at the seat of the fractured femur. I should state that, after the Pirogoff amputation had been dressed, six or eight pieces of bone were detached and removed from the broken femur. To do this the wound was sufficiently enlarged. and large counter-openings made for drainage. All the crushed muscle was cut away with curved scissors and knife. On opening the wounds on the third day they were covered with soft pultaceous and gangrenous masses; but the general condition of the patient was encouraging, and he was not depressed. I have seen cases after amputation presenting this appearance and in which I used formerly to apply creasote, and afterward a strong solution of carbolic acid, and I have seen this pultaceous, gangrenous coating of a wound clean off nicely in a few days under the use of such applications. So after cutting away with curved scissors most of the gangrenous surfaces, I mopped the parts with a concentrated solution of carbolic acid, then irrigated them thoroughly, and poured balsam of Peru liberally into the wounds, applied oakum, and completed the dressings. Tincture of muriate of iron in fifteen-drop doses, every three hours, and brandy and liquid nourishment were freely given.

The patient progressed favorably toward cure. After a few months a piece of dead bone was removed by incision, and the sharp spoon or curette was freely used.

To-day this man is a living example of what may be accomplished by an intelligent resort to free and bold incision to favor drainage, and to the liberal use of balsam of Peru to stimulate granulations.

SOUTHERN CALIFORNIA AS A WINTER RESORT.

BY HENRY C. ALLEN, M.D.,
OF LOS ANGELES, CAL.

To those persons who suffer from pulmonary complaints, or are otherwise in delicate health, the climate of the Eastern States is most trying, and too frequently fatal. Extremes of atmospheric conditions and radical changes of temperature succeed each other with a rapidity which is a source of danger to even the healthy and robust.

As winter approaches, physicians begin to consider where to send their more delicate patients to escape the rigor of an Eastern climate, and it is not always an easy matter to decide upon a locality which will not only secure immunity from actual danger, but at the same time prove beneficial and restorative to the patient.

There are very few places within reach that combine *both* of these desiderata. Colorado possesses some undeniable advantages, from a sanatory point of view, but its climate is subject to thermal changes almost as marked as in the New England States, and therefore not generally suitable to patients whose lungs are more or less affected.

Florida, as regards temperature, is recommended for its greater equability; but the sojourner in that section of the country is exposed to malarial influ-

ences, with all its febrile concomitants, and not infrequently to the scourge of yellow fever.

Nassau possesses many advantages for phthisical sufferers, but its deficient means of communication with the outside world has a tendency to give rise to a feeling of isolation from friends and loved ones at home, which is apt to detract greatly from that mental repose so necessary for the invalid.

The Catskills, the Adirondacks, and other mountain resorts are available only in the summer season, and can offer nothing but disadvantages at the period of the year when they are most needed.

Southern California is a region which possesses every desiderata that can be imagined for invalids. Its climate is wonderfully equable, the temperature varying few degrees above or below 70°; the greater portion of rainfall occurs at night, leaving the days clear and sunshiny. This peculiarity alone secures the advantages of out-door life, with an atmosphere abundantly supplied with ozone, so necessary and beneficial to the mind and body. The softly tempered sunshine is a perpetual tonic, and the bright and clear atmosphere inspirits and invigorates.

Therapeutically, the climatic conditions in Southern California are three-fold, combining in one region the choice of sea-coast, foot-hills, and mountains, each possessing its own distinctive advantages.

The coast extends from Santa Barbara to San Diego, both beautiful places and splendidly located. San Diego has the double advantage of being situated at the base of the foot-hills and also on the coast. The distance between these two places is about 300 miles, the intervening coast being diversified by attractive towns, affording constant change of scene and easy transit. These places are eminently favorable to invalids, as they are pervaded with a restful quiet, and at the same time offer pleasant social attractions.

Here, frost is extremely rare, and snow is unknown nearer than the highest peaks of the mountains. Day follows day of bright sunshine, never sultry, with a temperature varying very few degrees of daily, monthly, and yearly average.

Twelve out of the twenty-four hours can be daily spent out of doors, basking in the sun's rays, and inhaling the invigorating and health-giving ocean breeze, which is constant and regulated by the temperate waters from the coast of Japan.

This is a very paradise for the dyspeptic sufferer. The vitalizing effects of open-air life, and the great variety of food abundant at all seasons of the year, soon restore appetite and digestion to their normal condition.

Here, the weak or exhausted nervous system or over-taxed brain will soon respond to the tonic and bracing surrounding influences, with a result unattainable by drugs or artificial restoratives.

The foot-hills and the mountains offer the therapeutic conditions of dryness and atmospheric rarefaction in proportion to their distance inland, and their elevation above the sea level. These conditions are the most favorable for those suffering from malarial complications; the air is dry and pure, and the entire absence of dampness and night-dews precludes the deadly decomposition of organic matter; there is, therefore, nothing to promote malarial, remittent or intermittent fevers; on the contrary, every condition is favorable for the complete eradication of such diseases.

All these advantages of sea-coast and mountain are within easy reach of the beautiful city of Los Angeles. Along the foot-hills, from Pasadena to San Bernardino, numerous *sanitaria* are to be found, well appointed and pleasantly located; and the various mountain resorts, such as Arrowhead, Beaumont, Switzers, etc., offer health and comfort to all who visit them.

The scenery of Southern California is beautiful and ever varying; the air is exhilarating and invigorating. To those who need or desire it, there is ample opportunity for mountain-climbing with all its resultant benefits, expanding the chest, exciting respiration, increasing muscular vigor, and sending the blood bounding through the capillaries, giving tone to the system, firmness to the flesh, and health to the invalid, making the weak strong and the strong robust.

Suitable climate is a paramount necessity for invalids, but the accessory advantages of social surroundings are quite as important; in order to obtain the maximum benefit of climatic influences, mental repose and pleasant companions are indispensable. Many an invalid, who leaves home and friends to regain at some distant resort the health which is denied him among those who are dear to him, finds himself among strangers, from whom he fails to derive the sympathy and attention that his state of health requires; he becomes despondent, and returns home unbenefited and blaming the resort for his unimproved condition. To those who are unable to be accompanied by friends or relations in their search after health, the hospitality and social temperament which pervade Southern California generally will go very far to remove the sense of loneliness and consequent yearning after home that oppresses the mind and retards physical recuperation in most of the hygienic or sanatory resorts.

It is scarcely necessary to enumerate the special diseases for the cure or alleviation of which Southern California seems specially adaptable; the advantages of that region are so numerous, that profes-

sional men will have no difficulty in discrimination of locality, the variety and choice in that region being both varied and comprehensive. It is emphatically one of the most favored spots on earth for the delicate, the consumptive, the exhausted brain-worker, and all whose systems have become impaired either by insidious disease or overtaxed energies. In the cities and larger towns, scores of persons can be met whose condition, when they first arrived, was such that they could scarcely walk, but who are now able to live an active life, and are engaged in business pursuits.

MEDICAL PROGRESS.

Massage in Rickets.—DR. SILFVERSKIÖLD speaks very favorably of massage in the treatment of rachitis. He begins with the lower extremities, using considerable pressure in a direction from below upward, and making energetic passive movements of the ankle-, knee-, and hip-joints. He then passes to the abdomen, thorax, neck, and upper extremities, exciting increased respiratory movements by making pressure on the chest. Each *séance* lasts for from ten to fifteen minutes, and the treatment is continued through a period of from four to six weeks. At the beginning, the patient usually complains of pain during the manipulations, but this soon passes away. The author claims to have obtained excellent results in a number of cases.—*The Medical Record*, October 5, 1889.

A New Cardiac Remedy.—The alkaloid discovered in the common gorse, "whin," or furze, of Europe (*Ulex Europæa*), termed ulexine, is of a most powerful character. It appears to arrest all voluntary movements and reflexes by paralyzing the motor tract of the spinal cord and the trunks of the motor nerves. The heart muscle is paralyzed, though preliminary thereto there is an increase of arterial pressure. Further, it possesses a diuretic action similar to that of caffeine, but more definitely marked.—*The Medical Age*, September 25, 1889.

Treatment of Phthisical Night-sweats.—As one of the most unpleasant and, at the same time, most frequent symptoms of pulmonary phthisis is nocturnal sweating, the recommendation of DR. B. ALEXANDER, in the *Deutsche medicinische Wochenschrift*, September 12, 1889, that hypodermatic injections of the officinal camphorated oil be made in such cases seems worthy of note, particularly as he states that he has derived very encouraging results from it. We should think, in view of the fact that camphor is capable of acting very powerfully upon the human body in moderate amount, and is also locally irritant, that such treatment might not be entirely devoid of danger, although it may prove worthy of employment when care is exercised.

Treatment for Chronic Leg Ulcers.—DR. IVAN A. PRAXIN, of St. Petersburg, warmly recommends a simple method of treatment, successfully practised by him in atonic crural ulcers with sclerotized edges. The method consists in making multiple radiating incisions, penetrating through the whole thickness of the edge, and situated so that the inner third of each incision divides the granulating bottom of the ulcer, the middle one its edge, and the outer third the adjacent healthy skin. The distance between the incisions should be equal approximately to two or three breadths of the edge. To secure gaping, plugs should be inserted into each wound for a few days. When treated after this plan, callous ulcers, varying in size from a penny piece to a half of the palm, are said to heal as swiftly as any simple ulcer, provided their neighborhood is free from inflammatory œdema and venous congestion.—*Weekly Medical Review*, Sept. 28, 1889.

Ventro-fixation of the Uterus.—DR. THIRIAR publishes in *La Clinique* an instructive clinical lecture delivered to his class at the Hôpital St. Jean, Brussels, on Ventro-fixation for Prolapsus Uteri. The term he proposes to use for the operation is "hysteropexy," from ὑστερον (the uterus) and πηξις (fixation). The condition of the patient, an elderly woman, who had been suffering from complete prolapse for the last eight years, were such as to render all exploratory and operative procedures per vaginam difficult in the extreme, as she had ankylosis of the left hip, the thigh being fixed in an adducted position. There was a good deal of pain, and the uterus was visible on the outside of the vulva even when the patient was lying down. Pessaries had been tried, but were productive of no benefit. Under these circumstances it was determined to perform hysteropexy. The abdomen was opened in the linea alba between the symphysis and the umbilicus, and the uterus drawn forward and fixed to the lips of the wound by three points of strong catgut suture, an iodoform dressing being subsequently applied, which was renewed in a week's time. Seventeen days from the time of operation the wound was healed, and the uterus could be felt high up and firmly fixed, so that the patient might be considered cured. She was, however, kept in bed for three weeks longer, when the uterus, being still firmly fixed, she was allowed to get up. Unfortunately, a fortnight later the prolapsus returned, but no pain or dragging was felt. The only thing to be done was to give her a cup pessary and to discharge her as incurable. In his remarks upon the case Dr. Thiriar pointed out that the operation was a new one, and a good deal more experience was needed to determine the best method of performing it. He does not think Caneva's plan of cutting down to the peritoneum and suturing the parietal and visceral layers of peritoneum together a particularly practical one, as it prevents exploration for adhesions and removal of uterine appendages, if necessary. The plan adopted in this case was that of Leopold, except that catgut was substituted for silk, and no scraping of the epithelial layer of the peritoneum for the purpose of assisting the formation of adhesions was practised. The difficulty of fixing the uterus permanently to the abdominal wall is considerable. Müller, of Berne, who amputates the uterus and sutures the stump to the lips of the abdominal wound, has found the adhesions break down and the prolapsus recurs. Altogether Dr. Thiriar is not disposed to view hysteropexy with much favor—at all events when performed by itself—though he thinks there may be cases where the prolapsus is accompanied by hypertrophic elongation of the cervix, by rectocele or cystocele, where, as an adjunct to some other operative measure, it may

prove of value. He suggests that the chances of obtaining a permanent adhesion between the abdominal wall and the uterus would be increased by treating the uterus as Juffier treats the floating kidney—*i. e.*, by peeling off the peritoneum from a considerable surface, which is then sutured to the abdominal wall. A lesson which this case teaches is not to be in too great a hurry to publish results.—*The Lancet*, September 28, 1889.

Cocaine Poisoning.—Dr. Vinogradoff gives, in the *Ejenedêlnaya Klinicheskaya Gazeta*, an account of the post-mortem examination in a well-known and remarkable case of cocaine poisoning, where a young woman, who was suffering from a tuberculous rectal fistula, was given twenty-two grains of cocaine by means of repeated rectal injections in order to produce local anæsthesia for an operation which consisted in scraping the anterior wall of the rectum with a sharp spoon. In a quarter of an hour the patient became excited, and began to suffer from clonic spasms in the limbs, opisthotonos, and cyanosis. Death occurred from asphyxia, in spite of tracheotomy and prolonged performance of artificial respiration. At the post-mortem examination the blood was found to be fluid, and of a dark-brown color, as in cases of poisoning with chlorate of potash. There were hyperæmia of the brain and of the lungs, exudative glomerulonephritis, evidently of long standing, together with ulceration of the colon and rectum, reaching down to the submucous tissue. Microscopically, there was found albuminoid degeneration of the nerve-cells, of the cerebrum, of the heart muscle, of the liver-cells, and of the epithelium of the urinary tubules. Dr. Vinogradoff compares this with three other published cases of death from cocaine poisoning, and with cases in which large doses had been given with and without the occurrence of toxic symptoms, and shows that as much as forty-five grains have been given without any ill effects. The fatal result in the foregoing case—which led to the suicide of the surgeon who operated—is to be ascribed to the increased power of absorption of the ulcerated intestinal wall, and to the retardation of the kidney secretion by the diseased condition of the glomeruli. It would, therefore, appear that when there is any question of giving large doses of cocaine a careful examination should be made of the condition of the kidneys, and if there is any ground for supposing them to be diseased or functionally inactive the greatest caution should be employed. It may be remembered that before operating the unfortunate surgeon asked one of his colleagues, who was a professor of therapeutics. what dose of cocaine might safely be given, the answer being, "Not more than two grains." So that the greatest diversity of opinion exists regarding the maximum dose of the drug.—*The Lancet*, September 28, 1889.

Pathology of Severe Burns.—Dr. Oscar Silbermann, of Breslau, studying the clinical and pathological signs of the destruction of numerous red-blood corpuscles, found by his experiments: 1. That after extensive burns of the skin the red blood-corpuscles alter their form and lose their power of resistance to heat, drying, compression, and staining. 2. In consequence of these alterations numerous thromboses in the arterioles and capillaries, especially in the finer branches of the pulmonary artery, occur, leading to stasis in different organs—*e. i.*, lungs, kidneys, stomach, bowels, liver, spleen, skin, and brain. 3. The large distribution of the pulmonary capillary circulation produces a considerable impediment to the emptying of the right heart, and serious venous congestion as well as dangerous arterial anæmia. 4. This state, coupled with the above-mentioned symptoms, leads to bleeding and parenchymatous alterations in the affected organs. 5. The interference with the circulation also produces dyspnœa, a small pulse, angina, eclampsia, and anuria, as well as a remarkably low temperature.—*The Lancet*, September 28, 1889.

Pea Soup as a Substitute for Beef-tea.—Dr. Ris, of Kloten, Switzerland, says *The British Medical Journal* of September 28th, emphatically recommends pea soup as an excellent substitute for beef-tea for invalids, convalescents, and more especially for patients suffering from cancer of the stomach, or diabetes mellitus. Take peas, water, and sufficient amount of some vegetables suitable for soup; add one-half per cent. of carbonate of soda; and boil the whole until the peas are completely disintegrated; then let the soup stand until sedimentation is complete, and decant the fairly clear thin fluid above the deposit. The product is stated to resemble a good meat soup in its taste, to be at least equally digestible, and, at the same time, to surpass the very best meat soup in nutritive value. The latter statement may appear surprising, but the author reminds us that peas (as well as beans or lentils, either of which may be used instead of peas) contain a considerable portion of legumen—that is, a vegetable albumen which is easily soluble in a faintly alkaline water, is not coagulated by heat, is easily absorbed, and equal to the albumen of eggs in its nutritiousness.

The Microbes of Tumors.—Dr. Verneuil's conclusions as to the presence and influence of pathogenic microbes in tumors are as follows: Tissue of new formation of a malignant character, such as cancer, sarcoma, epithelioma, may at a given moment contain different microbes, of which neither the origin, kind, nor quantity can be accurately determined. The presence of these microbes may for a long time be innocuous, but, on the other hand, in some cases results in the rapid increase in softening and ulceration of the tumor. Microbes are not found in lipoma, fibroma, nor in cancers and sarcomas characterized by an initial slow development, but are almost always detected in softened and ulcerated tissue. These microbes, besides exercising a morbid influence on the surrounding tissues, affect also the general economy, and constitute a febrile element. During excision of the morbid growth, they are communicated to other parts of the wound, and are capable of provoking septicæmia, which may prove fatal.—*The British Medical Journal*, September 28, 1889.

The Choice of Operations for Vesical Calculus.—In an article in the October number of the *University Medical Magazine*, Prof. D. Hayes Agnew reaches the following conclusions:

First. All cases of vesical calculus in patients over fifteen years of age, with sound urethras, and in whom the stone is not too large nor too hard, should be treated by litholapaxy.

Second. All children under fifteen should be treated by lateral lithotomy.

Third. In the case of very large stones, suprapubic lithotomy should be substituted for either litholapaxy or perineal lithotomy.

Fourth. In adults, where perineal lithotomy becomes necessary, the median operation is to be preferred, provided the stone does not exceed three-quarters of an inch in diameter.

A Case of Nutmeg Poisoning.—On August 14, 1889, DR. AMOS SAWYER, of Hillsboro', was called to see a boy aged three. He found the little patient with a normal temperature and respiration; pulse regular, but a little slow; all the muscles completely relaxed. An attempt to arouse him failed, his head falling in whichever way the body inclined. An examination of the pupils revealed complete dilatation. Dr. Sawyer felt certain that this condition was the effect of something that the child had eaten, and, upon inquiry, was informed that he had, unknown to his mother, appropriated from her spice-box five large nutmegs, which he informed his little sister was his tobacco, and which by noon he had managed to consume, presumably spitting out the bulk of the spice. About 2 P.M. he complained of feeling dizzy and soon fell asleep, and they had been unable to arouse him. He had had one movement from the bowels, and had urinated twice while in this condition. There had been no delirium. He recovered consciousness as if awakening from a natural slumber, but with the greatest dislike for nutmegs, after having slept thirty consecutive hours.—*New York Med. Journal*, September 28, 1889.

Poisoning by Tansy.—The following case is reported in the *Medical Record* of September 28th:

"Mrs. K., not having her menses for some five weeks, thought herself pregnant, and not wishing to have any more children followed a neighbor's advice and set about taking five drops of the oil of tansy every few hours. Not succeeding in bringing about her menses, she took about one drachm on sitting down to breakfast. She felt no unusual symptoms for about a half-hour, when a 'dizzy sensation' came over her. She ran out doors, and a moment later was picked up by her husband in convulsions resembling epilepsy. There were present spasmodic contractions of the limbs, frothing at the mouth, and unconsciousness. The physician found her in this state, with a thready pulse, very intermittent, respiration scarcely perceptible, and cyanotic. Thinking there was enough food in the stomach from her breakfast to hold a good part of the oil yet unabsorbed, he administered apomorphia muriate, gr. $\frac{1}{10}$, hypodermatically. In a few moments she vomited very profusely, there being a great amount of gastric juice. After this she revived by repeated doses of brandy, but did not regain her consciousness for two or three hours. She remembered nothing about what had happened. Her tongue was lacerated, as is often seen after a severe epileptic fit, the pulse ran up to 120, and temperature to 101° F. for the rest of the day. Headache persisted for three days, and fainting every three or four hours for two days. The menses made their appearance, but not from the action of the drug, for she was nursing a child about six months of age, and they had been irregular. There were no signs of an abortion."

Fatal Result of a Wasp Sting.—The following case is reported in the *British Medical Journal* of September 21st:

A farm laborer, aged twenty-eight, was stung on the right side of the neck by a wasp, on August the 29th. He took no notice of it; but the next day, late in the evening, both sides of his neck began to swell, and on Saturday, the 31st, things looked so serious that a physician was sent for. He found the neck, cheeks, lower jaw, and even the pectoral muscles attacked with acute cellulitis. Careful inquiry elicited the fact of the wasp sting, and that when he received the lesion he had a boil under his left ear: also that, though a very healthy looking and well-nourished man, he was sadly troubled with constipation, and a member of a family among whom boils and abscesses were very common—thus evidently showing a natural tendency to suppurative mischief. The treatment consisted of the use of antiseptics both internally and externally, hot poultices, milk *ad libitum*, stimulants as far as could be tolerated, and plenty of fresh air; but, in spite of all, septicæmia, with violent rigors and delirium, supervened on the sixth day, and he died on the ninth day after the reception of the sting. No abscess formed, but the cervical tissues were very much indurated. August 29th was a very hot day, and, following as it did a period of rainy weather, the conditions were very favorable to the rapid decomposition of dead organic matter, whether animal or vegetable, and it is highly probable the wasp may have been feeding on some putrescent material previous to stinging the unfortunate man. As he had nothing whatever to do with the cattle, and as all the horses and cattle on the farm where he was employed are quite healthy, it is clear this was not a case of anthrax or malignant pustule, but death due to a wasp sting received when the system was not healthy.

Styrone, an Antiseptic.—We read in the *Medical Age* that styrone is again coming into use as an antiseptic. DR. H. A. A. BEACH was first to call attention to it in 1879; its cost, however, then precluded its extensive use. It now can be prepared at a reasonable figure and bids fair to enter into competition with other antiseptics. Styrone is a compound of styrax and balsam of Peru, and it is said to be especially valuable on account of its efficiency, non-poisonous character, and agreeable odor.

Lemon-juice in Epistaxis.—DR. FANCHON, in the *Revue Géneral de Clin. et de Thérap.*, speaks most highly of the value of lemon-juice for the local treatment of stubborn nose-bleed, In one case, in which the hemorrhage was most severe, and in which plugging of the anterior nares had been resorted to without avail, a single injection of lemon-juice made, with the aid of a glass syringe, into the nostril that was bleeding, immediately arrested the hemorrhage.

Transplanting of a Chicken's Cornea.—DR. GRAVENIGO, of the University of Padua, is said to have successfully performed an operation which hitherto has been vainly tried by various experimenters, both in France and elsewhere. The operation consists in the grafting of a chicken's cornea into the human eye. In the successful case reported by Gravenigo the graft is said to have united quickly and formed a cornea which was very transparent, shining, and convex.—*Le Progrès Méd.*, July 13, 1889.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 12, 1889.

MASSAGE OF THE HEART.

OERTEL'S mountain treatment of valvular disease has shown no signs of becoming popularized, at least in this country, where other and safer means of improving cardiac tone are wisely preferred. Benefit from hill-climbing undoubtedly accrues to some patients, and results partly from the general hygienic measures also employed, namely, open air, cheerful surroundings, and carefully selected food; partly also from the direct stimulating effect of exertion on the circulation. These useful features, great as they certainly seem, are overbalanced by the risks of dilatation and exhaustion of an already tired heart, dangers by no means theoretical.

Arrayed against Oertel are Liebenstein, Nothnagel, Lichtheim, Schott, Lépine, and Loomis, who have expressed themselves in more or less positive terms, Schott reporting several cases in which the treatment was of decided injury. Da Costa does not seem to have considered the method worthy of trial, and in his paper before the Association of American Physicians (*Amer. Journ. Med. Sciences*, Nov. 1888) says that his experience with valvular disease in the mountainous regions of Colorado would not incline him favorably to it. Franz, Hausman, Barr, and others who favor the treatment, do so guardedly and for selected cases only. No one has denied that with the dangers eliminated the method would be of value. Oertel now claims to have discovered, in what he terms massage of the heart, a safe method of attaining the same nutrition and circulatory improvements as in hill-climbing.

Donders long ago, in studying the effects of respiration on the circulation and heart, demonstrated that expiration aided the cardiac systole. Oertel's new method is largely based upon this fact, and might be termed an adjunct to expiration. The method, as described in his first paper in the *Munch. med. Wochenschr.*, Sept. 10, 1889, consists in the *masseur* placing his hands on each side of the patient's thorax at the height of the fifth or sixth rib. At the beginning of expiration firm pressure is made while moving the hands obliquely to the ensiform cartilage, the movement occupying the entire expiratory period. This pressure evidently must cause a more complete expiration than normal, which assists the heart in systole, hastens the blood current, and renders oxygenation more perfect. The direct pressure on the surface of the heart must in many patients be extremely slight, though Oertel considers it an important factor. In some cases use is made of prolonged expiration on the part of the patient.

Following this semi-artificial expiration is an increased inspiratory effort which in its turn aids the cardiac diastole. The blood current being accelerated and oxygenation rendered more perfect, it follows that nutrition is improved, not only of the entire system, but of the cardiac walls. This, in brief, is the theory and practice of Oertel's new treatment of failing heart power. Theoretically, there is a possibility of the prolonged inspiration dilating a weakened heart; practically, we think the danger may be ignored in all but the most advanced cases.

As yet, Oertel has made no comments on the use of drugs in connection with this treatment, but we cannot see why any of the cardiac tonics should not be used. The method is based on sound physiological principles, and seems worthy of careful trial. Oertel's standing in the profession renders it necessary that attention be paid to his statements, and we hope that the profession on this side of the water will at least give it a fair trial.

CARBOLIC ACID.

WITH the characteristic perversity of the law, we have a condition of affairs in the State of Pennsylvania which forbids druggists to sell to irresponsible parties substances which are known to possess distinctly poisonous properties, and yet it may be said

that many of the drugs included in this far-reaching law do not possess very distinct toxic power unless taken in large quantities.

Either because our legislators came to the conclusion that it would be well for the people in general to become easily possessed of carbolic acid for the purposes of disinfection, or because they were ignorant of the fearful power which it possesses as a poison, this substance is at present allowed to be sold by any one and to any one who may ask for it. As a consequence, within the last few years the number of cases of poisoning by this acid have very largely increased, and instead of such suicides becoming medical curiosities, they have ceased to attract the general attention which was given them when it was first resorted to.

Considering that carbolic acid has been proved by researches of the committee appointed by the American Public Health Association to be a substance far inferior to many others in germicidal power, and in view of the fact that it is, with one exception, perhaps the most rapidly acting poison known, we think that some law in regard to its sale should go into effect as soon as possible. That the acid is capable of acting with extraordinary rapidity if taken in large amount has not only been proved by a large number of cases on the continent of Europe and in England, but has found ample substantiation in those cases which have occurred in this country. Two of these cases with which we are acquainted emphasize this point very well. One was that of a marine hospital steward who, by mistake, swallowed an unknown quantity of the acid. He was heard to groan, step out of a small room, fall senseless in the passage-way, and was dead inside of three minutes. Still another case, occurring in this city, was that of a man who entered a drug-store, bought a vial of carbolic acid, tossed its contents down before he could be stopped, strode to the door of the store, and dropped dead on the step. That the profession is beginning to recognize the frightful power of this drug is evidenced not only by the cautions which are now given by physicians to their patients when directed to use it, but also by the articles which from time to time appear in the current medical journals. At the same time there are several text-books, one or two in particular for distribution among the laity, which recommend carbolic acid highly for its antiseptic powers, and its use in drains and cesspools, but contain no word of warning as to the character of its action when taken into the body, nor any reference to the antidotes which should be employed in case the poison be swallowed. A sufficient number of cases of poisoning by carbolic acid have occurred in the United Kingdom to force the medical profession in Ireland to request that the acid be placed upon the list of poisons. To this end the President and Fellows of the King's and Queen's College of Physicians in Ireland have requested the Privy Council to take such action as will necessitate more care in its general sale. It is customary in some places to require druggists, when selling a poison without a physician's prescription, to include, upon their labels, a brief account of the treatment which should be instituted should mistakes be made as to the contents of the bottle. Even supposing it is impossible to pass a law which will control the sale of this and similar drugs sufficiently to prevent persons with suicidal tendencies from using it, it might be well for druggists to be instructed to recommend, by a label, Epsom or Glauber's salts as the proper antidote to be employed, and to warn purchasers that great care should be exercised that children and other irresponsible persons should not be allowed to handle it.

THE TREATMENT OF HEPATIC ABSCESS.

THE interesting case of liver abscess reported by DR. TOMPKINS in the current number of THE NEWS, suggests some observations in regard to the recent advancements in the surgical treatment of this affection. The ideas of surgeons have, in the last few years, become fairly well crystallized in regard to the treatment of abscess affecting the liver. Although a great variety of means for relief are to be found in the standing text-books, the writings of more modern investigators point to the earliest possible incision as being, beyond all others, the most successful treatment. Thierfelder's interesting statistics give absolute proof of the justice of this opinion.

For the proper application of this principle an early diagnosis is absolutely essential. The typical symptoms of abscess are rigors, fever, tenderness over the liver, pain which is often referred to the right shoulder and is severe in character, steady emaciation, and rarely jaundice, together with the appearance of a tumor in the hepatic region.

The prognosis, if no surgical treatment is instituted, is exceedingly grave. Contrary to the accepted doctrine that pus points outwardly, it is as prone to discharge into the lungs, stomach, intes-

tines, or peritoneal cavity as to find its way to the surface. The case reported is an instance of this, the abscess pointing toward the surface and into the intestine.

Where typical signs are present, or where there is suspicion that liver abscess has formed, or is forming, the surgeon should at once perform an exploratory laparotomy; if swelling is present, the incision should be made over its most prominent part. If this important guide is absent, the incision should begin at the costo-chondral articulation of the tenth rib, and be carried directly downward in the long axis of the body. If the surgeon fears that his antiseptic precautions or his manual skill are not sufficient to prevent the entrance of microörganisms or blood into the peritoneal cavity, he can satisfactorily explore the liver surface by Bardenheuer's, or the so-called extra-peritoneal incision—that is, the knife may be carried down to, but not through, the peritoneum. The latter may be stripped from the parietes, and the fingers may be carried over nearly the entire surface of the liver with the interposition of only a thin membrane. In this way swellings, irregularities in surface, or fluctuation can be readily discovered.

If adhesions have not formed between the liver and peritoneum, the surgeon should suture these two surfaces together, and then, having so placed his threads that the peritoneal cavity is absolutely protected against the entrance of pus, should freely incise the abscess cavity, and should make ample provision for drainage.

Where, in spite of the use of large tubes, pus accumulates, the cotton ropes should be employed; these should be carried to the bottom of the drainage tubes, and removed every half hour or hour, if necessary. Under this treatment, the prognosis is exceedingly favorable. The liver heals with remarkable rapidity, sometimes an extensive abscess cavity being closed in a few days. Even though there be multiple abscesses, the evacuation of the principal cavity lessens pressure in this region to such an extent that the smaller abscesses will probably rupture spontaneously in the same direction. At the time of operation the surgeon should carefully explore for secondary abscesses, and, if found, should, by means of his finger or the point of a blunt instrument, break through the walls separating them from the major cavity.

In regard to the etiology of the case reported by Dr. Tompkins, it is unfortunate that, at the time of the autopsy, the large intestine and rectum were not examined. Although so-called spontaneous liver abscess has occurred, and the traumatic form is well recognized, by far the most common variety is that due to septic matter carried from the rectum or large intestine. A history of preëxisting diarrhœa or dysentery is almost conclusive evidence that this is the cause of abscess formation. It also suggests the probability of the abscess being multiple, and indicates that there should be made, not merely an incision, but a thorough exploration, with the idea of evacuating all the pus which the liver contains.

There have been many cases successfully treated by means of aspiration, but both statistics and anatomical reasoning would strongly indicate exploratory laparotomy. We can never be sure, unless superficial signs of inflammation are present, that the liver is adherent to the parietes. Any puncture into this organ would, if such adhesions had not taken place, expose the patient to the risks of septic peritonitis. Thorough evacuation, either through the canula or aspirating needle, is absolutely impossible, and the surgeon is left in ignorance as to the existence or non-existence of more than a single abscess.

Under any circumstances laparotomy can do no harm, and in the majority of instances it leads directly to the saving of life.

FISH POISONING.

During the past few years, through the labors of Brieger, Vaughan, Semi, Nencki, Gautier, and a host of lesser lights, our knowledge of food poisons has greatly increased, and the explanation of those instances in which a number of individuals are simultaneously seized with toxic symptoms after partaking of a particular article of food is no longer sought in the cooking utensils or in intentional adulteration. Among the staples which are known to have frequently caused poisoning are fish, and in countries where they form a large part of the food consumed, it has been recognized for centuries that by them poisoning would occasionally be caused, some species being more dangerous than others. This was usually explained by the supposition that the fish subsisted on food deleterious to man, or that they possessed inherent poisonous properties. So far as is now known, certain members of the family Scoparænidæ, and during spawning a few varieties of herring, alone are toxic *per se*, and

it is not proved that any species live upon food poisonous to man—putrefactive changes, with the development of those subtle compounds named by Selmi the ptomaines, being the toxic agents in the vast majority of cases.

In the *Lancet* of September 21st Lawrence-Hamilton, taking as his text "Ice Spoils Fish," reviews in detail and with many practical comments, the entire subject of preserving fish for the market—a subject of great and growing importance to physicians, for the belief that many of the acute intestinal disorders are in reality cases of ptomaine poisoning, and, therefore, preventable diseases, is steadily gaining ground. In this country more attention has been given to poisoning by milk and cheese; but when we stop to consider the methods by which fish are preserved from the time they leave the water, the ease with which they putrefy, and the great numbers consumed in all seasons, the hygienic importance of the subject can scarcely be overestimated. According to Lawrence-Hamilton, the proneness of fish to decomposition is due to the fact that, differing from mammals, all their tissues, including the blood and lymph, contain bacteria, and also to their readiness to absorb water when dead—water in most cases filthy from long-used boxes, baskets, vessel-holds, and market counters. Further, slight damage to the surface or bruising of the flesh opens a channel for the entrance and multiplication of putrefactive bacteria. This latter fact is so well recognized that in Great Britain railway transportation reduces the market value of fish twenty-five per cent. We can hardly believe with Lawrence-Hamilton that all chemicals, including common salt, are valueless as preservatives. Salt in sufficient quantities certainly preserves most fish, although Boehm has stated that in Russia poisoning with salted sturgeon is more frequent than with the fresh fish. That ice spoils fish is probably due more to the fact that it gives a false sense of security than to other reasons; although, as every housewife knows, all meats spoil more quickly *after* having been on ice. It is the moisture, maceration, and bruising that cause this tendency, for both meat and fish may be kept for long periods in a cold, *dry* atmosphere.

The prophylactic measures suggested by this review of Lawrence-Hamilton's paper are: First, to free the flesh as much as possible from putrefactive bacteria; all fish should be bled and gutted immediately after catching. "What butcher would dream of cutting meat from an ungutted or unbled carcass?" By the Scandinavian fishermen this is done, but in Great Britain and this country, we are informed by dealers, fish are shipped to market as taken from the water.

Secondly, that they should be transported with great care and freedom from bruising, and kept in a cold, dry air, such as is now furnished with several kinds of refrigerators. How far these measures are complied with is demonstrated by a few moments in any fish market.

The time is rapidly approaching—unfortunately for us, more slowly in this country than in many others—when medical thought will be directed as much to the prevention as to the cure of disease, and governments will be compelled to recognize and act upon wise prophylactic suggestions. When that time arrives stringent laws will protect the consumer from careless dealers; until then it is our duty to educate our patients to the dangers threatened by improperly preserved foods.

REVIEWS.

The Physicians' Library. Disordered Digestion and Dyspepsia. By Frank Woodbury, A.M., M.D. 12mo. Detroit: George S. Davis, 1889.

This paper-bound book is one of 77 pages, written by a former teacher in one of the medical schools of Philadelphia, who has placed the entire subject of gastric disorders, at least in their functional forms, with sufficient clearness to be readily understood, even by persons possessing very little medical knowledge. It contains chapters on "Digestion and its Disorders," the "Symptoms and Forms of Dyspepsia," "Treatment of Dyspepsia," and "Dietetic Hints for Dyspeptics." In the preface a brief review of the recent scientific changes in regard to gastrionic disorders is given, and scattered through the book are several tables giving differential diagnoses which aid in the separation of disordered states quite well.

The book is printed in the same style as the rest of the series, and while it lacks the thoroughness which the subject might be thought to command, and pretends to no originality, it will probably prove valuable to many physicians in giving them useful hints.

The Story of Bacteria, and their Relations to Health and Disease. By T. Mitchell Prudden, M.D. 12mo. New York: G. P. Putnam's Sons, 1889.

As stated by the author in his preface to this little volume, his chief aim has been to present the main features of the life-history of bacteria in such a form that the layman may readily understand them.

Difficult as is the task of writing or speaking upon an abstruse scientific subject in terms that are not too technical for the medically uneducated mind to grasp, the author has admirably succeeded in not only placing in

simple and readily comprehended language the "story of the bacteria," but has so clothed the plain narration of facts in the garb of fiction that in places the book reads almost like a fairy tale. After describing some of the more generally understood and more easily appreciated facts of biology, he leads the reader by easy stages toward the comprehension of the more intricate parts of the subject, Even the relation of phagocytes to bacteria is so touched upon in non-technical terms that he conveys to the reader a distinct idea of the outlines of the processes involved, without becoming too deeply surrounded by technicalities.

Probably the chief merit of the book, apart from the interesting character of its contents, is the manner in which the author deals with the *rôle* played by bacteria in various preventable diseases, deducing therefrom the well-understood, but little heeded, prophylactic measures that should be adopted.

The author has fulfilled his task well in producing a brochure that will be read not only with interest by physicians but also with understanding by the unprofessional reader.

Handbook of the Diagnosis and Treatment of Diseases of the Throat, Nose, and Naso-pharynx. By Carl Seiler, M.D. Third edition, thoroughly revised and greatly enlarged. 12mo., pp. 374. Illustrated with two lithographic plates and wood engravings. Philadelphia: Lea Brothers & Co., 1889.

Ten years ago the first edition of this little book appeared in the market, and the fact that already two editions have been exhausted proves that, though it deals almost solely with a special subject, it has, nevertheless, met with the approval of the profession. The book is enhanced in value very considerably, at least to the tyro in laryngology by the handsome lithographic illustrations which it contains, also by the unusually clear engravings which are scattered profusely through the work. The instruments which are to be employed by the specialist in this branch of medicine are also clearly portrayed. In regard to the book itself, we think that it is unusually clearly written, and that a very large amount of valuable information has been placed in a small space between its covers. Attention has been paid in a thorough manner to the rapidly increasing employment of electricity in the treatment of the diseases commonly seen by persons operating on the throat and nose.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

Fourteenth Annual Meeting held at the Institute of Technology, Boston, Mass., September 17, 18, 19, 1889.

Third Day—Thursday, September 19th.

Morning Session.

Although Dr. A. Martin, of Berlin, was absent, his paper entitled

THE RELATION OF UTERINE RETRO-DEVIATION TO PREGNANCY

was read.

The condition of retro-deviation of the uterus was especially significant with reference to pregnancy—in fact, pregnancy was impossible in many cases in which such faulty position existed. The author's experience included seventy-nine cases in hospital and forty-two in private practice, in which pregnancy was thus complicated. In all the cases there were typical symptoms resulting from the retro-deviation. It was important to consider two questions in this connection: 1st. Was retro-deviation a bar to pregnancy? 2d. Was retro-deviation during pregnancy as serious a condition as was commonly supposed? In many of the author's cases there had been important symptoms including hemorrhage, uterine catarrh, tubal disorders, and, in some cases, peritonitis. Cases were narrated in which pregnancy continued to term without the occurrence of any serious disturbing symptoms. If the retro-deviation were congenital, there was sufficient evidence that it might result in sterility. The author did not accept the assertion that all cases of retroflexion of the gravid uterus in multiparæ were due to improper treatment during childbed. In most of his cases conception occurred in uteri which were already retroflexed, an evidence that the displacement was not a bar to conception, and this was true whether the displacement was congenital or acquired. In all cases of sterility with uterine retro-displacement it was essential to ascertain the existence or non-existence of impotence in the husband. Catarrhs and abrasions of the uterus required local treatment the same as in the non-gravid condition. Abortion occurred only four times among his cases. In ninety-seven of them delivery was at term. The faulty position in his cases was discovered at periods ranging from the second to the sixth month. The treatment consisted in first having the bladder evacuated, then, with the patient in the knee-elbow position, the uterus should be replaced, if possible, with pressure from one or two fingers, a suitable pessary being introduced to hold it after such replacement. The pessary might remain until the sixth month, and in cases in which its use was inadmissible, or in which adhesions prevented the replacement of the organ, graduated pressure with a vaginal tampon of cotton-wool could be used. The author's results had been very favorable. Grave complications are now recognized earlier than they used to be. It is not to be doubted that many cases of retroflexion in the gravid uterus cause no symptoms, and the cases go to term, no diagnosis of a morbid condition being made. In case all efforts at replacing the uterus or holding it when replaced should fail, one must take into consideration the propriety of emptying the organ, or, as an extreme measure, extirpating it.

Dr. Bache Emmet had seen few cases in which pregnancy occurred in the retroflexed organ. Indeed, he had considered the retroflexion a bar to pregnancy in most of the cases which were brought to his notice. If the displacement was not or could not be corrected, it was at least desirable, and usually possible, to raise the uterus in the pelvis, which would favor conception, or its continuance, if already existing.

Dr. Howard Kelly had seen conception follow the cure of uterine retro-deviations. He believed that in most of the cases in which pregnancy coexisted with uterine deviation a spontaneous cure resulted, and that in a minority only was there abortion or other severe accident. A kindred fact consisted in the faulty development of the uterus during pregnancy, though its posi-

tion might have been normal when conception occurred. As an extreme resort, he could conceive of the necessity of opening the abdomen during gestation and relieving the displacement.

DR. T. A. EMMET believed that backward displacement never occurred without the existence of local inflammation. He did not think such malposition would have any bearing upon the question of conception, especially if the Fallopian tubes were sufficiently patent to permit the passage of the spermatozoa. He had seen cases in which he believed that replacement with vaginal packing had prevented abortion. He preferred the knee-elbow position for replacement; but great care was necessary in performing this operation, otherwise an abortion would be induced. The use of pessaries in this condition was attended with danger.

DR. A. J. C. SKENE could not conceive of any condition which would justify extirpation of the uterus, however grave the displacement.

DR. H. F. HANKS, of New York, thought that many cases of abortion could be prevented in the retroflexed gravid uterus, if judicious means were taken to relieve the displacement. Careful packing of the vagina was better for such a purpose than the use of pessaries.

DR. J. CHADWICK objected to severe measures of treatment in the condition under discussion. He thought that abortion was not a common result of the condition. Pessaries were allowable in his opinion. If there were retroflexion with adhesions, pregnancy rarely occurred.

DR. BOLDT stated that cases had been reported in which death had resulted from inability to reduce the gravid retroflexed uterus. In such cases an abdominal section would have been justifiable.

DR. E. C. GEHRUNG, of St. Louis, Mo., read a paper entitled

RESULTS OF REPRESSION OF MENSTRUATION.

It was a demonstrated fact that menstruation might with safety be stopped by the use of the vaginal or uterine tampon in cases in which the patient could not afford the loss of blood. The experience of the year since the reader had propounded his views on this subject had made his convictions firmer that this method of treatment was useful both for prophylaxis and cure. Menstruation did not necessarily include a sanguineous discharge. The menstrual molimina might be present without it. It was but an accidental accompaniment of ovulation, etc., and would be as harmful as repeated hemorrhage from any other source, were its effect not modified in many cases by the force of transmitted habit. Sanguineous menstruation is a potent cause of anæmia in women, and he believed it could serve no useful purpose, any more than did the old doctrine of Broussais that men should be bled monthly to relieve plethora. If plethora really existed, it was best treated by redistribution, not abstraction, of blood. If, as is asserted, bleeding sometimes acts a safety-valve, it is at least a safety-valve which should rarely be used. Even if it is a fact that women make blood rapidly, this is no advantage if they are to lose it as rapidly as it is made. It is a dangerous error that bleeding disposes of superfluous elements. The best method for stopping menstruation consists in the use of the vaginal tampon. It gives no shock to the nervous system, neither does it poison the blood, as might be the case if ergot or other drugs are used. If metrorrhagia or menorrhagia existed, the tampon should be used regardless of menstruation. Scanty menstruation is observed in anæmic women, and is usually the result of previous excessive losses. Repression in such cases tends to relieve the nervous symptoms, the anæmia, etc. In women with amenorrhœa it is generally necessary to relieve a depraved general condition, and when menstruation reappears the tampon should be used periodically until the patient becomes strong again. The paradox in this case is only apparent; the first step is to remove the cause, the second to correct the trouble. Certain neuroses and neuralgias are also amenable to treatment by the method under consideration. No bad results had been seen or heard of from the use of this method. It was believed that it would serve as a means of relief in many cases of uterine and pelvic trouble which would otherwise necessitate mutilating operations.

DR. BOLDT could not believe that menstruation was a pathological condition, nor that the bleeding which formed an important element of it, was an accidental hemorrhage. The condition of the majority of women refuted the assertion that continued menstruation tended to produce anæmia. That anæmia might be independent of menstruation was shown by its persistence in many cases in which the uterine appendages were removed and a premature menopause induced. That systematic bleeding was a functional habit in women was also demonstrated, he thought, in those cases in which *purpura hemorrhagica* recurred with regularity after the ovaries and tubes had been lost. No one would deny that a tampon was advisable if menstrual hemorrhage was excessive, but the speaker doubted if it would ever be wise to leave it in place as long as seventy-two hours, which had been recommended. If it were to be used at all to check excessive flowing, it was well to begin its use two or three days before menstruation was due.

DR. A. W. JOHNSTONE thought the reader had made a mistake in considering menstruation pathological as it was as necessary a function as respiration, its object probably being to wash away over-ripe lymphoid corpuscles. Among the higher animals, in which there is a discharge which more closely resembles menstruation than that which occurs in any of the other animals, and in which the uterus tends to the vertical rather than the horizontal posture, as in woman, this discharge is especially noteworthy in those varieties which stand particularly erect or nearly so. There would be no use in the vaginal tampon, as a means of repressing menstruation, unless one should also close the mouth of the Fallopian tubes. Harm from menstruation proceeded rather from nervous than from vascular influence. The tampon would be more or less dangerous, as congestion of the broad ligaments would be unrelieved, stasis would result, and an indication for operative measures upon the uterine appendages would be favored. The bloody discharge which occurred so frequently after laparotomy was probably due to the squeezing by the ligature of the nerve described by himself which was situated at the angle formed by the Fallopian tube with the uterus. He believed that menstruation was a portion of the mechanism for preparing woman for pregnancy, the end for which she seems physiologically destined.

DR. A. R. JACKSON did not feel satisfied with a theoretical explanation when it was in opposition to the facts of

observation. He had practised repression after the manner described by the reader for many years in cases in which menstruation was profuse and had seen only benefit as to the result. Profuse flowing must eventually result in anæmia, and, in so far as it applied to this, the method of the reader was endorsed.

Dr. Gehrung, in closing, stated that his proposition was to repress menstruation only in cases in which the patient could not well bear the loss of the blood. He was unwilling to agree with Dr. Johnstone that the free bleeding of menstruation was dependent on nervous influence, and thought it depended rather on the weakness of the womb, as a structure, and its vessels.

Dr. H. J. Boldt, of New York, read a paper entitled

Intermediate Trachelorrhaphy.

The majority of gynecologists were willing to admit that a great variety of ills might follow laceration of the cervix uteri, Noeggerath being one of the few prominent physicians who violently oppose it. Bad symptoms might appear as soon as three months after parturition. In an analysis of the histories of 3000 childbearing women, 109 were found in which symptoms were evidently referable to a tear of the cervix. If then bad symptoms were presumable, at a more or less remote period, in women who had suffered severe injury to the cervical tissue at parturition would it not be expedient to anticipate such trouble by performing trachelorrhaphy as soon as possible after the puerperal period was ended? The reader of the paper had acted upon this proposition in 26 cases, in only 4 of which was success wanting. The operation might be performed in one's office, and without anæsthesia, as it was unattended with pain. The surfaces of the torn portions were scraped, the angles freshened, and catgut sutures were carefully and not too tightly placed. A straight trocar needle was used, a very sharp scraper, and a tenaculum devised for the purpose. The object of the operation was to prevent or avoid the conditions for which Emmet's operation was indicated.

Dr. Bache Emmet thought that the object which the reader of the paper sought to obtain by his operation was a good one. He also thought that if the work of the obstetrician had been done properly many of the cases which require treatment would not need it. He did not think it well to anticipate symptoms, for one could not say in advance how well nature would do the work of repair, for that reason he did not believe the reader's operation would often be indicated. It would seem to him also that the tissues were not in good condition for a successful operation so soon after labor as had been advised. He believed it unadvisable to do such operations in one's office, and furthermore believed that the operation was one which required the skill of a gynecologist and should not be done by the general practitioner.

Dr. Skene did not approve of doing trachelorrhaphy until the appropriate symptoms appeared which indicated it. He was also opposed to doing such operations without an anæsthetic and in one's office.

Dr. B. F. Baer, of Philadelphia, understood the question of the paper to be whether laceration of the cervix *per se* was or was not a lesion. If it were to be considered a lesion, the reader was right in proposing that an obstetric patient with such a lesion should not be discharged until that lesion was repaired.

Dr. T. A. Emmet felt that the proposed operation had no place, that trachelorrhaphy should not be done in one's office, and that in the absence of symptoms it should not be performed. Nature would usually repair the damage done by a severe labor if a patient had proper care subsequently, including suitable diet, sunshine, hot douches, etc. Hence no one could say as early as a month after labor whether an operation would ever be called for. He had found that the cases which needed it most frequently, included those women who bore many children, the pregnancies following each other in quick succession.

Dr. Engelmann did not altogether agree with the reader of the paper, but did not think the paper had been fairly discussed, in view of the fact that there were many cases in which the extent of the injury was such that they were almost certain to give rise to the characteristic symptoms. Like the other speakers, he disapproved of doing such operations in one's office.

Dr. Boldt, in concluding, desired to maintain the principal proposition of his paper, that cases in which the injury was so severe that symptoms could be predicted, would be benefited by intermediate trachelorrhaphy.

Dr. T. A. Ashby, of Baltimore, Md., read a paper entitled

The Value of Laparotomy in the Diagnosis and Treatment of Minor Forms of Intra-abdominal and Intra-pelvic Disease.

It was stated that the limits of laparotomy would apply in general to those obscure conditions in the abdomen in which all other means of diagnosis and treatment had been unavailing. It was the only means of diagnosis for certain obscure forms of disease of the tubes and ovaries. There was still an unreasonable prejudice against it in certain directions, for it must be remembered that there was no danger in an abdominal section *per se*, but in the way in which it was done. Simple abdominal section should have no mortality, and was indicated in any condition which could not be treated by other methods.

The operation was indicated for morbid growths of the abdomen which might be small, but the relations of which could not be made out by other means. For ectopic gestation, he believes laparotomy is always indicated. As an expedient, it was preferable to electricity for many reasons. Neuralgic conditions of the pelvis, especially when associated with persistent pelvic pain, seemed to him an entirely legitimate indication for laparotomy. Intra-pelvic pain from displaced organs was an indication when other measures failed, and so were many forms of intra-abdominal and intra-pelvic hemorrhage.

Dr. E. W. Sawyer, of Chicago, read a paper entitled

Partial Rotation of the Ovum in Early Pregnancy as a Cause of Placenta Prævia, Suggested by Two Cases in Practice.

The hypothesis of the reader was that since in the earliest period of pregnancy the ovum is not very firmly attached to the decidua, violence of a certain character,

for example, a fall or a violent jump, might displace it, throw it more or less downward on its axis, and cause it to lodge in the lower or cervical segment of the body; its proper site being usually considered as in the upper segment. The villosities of the chorion being detached along the upper (relatively) surface of the sphere as it rolls downward, a new implantation must be found, and that would necessarily be in the lower uterine segment and in greater or less proximity to the os internum. This would result in more or less pronounced placenta prævia. Two placenta (battledore) illustrative of this condition were exhibited, also diagrams demonstrating the hypothesis.

Dr. C. Kollock, of Cheraw, S. C., read a paper entitled

THE PROTECTIVE INFLUENCE OF VACCINATION DURING THE INTRAUTERINE EXISTENCE OF THE FŒTUS.

The protective value of vaccination to a fœtus, by the performance of that operation upon the mother, had been demonstrated by several French investigators, and its importance had seemed great to the reader. He had many times witnessed, in the malarial country in which he lived, typical congenital malarial fever in newborn infants, and was induced by these facts to make a series of experimental inoculations upon pregnant women, 36 in number, 14 being primiparæ. After labor was completed, the infants were also vaccinated. Of the children of the 14 primiparæ, vaccination failed in 5; of those of the 22 multiparæ, it failed with 16. It was evident, therefore, that immunity could be communicated by this method. It was probably better to vaccinate the mothers during the latter months of pregnancy when the fœtal circulation was well established and active.

Dr. Sawyer, of Chicago, corroborated the statements of the reader, from an experience in vaccinating 30,000 times during the past few years, the large majority of the individuals being school-children.

Dr. J. R. Chadwick, of Boston, Mass., read a paper entitled

A CASE OF NEPHROTOMY FOR THE REMOVAL OF CALCULUS OF THE KIDNEY.

This was a case in which calculus of the left kidney had been diagnosticated by eminent authorities, and the symptoms pointed so strongly to its existence that an operation was advised. The kidney was incised, thoroughly explored and then carefully washed out, but no calculus was found. Since the operation the bad symptoms had returned, they were always exaggerated by worry on the part of the patient, and the reader of the paper believed that the symptoms were purely of nervous origin.

Dr. A. F. Currier, of New York, suggested that the stone might have been in the cortex of the kidney, but so small that it was overlooked, not appreciated by the examining finger, and so impacted that it could not be washed out, a case presenting somewhat similar phenomena being narrated.

Dr. G. J. Engelmann suggested that the possibility of obscure pelvic disease should be thoroughly considered in the case in question, and that it might throw some light upon it.

CORRESPONDENCE.

A NOVEL CATHETER.

To the Editor of The Medical News,

Sir: On May 27th I was called to attend a boy near Equimunk, Pa., twenty-two miles from here, and found him suffering from acute peritonitis. When I called three days later he was suffering severely from complete retention of urine. I did not have a catheter with me, and as I would have had to send twenty-two miles to my home or eighteen miles to Hancock, New York, before one could be procured, making forty-four miles one way or thirty-six the other, before the boy could be relieved, and as he was suffering such severe pain, I thought I would try an original plan of my own.

I went out into a field and cut several long stems of what is known as buttercup or yellow daisy crowfoot and botanically as *Ranunculus*. I rubbed the stem down very carefully not to break any of its longitudinal fibres, oiled it, and drew the patient's water with it as well as if I had had one of the best of catheters. The boy was well formed and large for his age, weighing one hundred and forty pounds.

As the employment of a weed as a catheter is certainly novel, and as neither I nor my colleagues have heard of a similar case ever being reported, I have ventured to send it to The News, trusting that your readers may find it of interest. Truly yours,

Sanford A. Kelly, M.D.

Honesdale, Pa., July 10, 1889.

NEW YORK.

(*From our Special Correspondent.*)

New York Academy of Medicine.—The corner-stone of the new building of the New York Academy of Medicine, in West Forty-third Street, near Fifth Avenue, was laid with appropriate ceremonies on the afternoon of October 2d. There was a large gathering of the medical profession, and distinguished men in other walks of life were also present.

The exercises were opened by an invocation by the Right Rev. Henry C. Potter, Bishop of New York, after which Dr. Abraham Jacobi, ex-president of the Academy, delivered an address, in which he spoke of the purposes and needs of the institution, and the relation of the medical profession to the community. In the course of his remarks he said: "The Academy has furnished a consulting bureau to all the Health Department's hospitals. A committee of the Academy was intrusted with the inquiry into the report on the condition of quarantine. It was to its report that the first appropriation for the rebuilding of the quarantine station was due, and to its recommendations that improvements are being carried out at the present time. In this way the medical profession excludes epidemics, and guards both physical health and the economic interests of the city."

Ex-President Grover Cleveland then delivered an address, which was in part as follows: "The congratulation and the satisfaction which attend this hour especially belong to the members of the Academy of Medicine. This is as it should be, for the exercises of to-day signalize an achievement wrought by their activity and energy, and give proof of their devotion and attachment

to their chosen profession. . . . . In these extensive foundations is also found proof of the progressive ideas of these earnest men, and their constantly enlarging estimate of what is necessary to meet the the purposes to which their energy is directed. . . . . I have spoken of the mission of the Academy. The nobility and sacred character of this mission have been often dwelt upon. It is an old story, but it will never lose its interest while humanity is touched with human woe, while self-sacrifice receives the homage of Christian hearts, while the sufferings and sorrows of our fellow-men start the tear of pity, nor while their alleviation brings comfort and satisfaction to the soul of sympathy. These reflections easily and naturally lead to the thought that the members of the Academy of Medicine are not entitled to the absolute monopoly of congratulation to-day. All your fellow-citizens may well claim a share, not only because they are interested in the promotion of the science and art of medicine, by reason of their liability to accident and disease, but because such advance in any profession as is here demonstrated adds to the glory and renown of our common country."

At the conclusion of Mr. Cleveland's remarks, the corner-stone was laid by the President of the Academy, Dr. Alfred L. Loomis.

THE RADICAL CURE OF HAY-FEVER WITH CHROMIC ACID.

To the Editor of The Medical News,

In the issue of The News for September 15, 1888, I presented a method of palliating the symptoms of hay-fever by the internal use of atropine and the local application of cocaine, both drugs being employed in doses much smaller than usual. Having followed the same method of local application with another agent, chromic acid, I am now enabled to present a means of radically curing obstinate cases of this disease.

The wire applicator shown in the engraving is identical with the form used last year, no advisable change having suggested itself. With this instrument carrying a medicament on cotton, applications may be made in all parts of the nose, an essential advantage which it does not share with any practicable form of galvano-cautery. The cautery, moreover, has several other disadvantages, among which the most important is its tendency to stick to the surface against which it is heated, and to require a pull for separation which effectually prevents the brushing movement necessary for the complete covering of a surface. None of the disadvantages inherent in the cautery are presented by the wire cotton-carrier bearing a proper fluid caustic. Of the many agents of this class, chromic acid possesses preëminent qualifications for our purpose. It is freely soluble, and can therefore be applied to every portion of a given surface; its solutions in successive strengths pass by continuous gradations from a mild astringent to a most powerful destroyer of animal and vegetable tissue. In proper strength it instantly combines with gelatinous and albuminous substances to form a tough, leather-like compound; it does not fume or evaporate, and has no smell, wherein it possesses a great advantage over the irritating acids, acetic, carbolic, and nitric, as well as over the cautery which generates pungent ammonia; and lastly, it is almost painless, and thereby distinguished from all other caustics, acid, alkaline, or thermal. This quality of virtual painlessness is only possessed by the absolutely pure chromic acid, the presence of a small quantity of sulphuric and arsenious acids, which accompany the impure article, giving rise to pain equal to that occasioned by other caustics. Merck's chromic acid has been found to answer the most rigid requirements, and is therefore recommended. Owing to its property of combining with gelatin and albumen, chromic acid instantly destroys the surface of mucous membrane, converting it into a leather-like film which adheres to the unchanged tissues beneath. The continuity of this film is proved by the fact that a second application of chromic acid to a spot once touched is scarcely perceived, from which it is obvious that the much milder irritant contained in the specific cause of hay-fever will likewise fail to act. The mucous surface being thus protected from irritants and microörganisms, will have the best conditions for rapid healing with normal nerve terminals, the only cure which can properly be characterized as radical. The extreme solubility of chromic acid places the operator in perfect control of the effect to be produced. In a solution of 1 per cent. it is astringent, in 10 per cent. it is a caustic as powerful as will be necessary except in special cases requiring removal of more than superficial tissue.

The only preparatory treatment which may be necessary is the checking of any abnormal secretion of mucus or serum. This is most readily accomplished with atropine, $\frac{1}{200}$ grain of which is given, and repeated in fif-

Wire applicator, two-thirds actual size; made of German silver wire one-twenty-fifth inch in diameter; low spring temper.

teen minutes if the desired diminution in the flow has not been attained in that time. Mucus interferes in two ways with the action of the acid: first it dilutes it to an unknown strength, and secondly, it combines to form a ropy substance which prevents the acid from reaching the surface of the membrane. Before introducing the acid, the physician should map out the surfaces requiring treatment. Polypi and hypertrophies are distinguished by the light thrown by a concave mirror through the speculum placed in the nostril, or upon the rhinoscopic mirror placed in the pharynx. Large growths may be removed by the cold or hot snare, the cautery, or chromic acid in solution containing 15 to 20 per cent. Cure will often follow the restoration of the nose to normal calibre; but on the other hand, hay-fever may occur in patients whose nostrils are entirely normal as far as present methods of inspection can reveal. In such cases the physician must resort to other means of diagnosis. With

the wire applicator carrying cotton soaked with pure water he can investigate parts of the nose into which light cannot penetrate. Sensitive spots, when touched, disclose themselves by the watering and winking of the patient's eye on the side under investigation and by the excitation of coughing or sneezing. The wire can and always should be withdrawn in advance of a cough or sneeze. The position of the cotton is of course known by the position of the end of the wire in the physician's hand. Having mapped out the spots at fault, he carries to them the chromic acid, preferably in 5 to 8 per cent. solution, and moves the cotton *slowly* over them to insure a thorough covering of the whole surface. It is well to make several applications over the same spots in one nostril at a sitting, as mucus may prevent a sensitive spot from being touched. If the patient is anxious for relief and willing to stand the greater discomfort for a shorter time, both nostrils may be treated at once. Should the new surface prove endowed with abnormal sensibility the process may be repeated without hesitation till the desired grade of nerve adjustment is reached. Treatment may be begun during the height of an attack, although if severe conjunctivitis is present it is well to proceed cautiously, as the inflammation excited by the acid, when applied in places most likely to be diseased, may increase the determination of blood to the eyes. Severe conjunctivitis is well treated by allowing fifteen drops of a solution of ½ per cent. of cocaine and 3 per cent. of boracic acid to fall into the eye and to be carried about for a few minutes by winking. The prone position is necessary for this purpose. Special attention should be paid to the anterior part of the upper turbinated body and to the anterior angle of the nose, as nature seems to have placed there the most sensitive nerves for the purpose of excluding noxious gases and irritants at the threshold of the respiratory apparatus. If the patient is unusually intolerant of pain the nostrils may be painted with a 2 or 4 per cent. solution of cocaine, but this drug should not be mixed with the chromic acid, as it is immediately precipitated in a gummy mass. The patient may advantageously make these applications himself under the supervision of a physician. Assured that his sensations will not allow him to do harm, he will quickly learn to distinguish the peculiar and indescribable feeling of the hyper-sensitive spots and to make applications to them with certainty. The amount of cotton to be used is shown in the cut. This should be soaked, and any excess allowed to drop off, as it might be drawn back into the throat by inspiration, and cause pain and coughing. The treatment will at the least consume several days, and possibly a few weeks. For instant relief only palliative measures will answer, and a year's experience with the cocaine and atropine treatment in the hands of other observers has confirmed the claims made for it as being effective and free from danger of poisoning or habit creation.

The immediate effect of chromic acid is to cause obstruction and watering of the nose and lachrymation. These symptoms displace the complex and far more annoying symptoms of hay-fever. Within a few minutes the discomfort and watering of the eyes begin to diminish, and in about one-half hour the watering and obstruction of the nose begin to abate. The patient should be instructed to use a cheap handkerchief at least during the hour after an operation, as the mucus is then capable of destroying even such resistant fibres as silk and linen, a good evidence of its energy in the solutions recommended. Neither the interior nor the exterior of the nose is rendered sore by any acid which happens to touch a place not intended. The imperfect sleep of hay-fever is improved. The power of chromic acid to promote the growth of normal mucous membrane is proved by the increase it effects in the delicacy of the sense of smell. This effect is due in part to the tendency to contraction exerted by chromic acid on the tissues, of which tendency advantage is taken by this method of application which is able to carry the acid directly to the surface exposing the end filaments of the olfactory nerve. The principal seat of the sense of smell is a narrow chink situated in the upper anterior region of the nose, a space prone to engorgement, as is proved by the obliteration of smell in incipient coryza before the wider breathing spaces below are obstructed. Obviously the widening of this chink, by allowing access of scent-bearing air to the olfactory nerve, will promote the perception of smells, and, furthermore, it will *add to mental activity, which is very closely dependent upon perviousness in this region* owing to the path followed by blood going to the fore-brain. The contraction of tissues is often sought by means of the cautery, and frequently defeated by the total regeneration of the burnt portion. When attained it is often attributable to the formation of scar-tissue, which is well known to be abnormally subject to malignant degeneration. Moreover, scar-tissue is insensitive to normal stimuli, and therefore a permanent damage to the organ.

The wider knowledge arising from the attention paid to hay-fever within the last decade has demonstrated beyond question that this misnomer improperly groups varying combinations of symptoms arising from a large number of causes. The physician should not accept a patient's self-diagnosis, but should draw his own conclusions from a separate examination of each case. By such examination he will be guided to a knowledge of the special cause, and therefore to the most effective treatment—for some tonics, for others sedatives or antipyretics, for others surgical or local measures. But, after all known methods of treatment have been tried, there has still remained a proportion of unexplained failures to cure, and it is believed that the measures above outlined will lead to the reduction, if not the entire obliteration, of this remainder.

NEWS ITEMS.

Rembrandt's "Lesson in Anatomy."—Rembrandt's celebrated picture entitled "A Lesson in Anatomy," a full size copy of which hangs at present in the hall of the College of Physicians of Philadelphia, has, we understand, been purchased by Mr. Ellesworth, for the Institute of Art, of Chicago. It formerly belonged to the Princess de Sagan, and until recently has been in an art gallery in the Hague.

Execution by Electricity.—At a recent meeting of the Paris Academy of Sciences a communication from Mr. Edison was read respecting the use of electricity as a means of inflicting capital punishment. He is of opinion that an alternative current will cause death without pain, but he adduces no experimental evidence in support of

that contention. The matter was referred to the Medical Section of the Academy, which is to have the assistance of M. Marcel Desprez, the electrician, in drawing up a report on the subject.—*British Med. Journal*, September 21, 1889.

Opening of the Training School of the Johns Hopkins Hospital.—The Training School of the Johns Hopkins Hospital, Baltimore, was opened with appropriate ceremonies on Wednesday afternoon, October 9th, at half-past three o'clock.

The Medical and Chirurgical Society.—The London strikes have had their effect in medical circles. The erection of the new edifice of the Royal Medical and Chirurgical Society, in Hanover Square, has been seriously delayed, so that it is doubtful if the new library and rooms for meeting can be utilized during the coming winter. Three other societies, the Pathological, the Clinical, and the Obstetrical, expected to enjoy the privileges of the new buildings, but are now, for an indefinite period, without suitable accommodations for their meetings.

Vindication of an Accused Physician.—The *cause célèbre* at Brooklyn, known as the Bogert-Duncan case, has passed its first stage. The charge against Dr. Bogert, brought by the Commissioner of Health, Dr. Griffin, has been dismissed in the police court. Dr. Bogert was accused of wilful violation of the sanitary ordinances in that he did not report the case of his friend, Dr. Duncan, of the steamer "Colon," when treating him for yellow fever. Dr. Bogert, who has always denied the fact of yellow fever, and who, the other day, had the Health Officer of the Port, and five other medical witnesses, ready in court to testify to his correctness in diagnosis, has been anxious to have his hearing in the courts. The complainant asked for an adjournment, the fifth or sixth, which was more than the Justice could allow, and the case was dismissed in default. It may, of course, be heard anew, but the present position is practically a vindication of the accused. Again, Dr. Bogert has a serious grievance against the Board of Health for holding him a prisoner, at the residence of his patient, under the guise of a quarantine. He and his friends have repeatedly threatened to bring suit against the city for damages due to this duress, which lasted two days and over. That this will ever be done is most doubtful, for such matters move too slowly to be either entertaining or instructive. A lesson has probably been learned, however, by the health officials. They know that if they imprison a medical man at the house of his patient, in *quasi* quarantine, there is very soon thereafter to be a storm in the profession which will be unpleasant and injurious. Not even the fear of yellow fever will ward off this result.

American Public Health Association.—We are in receipt of the circular of the American Public Health Association, which contains the programme of the seventeenth annual meeting, which is to be held at the Brooklyn Institute, Brooklyn, N. Y., from October 22d to 25th, inclusive. Among the principal subjects for consideration we note the following:

1. Causes and Prevention of Infant Mortality.
2. Railway Sanitation.
3. Steamship Sanitation.
4. Methods of Scientific Cooking.
5. Yellow Fever.
6. The Prevention of Tuberculosis in Man.
7. Methods of Preventing Diphtheria, etc.

Over twenty original papers will be presented. Among the speakers we notice the names of Drs. John S. Billings, George M. Sternberg, Henry B. Baker, Henry Leffmann, J. N. McCormack, and others equally well known. The meeting will be rendered still more interesting by an exhibition of sanitary goods and appliances. An address of welcome will be delivered by Hon. Alfred C. Chapin, Mayor of Brookyn, and also by Dr. Alexander Hutchins on behalf of the profession.

The Secretary, Dr. Irving A. Watson, gives, in the circular, all necessary information concerning reduced hotel and railroad rates. The meeting will be presided over by Professor Hosmer A. Johnson, M.D., of Chicago.

The profession in general is cordially invited to attend the meeting, and both ladies and gentlemen of the laity will be welcomed to the evening sessions.

Cholera on the Euphrates.—Latest advices inform us that cholera still continues to be epidemic at Bassorah, Bagdad, and other places on the Euphrates. The death-rate is said to be very great.

New German Pharmacopœia.—The Imperial Pharmacopœia Commission of Germany is to meet in Berlin this month, in order to frame the third edition of the Pharmacopœia Germanica. It is their aim to have the work completed by 1890. All recent additions to materia medica will be incorporated in this new edition. In addition to the Pharmacopœia the German Society of Apothecaries intend issuing a supplement which will deal with all the remedies not given in the official dispensatory. The profits accruing to the Society from the sale of this supplement will, it is said, be devoted to a philanthropic cause.

Mortality in Philadelphia.—During the week ending September 28th there were 312 deaths in this city. This includes the following deaths from infectious diseases:

Enteric fever	15
Scarlet fever	2
Diphtheria	3
Whooping-cough	2

Scarlet Fever in London.—The epidemic of scarlet fever in London seems to be steadily on the increase. According to the *Medical Press and Circular* of September 25th, the number of cases under treatment in the hospitals of the Metropolitan Asylums Board, on September 17th, amounted to 1070.

Illness of Dr. F. X. Dercum.—We regret to learn that Dr. F. X. Dercum, the Instructor in Nervous Diseases in the University of Pennsylvania, is seriously ill with typhoid fever.

New Building for the Philadelphia Polyclinic.—The contract for the erection of the new college, hospital, and dispensary building of the Philadelphia Polyclinic and

College for Graduates in Medicine was awarded last Saturday.

The new structure will rest on a lot 96 feet by 143 feet, about three blocks from the present temporary quarters, and will be of brick, sand-stone, and terra-cotta. It will be four stories in height, and will occupy at present only one-half of the lot.

The important features of the building will be the incorporation of the most modern accepted plans in hospital construction.

The system of heating will be by indirect radiation, and the ventilation that of sub-stratum suction. All corners in the building will be rounded to avoid the accumulation of dust. The water-closets and bath-rooms will be in a separate building easily accessible from all parts of the building. The kitchen and laundry will be at the top, separated from the lower floors by an artificial stone floor. The clinic rooms will be on the first floor in direct communication with a spacious waiting-room.

The corner-stone will be laid with the impressive masonic ceremonies on November 2d, on which occasion it is hoped that the committee having the matter in charge, will be able to present the fund for the perpetual endowment of a free bed in the name of Dr. R. J. Levis, as a testimonial of esteem, and in recognition of his professional eminence.

Electricity at the Howard Hospital.—At the Howard Hospital, Broad and Catharine Streets, Philadelphia, electricity is now a special feature of one of the gynecological clinics, under the charge of Dr. G. Betton Massey, who invites the profession to send cases there for which this treatment is appropriate, particularly fibroid tumors. The clinics are held Mondays, Wednesdays, and Fridays, at 12 M.

Dr. Roberts Bartholow.—For the past few days a report has been widely circulated through this city to the effect that Dr. Bartholow had been called to Milwaukee to see one of the millionaires of that city, the fee to be paid being one of the largest in the history of medicine. An enterprising New York reporter has prepared a long article on the subject. We learn from correct sources that the story is a hoax, and that there is no truth in it, except the fact that the members of the profession of this city are recognized as worthy of handsome remuneration.

Death of Professor Rudolph Voltolini.—Laryngology abroad has lost one of its most prominent representatives in the person of Professor Rudolph Voltolini, of Breslau, who died on September 11th, in his seventy-first year. Voltolini was an enthusiastic worker in the field of medicine which he had chosen. He has been not unjustly called the father of rhinoscopy, and certainly did more to improve the *technique* of that difficult art than any other teacher. He was a most able writer, being one of the editors of the *Monatschrift für Ohrenheilkunde* up to the time of his death. He was also the author of numerous works dealing with his specialty.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING OCTOBER 5, 1889.

HARMON, GEORGE E. H., *Surgeon.*—Detached from the U. S. S. "Constellation," and ordered to the Naval Academy.

LOWNDES, C. H. T., *Assistant Surgeon.*—Detached from the U. S. S. "Constellation," and ordered to the Naval Academy.

WINSLOW, GEORGE F., *Surgeon*—Ordered to Marine Rendezvous, Boston.

HENRY, CHARLES P., *Assistant Surgeon.*—Ordered before the Retiring Board for examination.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM AUGUST 24 TO OCTOBER 5, 1889.

FESSENDEN, C. S. D., *Surgeon.*—Granted leave of absence for thirty days, October 3, 1889.

WYMAN, WALTER, *Surgeon.*—Granted leave of absence for thirty days, September 3 and 21, 1889.

SAWTELLE, H. W., *Surgeon.*—Granted leave of absence for seven days, September 26, 1889.

AUSTIN, H. W., *Surgeon.*—Granted leave of absence for thirty days, September 9, 1889.

GASSAWAY, J. M., *Surgeon.*—When relieved at New Orleans, La., to rejoin station at Cairo, Ill., September 30, 1889.

GOLDSBOROUGH, C. B., *Surgeon.*—Leave of absence extended thirty days, on surgeon's certificate of disability, September 16, 1889.

ARMSTRONG, S. T., *Passed Assistant Surgeon.*—Relieved from duty at New York; ordered to command of Service at Cleveland, Ohio, September 17, 1889.

AMES, R. P. M., *Passed Assistant Surgeon.*—Assigned to duty at New Orleans, La., upon expiration of leave of absence, September 30, 1889.

WHITE, J. H., *Passed Assistant Surgeon.*—Leave of absence extended thirty days, on surgeon's certificate of disability, September 21, 1889.

NORMAN, SEATON, *Assistant Surgeon.*—Granted leave of absence for thirty days, to take effect when relieved, October 4, 1889.

PETTUS, W. J., *Assistant Surgeon.*—Ordered to Portland, Me., for temporary duty, September 26, 1889. Granted leave of absence for twenty-six days, to take effect when relieved, October 3, 1889.

KINYOUN, J. J., *Assistant Surgeon.*—Granted leave of absence for thirty days, September 21, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 1 TO OCTOBER 7, 1889.

POINDEXTER, JEFFERSON D., *Assistant Surgeon.*—Granted leave of absence for one month.—*S. O. 115, Headquarters Department of Dakota*, September 30, 1889.

BILLINGS, JOHN S., *Surgeon.*—Detailed as delegate to represent the Medical Department of the Army at the annual meeting of the American Public Health Association, to be held at Brooklyn, New York, October 22, 1889.—Par. 10, *S. O. 230, A. G. O.*, October 3, 1889.

POPE, BENJAMIN F., *Surgeon.*—Relieved from duty at Fort Clark, Texas, and will report for duty to commanding officer Whipple Barracks, Arizona Territory.—Par. 11, *S. O. 230, A. G. O.*, October 3, 1889.

TREMAINE, WILLIAM S., *Surgeon.*—Relieved from duty at Fort Leavenworth, Kansas, and will return to his home, Buffalo, New York.—Par. 13, *S. O. 230, A. G. O.*, October 3, 1889.

KENDALL, WILLIAM P., *Assistant Surgeon.*—Granted leave of absence for one month.—*S. O. 93, Department of the Platte*, October 2, 1889.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

THE RELATIONS OF ANÆMIA TO CHLOROSIS.[1]

BY F. FORCHHEIMER, M.D., *Co-referee*,

PROFESSOR OF PHYSIOLOGY AND THE CLINICAL DISEASES OF CHILDREN IN THE MEDICAL COLLEGE OF OHIO, CINCINNATI.

IN order to bring the whole subject up for discussion, as proposed by the Council of the Association, the referee and co-referee have thought it judicious to divide it into two sections. This has seemed the more proper as, upon mature consideration, compression of the more or less vague data into the allotted space and time seems almost impossible. To those who have occupied themselves with the pathology of the blood, and there are several in our midst whose names occupy a high position in this respect, the fact is apparent that confusion reigns supreme in this field which might, possibly, be easily cleared away if exact methods of examination were employed. Under all circumstances, our lines might be more strictly drawn and a beginning made for the more accurate and scientific study of these subjects; in this way elimination of one disease from another or identification would follow, and much benefit would accrue.

In the discussion of our present subject, the first thing that comes up to confuse us is the definition of the two diseases. Immermann (Ziemssen's *Hdbch.*, xiii. p. 275) begins his definition as follows: "The conception of anæmia, somewhat indefinite in its elasticity, etc.," and follows it up with nearly two pages of text, from which the final conclusion is to be drawn that, partly from clinical and partly from direct (analytical) evidence, we are justified in stating that anæmia is that condition in which there is a diminution of red corpuscles as well as of the albumins of the plasma in the blood (hypalbuminosis). Strümpell (*A Text-book of Medicine*, edited by Frederick C. Shattuck, A.M., M.D., p. 874) states that "the essential element in anæmia is, therefore, a diminution in the number of red corpuscles, or so-called oligocythæmia," and states further on that "oligocythæmia is not invariably accompanied by a diminution in the amount of serum-albumin (by which he means plasma—hypalbuminosis)."

If we go on we shall find that anæmia or oligæmia vera really means a diminution of the whole quantity of the blood, and that this condition can be subdivided into hydræmia, oligocythæmia, oligæmia sicca, and oligæmia hypalbuminosa. We have, then, three representative definitions: the one broad and general, including a diminution of any one, or all the constituents of the blood; a second, in which hypalbuminosis and oligocythæmia are the principal, if not the only factors; and a third, which makes oligocythæmia alone the characteristic feature. It seems to me that, from a purely practical standpoint, the latter is the best; we are not in a position to determine the whole quantity of blood in a living animal, nor, for more reasons than one, can we make a chemical analysis of blood in any individual case. But we can readily determine the number of red corpuscles in any patient, and, if it be admitted that hypalbuminosis and oligocythæmia go together in the great majority of cases, it will become unnecessary to make a chemical examination of the blood.

A search amongst the authorities for a definition of chlorosis puts us in a much sadder plight than did anæmia. One type of writers is, perhaps, best represented by Coupland in his excellent course of Gulstonian Lectures (*Lancet*, 1881), who says: "I believe chlorosis to be a form of anæmia depending upon similar changes, and, therefore, to be considered as falling under the head of idiopathic anæmia." It is but just to add that this author defines anæmia as that condition in which the essential feature is the reduction of the hæmoglobin. Zender (Virchow's *Archiv*, 1881) conceives chlorosis to consist in defective formation of red blood-corpuscles, both quantitatively as well as qualitatively, and adds, further on, that, as iron is diminished in the blood and not excreted, the fault must lie in defective absorption. Then we have authors like Strümpell (*loc. cit.*), who, defining anæmia as oligocythæmia, state that chlorosis is a term applied to the mild forms of essential anæmia, such as are most often seen in females at the time of puberty. Immermann makes the disease dependent upon a diminution of hæmoglobin, but is not willing to commit himself by stating whether this is absolute for a single red corpuscle or for the whole quantity of blood.

We now come to what seems to me to be the turning-point in the finding of a sharp, distinctive definition, which is to be found in Duncan (*Sitzungsberichte d. Acad. d. Wissenschaften*, Wien, 1867). As far as I know, he was the first to make the distinctive feature oligochromæmia characteristic for

[1] Read before the Association of American Physicians, September, 1889.

chlorosis—that is, in chlorosis we find the individual red corpuscle deficient in hæmoglobin. It will be readily seen that a deficiency in hæmoglobin would exist in any condition in which the number of red corpuscles is diminished; this would be called anæmia according to the definition we have accepted. But the red corpuscles being normal as to quantity and the hæmoglobin diminished, we would be justified in concluding that each individual red corpuscle carries too little hæmoglobin, and this condition would be called chlorosis.

Unfortunately for this definition, the term chlorosis is to be looked upon as an essentially clinical one; it is not going too far to state, I think, that by far the great majority of reported cases of chlorosis are not chlorosis at all. In Germany every other girl is called *bleichsüchtig* (chlorotic), the diagnosis being made by the people and then verified by the physicians; with us chlorosis is a comparatively rare affection, and yet no one doubts for a moment that there are just as many, if not more, anæmic girls in this country than in Germany. In Russia almost all women are said to be chlorotic, especially in the cities; even the lower strata of society are convinced that they have chlorosis. Five or six years ago a great tide of emigration swept from that country to ours; I had occasion to examine a great many of these women, and every case was one of anæmia and not of chlorosis. Within the last year I have seen an American girl who had been compelled to stay in St. Petersburg for several years; she was pronounced chlorotic there by an eminent physician; examination of her blood revealed oligocythæmia (about seventy per cent.) and a proportionate oligochromæmia. This girl was very anæmic, but, according to the conception which we would ask to be accepted, she was not chlorotic.

Another difficulty in the drawing of strict lines consists in the fact that both oligocythæmia and oligochromæmia may occur in the same individual, so that the term chloranæmia is one that is justified by observation of existing conditions. It is more than probable that anæmia is a forerunner of chlorosis in a great many instances, and, possibly, a very great number of cases occur in which there is a combination of both conditions.

As far as the causes for both conditions are concerned, it will be seen that almost every one put down for anæmia will hold good for chlorosis. Without entering into detail upon this division of the subject, it can be stated that sex, age, a peculiar composition of the blood, and certain vascular anomalies first pointed out by Virchow in 1870, are held to be especially characteristic for chlorosis. If we analyze each one of these causes, it will be seen that the latter two are the only ones to be found in chlorosis. While there can be no possible doubt that chlorosis is a disease of females at puberty, yet cases have been described in which chlorosis has been found in males, and a great many cases are upon record in which the disease has developed either earlier or later than puberty (as late as fifty-seven years, Cantrel). Here, again, the "elasticity" of the term chlorosis must be taken into consideration. In regard to chlorosis in males, if we read the report of the case given by Immermann (p. 532, *loc. cit.*), it will be seen, that this author has given us no positive proof at all that his case is not one of anæmia, although he warns against the too ready acceptance of cases of anæmia as chlorosis. The fact that this case was relieved by energetic chalybeate treatment is apparently looked upon by the author as convincing evidence that it was one of chlorosis. In cases of so-called school-anæmia we are accustomed to expect good results from removal from school and the administration of iron.

As to the age of patients, the process of sexual development has always been looked to as the time of most common occurrence of chlorosis; in anæmia this age also produces a great number of cases, but children and old people are subject to anæmia and, practically, excluded from chlorosis. For the explanation of this fact it became necessary to conceive of the existence of some physical anomaly in the sexual organs; lack of development, malformation, etc. The clinical fact that in some cases we find amenorrhœa, in some comparatively normal menstruation, and in others menorrhagia, ought to have been sufficient testimony to show that there was no constant genital factor, and, in some cases, none at all. Investigations upon the post-mortem table have verified these statements, and we, therefore, find the genitals well and normally developed in some cases, in others too great a development, and in others a deficiency. These changes are so varied as to the external genitals, the uterus, and the ovaries, that no causative relation can be established between these lesions and the disease. It is more than probable that the relation is that of effect to cause and not of cause to effect; in other words, that the lesions in the genital organs are due to chlorosis (or anæmia).

It will be seen by examining statistics that by far the greatest number of cases occur between the ages of fifteen and twenty-five—*i. e.*, decidedly after the time of the age of first menstruation, which is supposed to occur between the ages of twelve and fifteen years. Furthermore, the observation that an anæmic constitution is a very strong predisposing cause for chlorosis, has been made by almost every author; some authors, in their description, make cases of anæmia more intense and then call the condition chlorosis. It seems justifiable to conclude that a great many cases of chlorosis have their inception in ordinary cases of anæmia. The continued effort of menstruation and, possibly, the un-

accustomed loss of blood going on for a period of time extending over from three to ten years, in an anæmic patient having the peculiar metabolism of anæmia, seems to be sufficient to establish the condition we consider characteristic for chlorosis. Again, the fact must not be lost sight of that a comparatively slight cause may set up the condition of chlorosis in a female who has always been considered perfectly healthy. Yet, occurrences like these must be looked upon as exceptions.

The clinical characteristic of chlorosis lies in the peculiar changes in the blood—changes which have been denied by some authors, and the strict meaning of which has been accepted by few. In anæmia we have the red corpuscles as well as the albumins of the plasma reduced in quantity; frequently there is a change in size, shape, and quality of the corpuscles (Osler, Cartwright Lectures, 1886). The change in size of the red corpuscle is in the direction of production of a greater number of smaller corpuscles (microcytes). As a result of the reduction in the number of red corpuscles the hæmoglobin is correspondingly reduced in quantity. In pure chlorosis the number of red corpuscles is not diminished at all, or so slightly that the diminution may be ascribed to the method of enumeration. On the other hand, the tendency to the production of red corpuscles of larger diameter than normal (megalocytes) is especially well marked in chlorosis. While we do not fail to find an appreciable number of microcytes, the large number of megalocytes found is apparent upon very superficial observation. Malassez gives the average size of the red corpuscle in chlorosis as 8.29 μ (7.60 being normal), and the relative size as 1.09 μ (1 being normal). These changes, although present to a greater or less extent in every case of chlorosis, are by no means sufficiently characteristic to establish a diagnosis or to enable us to exclude other forms of alterations in the blood. The red corpuscle in chlorotic blood seems decidedly pale to one who has had the color of the individual corpuscle firmly impressed upon his mind. When we deal with large quantities of blood this is apparent to the untrained without any further remark, but the change under the microscope is just as appreciable when the comparison is made with healthy blood. When the blood is examined with the spectroscope or the hæmoglobinometer, the reason for this paleness is readily explained; we find a great diminution in hæmoglobin. But this is found in any form of anæmia, so that it becomes necessary to establish the amount of hæmoglobin in each individual corpuscle. In order to do this we must employ the fraction first suggested by Gowers, in which the numerator is the percentage of hæmoglobin, and the denominator the percentage of corpuscles. It is not necessary, before this Association, to point out the possibilities of errors in this computation. Gowers says of his instrument that it "is only expected to yield approximate results, accurate within two or three per cent." The more recent instruments are more accurate, possibly, but nevertheless errors are unavoidable.

It seems to me that one great source of error which has been overlooked in all these computations is the neglect of taking the average size of the red corpuscle into consideration. It is true that this is comparatively small when compared with an error of three per cent., yet it would be appreciable when we are dealing with a sample of blood in which the average size of the red corpuscle is very much increased. In order to correct this, the following computation could be made, A representing the average size of the red corpuscle of the examined blood, and B Gowers's fraction:

$$A : 7.50 :: B : x, \quad \text{where } x = \frac{7.50 \times B}{A}.$$

Thus, if we take a sample of blood in which, by Gowers's equation, the quantity of hæmoglobin in an individual corpuscle is estimated at $\frac{30}{60}$, and correct by the above formula, using Malassez's figure (8.29 μ), it will be found that the individual corpuscle contains only $\frac{27}{60}$ of hæmoglobin, certainly a decided difference. At the end, however, the point to be made in the establishment of the diagnosis of chlorosis is that the single red corpuscle contains less hæmoglobin than normal. It must be added that the amount must be greatly reduced, because of the fact that our methods of computation are not such as could be called mathematically precise, though sufficiently so for clinical purposes.

The difference in the quantity of albumins may be considered another distinctive feature between anæmia and chlorosis. It is said that in anæmia we always have hypalbuminosis, while in chlorosis this is absent. It must be confessed that the statements of authors are so contradictory upon this question, that a definite conclusion cannot be arrived at. It is necessary that this part of the subject be reinvestigated and then, possibly, a positive result will follow. The statement that chlorosis is a cytogenic affection and anæmia both a cytogenic as well as a general affection of the blood is one that, as yet, cannot be considered proven.

One respect in which chlorosis is said to differ materially, if not absolutely, from anæmia, consists in the pathological changes first described by Virchow. These changes can be briefly characterized as hyperplasia of the vascular apparatus—narrowing of the lumen of the aorta and larger arteries, as well as thinning of their walls. The heart itself is sometimes found small, at other times hypertrophied. According to this view, every case of chlorosis is congenital and must be due to some faulty develop-

ment of the mesoblast; it would permit us to state that chlorosis is always congenital, in some cases latent for years, while anæmia, in most cases, is acquired.

A great many objections have been raised against this view; they cannot "be considered as underlying every case of chlorosis or, at any rate, existing as a cause of the anæmia;" "no proof has been given that the diminution in size of the vessel has not followed upon diminution in the total quantity of blood" (Coupland, *loc. cit.*). The first of Coupland's objections certainly holds good; hyperplasia occurs in a great many males, in a far greater number than will be admitted by even the most enthusiastic defenders of male chlorosis, and, in proportion to the number of females attacked, it is found in a very small number of post-mortem examinations. The second objection—*i. e.*, that we may be dealing with an effect and not a cause—is one that is not easily proven; if it is an effect, it can certainly not be due to a "diminution of the total quantity of blood," for, when this does occur in chlorosis, it is not as great as it is in anæmia, and, probably, with this hyperplasia there frequently occurs a plethora. However this may be, to the best of my knowledge no author has been found who is willing to state that this condition of the bloodvessels is found in any other disease than chlorosis. Even if we are not disposed to look upon these changes as a direct cause, we must certainly be prepared to consider them as predisposing to chlorosis on account of the frequent coincidences of the two.

The relation of the symptoms of anæmia to chlorosis depends upon the conditions of the blood and the anatomical substrata. Given a case of anæmia in which there is only a reduction of hæmoglobin as a result of oligocythæmia, and a case of chlorosis in which there is a reduction of hæmoglobin as a result of oligochromæmia, and metabolism in both of these cases will be approximately the same. It is true that the patient with chlorosis will have a different facies; as the essence of the affection lies in oligochromæmia, the amount of reduction in hæmoglobin, if due to oligocythæmia simply, would be so great as to become a physical impossibility, inconsistent with life. But if, in anæmia, we have oligocythæmia as well as hypalbuminosis, which is said to be coexistent in the majority of cases, the metabolism must be different from that of a pure case of oligochromæmia. As a result of reduction in hæmoglobin we have simply a reduction in the process of oxidation in the body; at the same time the waste products are carried off and sufficient albuminous food is carried to the tissues by the plasma of the blood which is unchanged. In this way the general nutrition of the body is apparently not interfered with. Indeed, there may be, and there frequently is, an increased deposit of material in chlorosis, because oxidation is not sufficient to utilize the albumins of the plasma; the result of this process of suboxidation is a deposit of fat, all of which Immermann calls the "nucleus" of the clinical differences between anæmia and chlorosis.

Hypalbuminosis and oligocythæmia produce an entirely different result; as before, we have the same factor, suboxidation, but we have, in addition, a deficiency in supply. Furthermore, those functions of the plasma otherwise than nutritive are seriously interfered with. Its physical conditions are changed, it does not serve the processes of secretion and excretion as it should, and, being full of excrementitious material, the result is the retention of these substances, the production of fever, etc. In mild cases of anæmia there is produced a loss in weight, in severe cases there is produced that condition which we call marasmus. In chlorosis very little, if any, loss of weight occurs; very frequently the opposite is brought about by a too great supply, and especially by the presence of too much CO_2, preventing the decomposition of the fats. But when anæmia is associated with chlorosis we have a very unfortunate combination, especially where there is a great amount of hypalbuminosis. These are the cases in which the development of pernicious anæmia as a direct consequence of chlorosis can be readily explained. The chlorosis produces oligocythæmia and hypalbuminosis as a result of deficient external food-supply; these two produce the metabolic combination stated above; and, finally, we have established a *circulus vitiosus* into which it seems impossible to break. But these combinations must certainly be looked upon as of extreme rarity.

Unless we believe Virchow's anatomical lesions to belong only to chlorosis, there exists no difference between the symptoms of the two diseases. When these are present they manifest themselves by the ordinary objective signs of whatever change there may be in the heart. We have a normal heart, one that is too small, or one that is larger than normal. The most interesting change that we find is the dilatation of the left ventricle. Considering the hæmic bruits that occur in the heart, it sometimes becomes quite difficult to state whether or not we are dealing with a valvular lesion. The dilatation of the left ventricle may be transitory in its nature, depending, as it does, for its existence upon the quantity of blood to be pumped through the narrowed arteries.

Reference must also be made to symptoms on the part of the nervous system; these have been made one of the characteristics for chlorosis. Hysteria and hysterical conditions are of such common occurrence nowadays, that it seems impossible to make any one condition responsible for them. A careful analysis of female anæmic cases would, I think, demonstrate the fact that just as many of these are

hysterical as in the same number of chlorotics. Before making a careful examination of the blood, it would be very risky to make the diagnosis of oligochromæmia in a patient who is both anæmic and hysterical.

Lastly, we have to consider the therapeutic relations of both diseases. While the reasoning of *ex juvantibus* is certainly justifiable under certain circumstances, it seems to me to be strained in its application by Immermann. He speaks of specific medication, and says that the ease with which iron controls the symptoms of chlorosis is "characteristic" for the latter disease—as "a fortunate relation, which is not found, to the same extent, in any other form of anæmic process, and which, therefore, deserves to be considered as one of the essential peculiarities of the trouble." The degree of success and the time in which it follows the use of chalybeates are to be distinctive for chlorosis as opposed to all other anæmic processes. From a scientific standpoint, this certainly seems a very weak argument to offer, and one that depends, for its verification, upon the individual employing it. To what extent must improvement follow, and in what time, before one case can be called chlorosis and another anæmia? The fact must not be lost sight of, that a great many cases of anæmia are just as much improved by iron as are cases of chlorosis. Although the indiscriminate use of iron in anæmia must be deprecated, yet, upon the whole, iron is just as much looked upon as a specific in anæmia as in chlorosis. As we are led to expect from the essential symptoms of chlorosis, iron would be indicated in every case, and very few authors will be found who do not confirm this therapeutic indication. While, then, we would not be willing to separate anæmia from chlorosis, we are justified in the statement that iron ought to be given in every case of chlorosis, on account of the rapidity and intensity of the chalybeate effect.

Where, in anæmia, we try to remove the cause and institute causal treatment, we are satisfied, in chlorosis, with removing that symptom which is the essential of the disease, either on account of the fact that we are ignorant of the first cause, or on account of our inability to remove it. It has been repeatedly demonstrated that this can be done, and, furthermore, that the removal of this essential symptom is followed temporarily by complete recovery. Whereas, in anæmia, treatment is followed by complete recovery or complete failure, iron in chlorosis will always result in amelioration, even if we cannot remove the tendency to relapses. There are very few cases of chlorosis, even those with the lesions of Virchow, that are not benefited by the administration of iron in sufficient quantity. In a great many cases of anæmia the use of iron would be followed either by negative or by bad results.

AGAINST SECTARIANISM IN MEDICINE.[1]

By EDWARD JACKSON, M.D.,
PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC.

The idea on which the following argument is based has been thus expressed by the late Prof. George B. Wood: "Conscientious convictions should be respected, even though based on ignorance and delusion, and so prone is the human intellect to every kind of aberration that we may readily admit the possibility of an honest conversion from orthodoxy in medicine to the wildest creed that ever sprang from a deluded imagination."[2]

There are many things to engender mutual distrust among practitioners of medicine, and set them against one another. Beside the rivalry, which often seems to preclude the possibility of kindly relations in every walk of life, there is much that is peculiar to our profession. The dogmatic way in which a professional opinion must be stated to make it clearly intelligent to the patient, is often at variance with the meagreness of the scientific facts that could be adduced to support it, and we must often speak positively of matters concerning which there can reasonably be great doubt; the demands of the sick-room for positive action are so opposed to the nice balancing of scientific probabilities—that the management of each case lays the physician open to controversial attack. Then, too, in the domain of medicine, so much is half-knowledge and surmise, there is so much room for honest difference of opinion, that uniformity cannot be looked for, while the issues that hang on the correctness of opinion are so important as necessarily to elicit strong feeling, making diversity of view particularly liable to end in strife.

But there are most weighty reasons why strife should be prevented. There is no attitude of mind more unsuited to the perception of truth, the observation and correct interpretation of phenomena, the exercise of the best judgment, than the controversial. The medical controversies of all times illustrate the evils of intolerance, the benefits of coöperation. Whether we study the struggle of the empirics and methodics, of Cullen and Brown, of Rush and most of his prominent contemporaries, or the controversies over the tubercle bacillus, or the treatment of pyosalpinx in our own societies, the lesson is the same. All experience teaches that the condition of professional harmony and coöperation which renders the skill and learning of each available for the aid and instruction of all, furnishes the most efficient service to the community, and conduces most to the welfare, influence, and honor of the profession.

[1] Read before the Philadelphia County Medical Society, September 25, 1889.

[2] Introductory Lectures and Addresses.

To associate all members of the medical profession in hearty good feeling and earnest coöperation has been the dream, the desire, the high purpose of our best leaders in professional organization. Such was the purpose that founded the American Medical Association, shaped its code of ethics, and drew to its support the best part of the profession. That purpose is fulfilled in so far as our organization is made to include every worthy member of the profession, and is defeated in so far as any are excluded. If, as a branch of the American Medical Association, we should stand for any one peculiar idea, it is for that of the organization of the whole profession into one body, as opposed to that of its organization upon lines of medical dogma into separate and antagonistic sects.

In the process of organization it became necessary to indicate who should, and who should not, be regarded as members of the profession. But the only exclusive clause in our code of ethics reads: "No one can be considered a regular practitioner or fit associate in consultation, whose practice is based on an exclusive dogma, to the rejection of the accumulated experience of the profession, and of the aids actually furnished by anatomy, physiology, pathology, and organic chemistry." The same paragraph of the code says: "A regular medical education furnishes the only presumptive evidence of professional abilities and acquirements," but gives no definition of a regular medical education other than such as may be inferred from the foregoing passage, viz., that it shall not be confined to the study of a single dogma, or set of dogmas, or neglect the aids of anatomy, physiology, or organic chemistry.

There is, however, a tendency to narrow the interpretation of the word "regular" until it shall no longer convey its proper meaning, namely, that the person to whom it is applied has successfully completed a full course of medical study; but merely that he belongs to a certain school or sect in medicine, which differs from other schools or sects mainly as to the importance of certain medical dogmas or doctrines.

As generalities are so easily misunderstood or misinterpreted, let us take a special case. In this city there is an institution called "The Hahnemann Medical College and Hospital." I certainly do not share the feeling that led to the naming of it from Hahnemann. Still it is conceivable that, in spite of its name, the study of anatomy, physiology, or organic chemistry will yield within its walls very much the same results as elsewhere; and the only fair way to judge whether or not its graduates have received a regular medical education is to examine its curriculum, and to find out how thoroughly that curriculum is enforced.

In judging how the compilers of our code of ethics used the phrase "a regular medical education," it should be borne in mind that at the time the code was drawn up there was no homœopathic medical college in existence. An institution to teach homœopathy had been started a few years before at Allentown, Pa. It soon became extinct. But it had conferred the degree, not of Doctor of Medicine, but of Doctor of Homœopathia, and its curriculum could not be fairly said to offer a regular course of medical instruction. At this time, too, the homœopathic medical societies consisted often largely of laymen, and a large proportion of those who were professing to practise homœopathy were as destitute of any medical education as many of the faith-curers of to-day. Such being their lack of qualification for medical practice, they, of course, fell under ban as irregular practitioners. But time that changes all things has wrought a transformation in the homœopathist that many of us have not fully realized. Consider the requirements for graduation in the Hahnemann Medical College, as set forth in its last annual announcement, and I know of no reason for doubting that these requirements are lived up to as well as are the corresponding requirements in most of the medical schools that we all agree are "regular." The course is a three years' graded course, the length of term six months. In anatomy, two courses, four lectures a week, and the text-books are Gray's and Wilson's. In practical anatomy, one course, one lecture a week; text-books, Holden's and Allen's. In physiology, two courses of lectures, three a week; text-books, Dalton and Foster. In general pathology, two courses, one lecture a week, with the use of Green's text-book. In chemistry, two courses, three lectures a week, and the text-books of Draper, Ganot, Fownes, and Attfield, with a course in practical chemistry, including laboratory work. The student is recommended to study: in surgery, the works of Bryant, Erichsen, Holmes, Gross, Agnew, and Smith; in obstetrics, those of Playfair and Lusk. Even for practice of medicine he is sent to Loomis, Roberts, or Pepper's *System;* for therapeutics, to Stillé and Maisch's *Dispensatory;* for pharmacy and toxicology, to the *U. S. Pharmacopœia*, Mann on *Prescription-writing*, Taylor on *Poisons*, Wood's *Materia Medica*. But the list need not be further extended. Suffice it to say that of all the text-books this institution recommends to its students, about two-thirds are of authorship unquestionably orthodox, while the remainder are largely compilations from sources equally creditable. Can it be claimed that those so educated have based their practice "on an exclusive dogma, to the rejection of the accumulated experience of the profession, and of the aids actually furnished by anatomy, physiology, pathology, and organic chemistry?"

For them to pretend that they practise an exclu-

sive system of medicine is an imposture. But for us, by our attitude toward them, to support that pretence is imbecility. We do support it if we exclude them *en masse*, giving as our reason their system of practice.

But when it is admitted that they are practitioners who have received a regular medical education, it is claimed that they should be ostracized for false pretence. Let those who are guilty of false pretence feel such disapprobation. But the penalty may be made most effective by confining it strictly to those who have deserved it; and the guilt or innocence is to be determined separately for each individual case. I believe those connected with the institution I have referred to, do not place upon sign, or card, the words homœopathist, homœopathic doctor, or other words of similar import, and that they discourage such a practice. The announcement from which I have quoted bears the motto: "*In certis unitas, in dubiis libertas, in omnibus charitas.*" The most prominent adherents of the doctrine of "like cures like," publicly deny that their practice is based exclusively upon it. Not long ago several of them resigned their positions in one of their hospitals in this city, rather than practise it exclusively in an institution founded for its illustration and propagation. The societies into which these practitioners have banded themselves make no profession of an exclusive dogma. Some, as the American Institution of Homœopathy, require no expression of belief whatever.

Much of what has been said of this group which is commonly regarded as made up of irregular practitioners may, with slight modification, be said of another, the so-called eclectics. If I can understand the profession made by both of these sects, it is that they take experience as their teacher and guide. If the experience they follow leads them in certain directions to absurd conclusions, looking back upon the history of medicine I cannot therein find ground for their exclusion from all professional recognition. "Conscientious convictions should be respected."

The medical profession can never afford either to prescribe or proscribe opinions for its members. Whenever you divide medical practitioners upon a line of dogma, whether that line be to include the believers in a certain doctrine, or to exclude them, you introduce with all its evils sectarianism. Let us hope that the American Medical Association and its code of ethics, designed to bind together the profession into one harmonious whole, shall not, by false interpretations and failure to understand its catholic spirit, be suffered to hinder such a union.

Women's Medical College of Cincinnati.—Dr. George A. Fackler, for a number of years Assistant to the Chair of Materia Medica at the Medical College of Ohio, has been elected Professor of Materia Medica in the Women's Medical College of Cincinnati.

AN ETHICAL QUESTION.[1]

BY SOLOMON SOLIS-COHEN, A.M., M.D.,
PROFESSOR OF CLINICAL MEDICINE AND APPLIED THERAPEUTICS, PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.

IT is true that no man is so sure of the accuracy of his knowledge or the wisdom of his judgment, that he can refuse to respect the honesty with which others maintain opinions from which he may dissent. Nevertheless there are certain facts of nature which have passed beyond the region of opinions into that of established truths: there are certain methods which the well-settled judgment of scientific men requires to be pursued in our interrogation of nature for yet other truths. To respect the honesty with which a man entertains beliefs contradicted by all that is known of natural law, and by the collective experience of mankind, is one thing: to dignify manifest absurdities with the name of scientific opinion, is quite another.

The Rev. John Jasper and the Grand Llama of the Trans-Baikal are honest enough in their opinion that the sun makes a daily circuit about the earth; but scientific men and the world of thought they influence, have long since accepted as final the contrary teaching of Copernicus and Galileo, and will not now intermit more important labors to debate the question.

But though we may respect the man who honestly errs, we are not called upon to entertain any such feeling toward him who is ignorant through wilfulness; and as for him who, knowing truth, wears for hire the livery of error, even divine charity can ask us to do no more than withhold judgment.

I have no desire to attack the opinions or the characters of any body of men—certainly not those of the homœopathic practitioners of this city, many of whom I have the pleasure of knowing as cultivated and honorable gentlemen. When, however, the charge of illiberality is made against the members of this Society and of the profession of medicine, because they refuse to recognize certain practitioners as entitled to the honored name of physician, it becomes proper, in repelling that charge, to exhibit plainly the reasons which make such recognition impossible.

The question interjected by Dr. Jackson into the deliberations of this Society, when stripped of the sophistry with which it has been overlaid, is a very simple one. Disregarding the attempts to erect fine distinctions upon unsubstantial grounds, the gist of the matter may be tersely and bluntly stated as follows: Can physicians conscientiously consult with, or recognize as members of their profession, prac-

[1] Read, as a reply to Dr. E. Jackson's paper on "Against Sectarianism in Medicine," before the Philadelphia County Medical Society, September 25, 1889.

titioners of that system of therapeutics known to the public, in the language of its founder, as "homœopathy"?

Proceeding to discuss this as a casuistical question, there are two hypotheses to be taken up in turn, upon each of which an independent answer must be given.

The first hypothesis is, that all who are called homœopathists are what they profess to be, and allow the public to consider them; namely, practitioners of homœopathy: homœopathy being the system of therapeutics invented by Hahnemann, and asserted by its founder (*Organon*, § 53) to be based upon an "eternal and unerring law of nature," expressed in the formula "*similia similibus curantur*" (or *curentur*). Upon this hypothesis I shall show by citations from the most authentic and authoritative exposition of homœopathic doctrine and practice, namely, Hahnemann's *Organon*, that consultation between physicians and homœopathists could be productive of no result; for there is no possible common meeting-ground. It is not a mere question of the expediency of this or that therapeutic measure in a given case, such as often comes up in discussion between physicians, but one of fundamental difference in principle, making agreement as to practice impossible—if both be honest. Their doctrines and their practices, whichever be right and whichever be wrong—a question which it is needless to discuss—are mutually antagonistic and destructive. From this point of view alone, and leaving out of consideration the larger ethical questions of public duty, it is obvious that a consultation would be condemned from the first to be a barren union, and must therefore be an immoral one. The question as to its permissibility will thus be at once answered in the negative; and it has so been answered by sincere homœopathists.

The second hypothesis is, that men who profess to be homœopathists, who allow the public to consider them such, and who accept the fees of persons desiring homœopathic treatment, are not what they profess to be, but something else. It matters not what that something else is; so long as it is not consistent with homœopathy, it is something that contradicts the profession made to the public.

Upon this hypothesis — which I do not allege represents the existing state of affairs, but which, if I understand Dr. Jackson aright, he distinctly declares to be the case so far as concerns the Managers of the Hahnemann Medical College of Philadelphia—I shall contend that there is a very important question of public honor and private honesty involved; and that until it can be shown that it is right to take money or other valuable considerations under false pretences, no honorable man can consult with practitioners of this type—if any such practitioners exist—for he would, by so doing, become accessory to a fraud. Let me repeat, in order not to be misunderstood, that I do not assert that anybody whatever is guilty of the false pretence of professing to be a homœopathist while in reality he is something else. I shall show by citations from the gospel of homœopathy—namely, the *Organon* of Hahnemann—what homœopathy is. Then, if the state of affairs described by Dr. Jackson is actual, and he is not laboring under a misapprehension as to the facts, it will become self-evident that the practitioners whom he describes have been refused the name of homœopathists by the one who had the best right to define that name;[1] and the question as to the propriety of consulting with them will again be answered in the negative.

My propositions, then, are three:

1. Either the so-called "new-school physicians" are what they profess to be—homœopathists—or they are not.

2. As to the honorable men who are what they profess to be: We cannot honestly consult with them, nor do they wish to consult with us—because consultation would be fruitless.

3. As to the not-honorable men who are not what they profess to be: We cannot honestly consult with them, because we would become participants in an act of deception.

This is the issue as I understand it, freed from glossing and concealing verbiage. Truth requires it to be frankly stated and as frankly met.

To prove these propositions I must establish two things:

1. That the practitioners in question profess to be homœopathists, or "new-school physicians."

2. That the principles and practice of homœopathy, as set forth by competent authority, are such as to be utterly irreconcilable with the principles and practice of medicine and with the sciences upon which medicine is founded, as these are understood by the great body of modern physicians and by the members of this Society.

The first of the facts I must establish, I did not, until to-night, understand to be denied by any one. It has seemed to me as much a matter of public knowledge, as the fact that President Harrison professes to be a member of the political party called Republican, and that ex-President Cleveland professes to be a member of the political party called Democratic; that the Archbishop of Canterbury is a dignitary of the Anglican Church, and the Cardinal at Baltimore, of the Roman Catholic Church. For

[1] See a paper by Edward Bayard, a homœopathist by conviction and not "for revenue only," entitled "Plea for Pure Homeopathy against Eclectic Homeopathy." Proceedings in the Homœopathic Medical Society of the County of New York, on March 8 and 13, 1878.

the sake of completeness of proof, however, let me cite these facts: There is in existence a "Homœopathic County Medical Society" in Philadelphia, and a "Homœopathic State Medical Association" in Pennsylvania. Members of these bodies succeeded in defeating the efforts of this Society, and of the Medical Society of the State of Pennsylvania, to secure the passage of an act establishing a State Board of Examiners and Licensers, by alleging the existence of separate and irreconcilable "schools of medicine," and thus securing the adoption of an amendment providing that the majority of the proposed Board should not be adherents of any one "school." Not only does the Hahnemann Medical College connect itself by its name with the author of the *Organon of Homœopathic Medicine*, in whose mystic, metaphysical brain the strange delusion originated; but it distinctly recognizes as its associates other homœopathic colleges, and accords their students and graduates such privileges as colleges of medicine accord to students and graduates of colleges recognized by them. Furthermore, I have never heard, nor do I think Dr. Jackson has ever heard, of cases or fees having been refused by the professors or graduates of the Hahnemann Medical College on the ground that patients desired the services of homœopathists, while said professors and graduates were not homœopathists. Nor has there been any public announcement that the Hahnemann Medical College is not a homœopathic college, or that its professors or graduates have realized the errors of homœopathic ways and have repented and abandoned them.

If, then, the case of Dr. Jackson rests upon the fact that the Faculty of the Hahnemann Medical College and its graduates are not professedly homœopathists, I respectfully submit that the very parties concerned would not endorse his special plea, and it consequently falls to the ground without further waste of words. Until the teachers and practitioners in question publicly repudiate homœopathy, I cannot see why we should assume that they have clandestinely done so. And until they do repudiate homœopathy, as I shall show in a moment, a Surgeon-General's Library of scientific text-books could not neutralize the absurdities to which its profession commits them.

I have devoted to this subject much more time than it deserves, in order to prevent misunderstanding of the position. I confess, that to carry on my argument I must establish the fact that the profession of homœopathy is made by certain persons. I claim that I have established that fact by citing certain matters of public knowledge. Dr. Jackson must either admit that I have established this point, or he must frankly meet it and show that these persons neither actively profess to be homœopathists nor tacitly allow their patients and the public so to consider them.

Secondly, I must show that homœopathy and scientific medicine are absolutely irreconcilable; and I must show this upon unimpeachable authority.

It is neither my purpose to defend those against whom the inventor of homœopathy directed his invective and his sarcasm, nor to detract from his possible[1] services to medicine in attacking some palpable errors of his time. Nor do I wish to debate the question of the truth or error of the homœopathic doctrine. To waste time in demonstrating before this body the fallacies and gratuitous assumptions upon which that doctrine is founded, would be as superfluous as it is needless to my argument. For whether the so-called "law of homœopathic cure" be a profound truth or an insane delusion, all that I need show is its incompatibility with what we recognize as sound teaching concerning the nature of disease, the action of remedial agents, and the manner in which the physician should proceed in investigating the one and applying the other.

If the authority to which I shall refer for every step in this proof is not beyond cavil, then, indeed, may we at once admit that the moon is made of green cheese, that two and two never did make four, and that words have no meaning. It is the sacred scripture of the great prophet of the "new-school of medicine"—Samuel Hahnemann's *Organon of Homœopathic Medicine*, in an authorized translation,[2] edited by the prophet's greatest disciple and apostle in America, C. Hering, and certified by the "Chairman of the Board of Directors" of the "Academy of the Homœopathic Healing Art," at Allentown, Pa.

If I am not in error, the *Organon* of Hahnemann still holds an honored place as a text-book at the Hahnemann Medical College of Philadelphia, as it does at the homœopathic colleges of other cities.

Time necessitates limitation of the number of quotations,[3] and the selection of the most characteristic. It will be impossible to cite *verbatim* the full text of every section to which reference may be made; but wherever I have condensed the loose-jointed and bewildering verbiage, I have scrupulously endeavored to be fair and correct.

From the *Organon* of Hahnemann I purpose to show four things, any one of which is fatal to the possibility of fruitful consultation.

1. Homœopathy as expounded by Hahnemann,

[1] Possible, but exceedingly problematical; inasmuch as he inveighed indiscriminately against error and truth, bad practice and good practice; and the substitute he offered has been proved worthless.

[2] New York, Wm. Radde, 1849.

[3] For the same reason no reference has been made to the excellent expositions of the fallacies of homœopathy by various writers.

its inventor, is exclusively a system of drug-therapeutics; explicitly renouncing the aid of the *vis medicatrix naturæ*;[1] and denouncing the study of anatomy, physiology, pathology, etiology, semeiology, nosology, and diagnosis.

2. It is an arbitrary and exclusive system; inflexible; and claiming to be infallible.

3. It expressly prohibits the endeavor to interpret morbid symptoms as indications of changes in the structure or functional activity of definite tissues and organs; declares that an all-wise Providence has denied to man the power of learning what takes place within the human body; with logical consistency rejects the attempt to direct treatment against definite pathological conditions and processes or their dangerous consequences; and fixes attention upon the symptoms alone, independent of their origin, as constituting the whole of the disease, and affording the sole indication for treatment.

4. The doctrine of *homœopathia*—or the casting out of "natural diseases"[2] by artificial diseases closely resembling them, but excited by drugs—is inextricably bound up with the practice of infinitesimal dosage.

If these points be established, the logical inference will be not only the utter impracticability of consultation between physicians and genuine homœopathists; but also that those who make diagnoses—direct treatment to the production of definite effects upon particular tissues or organs—give any other than "homœopathic" remedies—refrain from the use of drugs in any case—or give drugs in any other than infinitesimal dosage—are not true homœopathists. If any such profess to be homœopathists, we will be compelled to conclude that they are either deliberate deceivers or, at best—in the language of Hahnemann—members of "the new mongrel sect" who try to "find a pretext everywhere for . . . exceptions to the general rule, in order to introduce their allœopathic palliatives, with other mischief of a like character, merely to save themselves the trouble of searching for suitable homœopathic remedies for every case of disease—one would say, to save themselves the trouble of being homœopathic physicians, though they wish to be considered such. But," continues the prophet, whose hearty contempt for such insincerity provokes admiration, "their deeds will follow them; they are of little moment."[3]

I. Homœopathy is exclusively a system of drug-therapeutics.

The introduction to the *Organon* of Hahnemann consists principally of denunciations of all medical practice prior to, or differing from that of, the author; and especially of the efforts of physicians to discover the causes of disease, in order to direct treatment, where possible, to the removal of those causes. Nothing, according to Hahnemann, is more vain and irrational than to endeavor to seek out the cause of disease. "It was the boast of the former schools of medicine,"[1] he says, "that their doctrine alone deserves the title of 'rational art of healing,' because it was pretended that they alone sought after and removed the morbid cause and followed the traces of nature herself." A vain boast, because "by far the greater number of diseases [are] of dynamic origin as well as of a dynamic nature, and their cause therefore [does] not [admit] of discovery to the senses." Among the irrational procedures committed in this foolish search after causes, he especially condemns the habit of "comparing, on the one hand, the normal state of the parts of the dead human body (anatomy) with the visible changes which those parts had undergone in subjects that had died of disease (pathological anatomy), and on the other, the functions of the living human body (physiology) with the endless aberrations to which they are subject in the various stages of disease (semeiotics, pathology), and drawing from thence conclusions relative to the invisible manner in which the changes are brought about in the interior of man when in a diseased state."[2]

Thus if—together with etiology—anatomy, physiology, pathological anatomy, semeiology, and pathology by name, and diagnosis by implication, are denounced as senseless and misleading, there is little left of medical science; and of its art, simply applied therapeutics. That this is the most important to the patient is true; and it is the goal to which our studies of normal and morbid anatomy, of physiology, pathology, and other sciences, are to lead us; but surely none here present will subscribe to the doctrine that the goal can be reached by any other road than that which the inventor of homœopathy so explicitly rejects and denounces.

One or two additional citations will serve to show more clearly the significance for our second main hypothesis, of this position of Hahnemann's. Meaning to be satirical, he says of physicians: "The sublime project of discovering . . . some internal and invisible cause of disease resolved itself . . . into a search, guided onward by the symptoms, after that which they might term to be the generic character of the existing malady. They endeavored to find out whether it was spasm, debility, or paralysis, fever or inflammation, induration or obstruction in

[1] *E. g.*, op. cit., pp. 40, 42, *et seq.*
[2] The two diseases fight it out, and the patient escapes.
[3] Note to § 67, ed. cit., p. 132.

[1] Ed. cit., pp. 26 and 27.
[2] The context, which I have omitted, denounces, it is true, some particular conclusion said to be thus reached; but our concern being only with the explicit condemnation of the method, it is of no moment whether the conclusion be or be not truthfully stated or justly criticised.

some one of the parts; excess of blood (plethora) or increase or deficiency of oxygen, carbon, hydrogen, or nitrogen in the fluids; exaltation or depression of vitality in the arterial, venous, or capillary system; a defect of relative proportion in the *factors* of sensibility, of irritability, or of nutrition."[1]

Allowing for the animus of the author, for changes in terminology, and for the progress of science, this would describe with a sufficient degree of accuracy the course still pursued by the intelligent physician in the endeavor to reach a diagnosis. To Hahnemann, however, such a course was fit subject for ridicule, and in a foot-note he says: "Every physician adopting a treatment of such general character"—that is to say, every physician who seeks to make a diagnosis, or to arrive at a knowledge of the morbid changes in the organism which he is called upon to combat—"however unblushingly he may affect to be a homœopathist, is and always will remain a generalizing allœopathist, as without the most special individualization *homœopathia* has no meaning." Surely no language can be plainer than this!

This denunciation of diagnosis and nosology, following, as it does, the explicit rejection of anatomy, physiology, and the other branches of medical science, and showing the complete dependence of the whole homœopathic system upon a deliberate shutting out of the light, becomes readily understood upon looking further into the peculiar theories of Hahnemann. He assumes the existence of an "immaterial vital principle pervading the physical organism" (§ 11). "It is solely the morbidly affected vital principle which brings forth diseases[2] (§ 12)." "The vital principle as a spiritual dynamis" (whatever that may be) "cannot otherwise be assailed and affected than in a spiritual (dynamic) manner; neither can such morbid disturbances be removed by the physician, except in like manner by means of the spiritual (dynamic virtual) countervailing agency of the suitable medicines acting upon the same vital principle" (§ 16).

Here we have not only the affirmation of the spiritual nature of disease, of its causes and of its cures—explaining the futility of the rejected studies which concern themselves with the material body, and its material morbid changes—but also the distinct assertion that diseases can only be removed by medicines; while again and again, throughout the introduction, and in a mass of foot-notes to various sections of the *Organon*, are violent denunciations of the idea of trusting in any degree whatever to the efforts of nature, or of accepting as a guide to therapy indications derived from a study of the natural history of disease. Let me cite one of the mildest of these maniacal outbursts: "The miserable and very imperfect attempts which the vital powers make to assist themselves in acute diseases, is a spectacle that ought to excite man to use all the resources of his learning and wisdom, to put an end, by a real cure, to this torment which nature herself inflicts. If nature cannot cure, homœopathically, a disease already existing in the system, by the production of a fresh malady *similar* to it (§§ 43–46)—a thing not often in her power to effect (§ 50) . . . we see nothing but painful and often dangerous efforts of the constitution to save itself at all hazards, efforts of which death is most frequently the result."[1]

I have thus, I believe, established the proposition that homœopathy, as expounded by Hahnemann; is exclusively a system of drug-therapeutics.

II. It is an exclusive system, arbitrarily devised, inflexible, and claiming infallibility.

"Observation, reflection, and experience have unfolded to me," says Hahnemann, "that in opposition to the old allœopathic method, the best and true method of cure is founded on the principle *similia similibus curantur*. To cure in a mild, prompt, safe, and durable manner it is necessary to choose in each case a medicine that will excite an affection similar to that against which it is employed. Until the present time no person has ever inculcated this homœopathic mode of treatment, and yet more, no one has ever put it into practice. . . . In all ages the diseases which have been cured by medicines . . . have yielded, although without the knowledge of the physician, to a homœopathic remedy . . . a remedy in itself capable of exciting a morbid state similar to that whose removal it effected."[2]

Having assumed that for every disease there must be a remedy—and that this remedy is a medicine—he further assumes that medicines can accomplish the cure of disease, only in one of three ways: (1st) by exciting a disease similar to the natural disease, which he calls "homœopathy;" or, (2d) by exciting a disease opposite to the natural disease, which he calls "antipathy;" or (3d) by exciting a disease which is neither similar nor opposite to the natural disease; and this, which he incorrectly states is the common practice of physicians, he dubs "allœopathy" (§ 53). Antipathy and allœopathy have been tried up to his time and have failed; consequently, homœopathy must be the only true method (§§ 24, 61, *et al.*).

The "discovery" of the homœopathic "law" was not the result of experience, but, according to his letter to Hufel,[3] was reached by reflection,

[1] Ed. cit., p. 28.

[2] Compare also this gem from the introduction (ed. cit., p. 35): "Diseases will not, out of deference to our stupidity, cease to be *dynamic aberrations which our spiritual existence undergoes in its mode of feeling and acting.*"

[1] Ed. cit., p. 42. [2] Ed. cit., pp. 59, 60.

[3] Cited by Henderson: Homœopathy Fairly Represented. Phila., 1854. Pp. 116 et seq.

before any experiment had been made. "God," he says in effect, "made diseases; God must also have made a remedy for each disease; and He indicates its use by giving it power to produce in healthy persons symptoms like those of the disease it is intended to cure."

I have used the expression "exciting disease" in referring to Hahnemann's exposition of drug action. It is his own language. In many cases it is direct, as in § 29, where he says in conjectural explanation of the homœpathic cure, "The natural morbific power terminates . . . while the *medicinal disease*, which usurps its place, being easily subdued by the vital power, is . . . extinguished in its turn." But it is also implied throughout when he speaks of the symptoms produced by drugs, because it is one of his fundamental principles that, so far as human observation is concerned, symptoms and disease are one and the same (§§ 11–21).

Our way is now clear to set against one another certain fundamental propositions of Hahnemann's: "Every curable disease is made known to the physician by its symptoms" (§ 14). "The physician has only to remove the totality of the symptoms and he has cured the entire disease" (§ 17). "The totality of the symptoms is the sole indication in the choice of the remedy" (§ 18). "The morbid symptoms which medicines produce in healthy persons are the sole indications of their curative virtues in disease" (§ 21). "The homœopathic method, or that which employs medicines producing symptoms similar to those of the malady, is the only one of which experience proves the certain efficacy" (§ 24).

"It is as impossible that there should be any other true method of curing dynamic diseases . . besides homœopathy, as that more than one straight line can be described between two given points" (note to § 109). "By this method alone can we cure diseases in the most speedy, certain, and permanent manner, because it is grounded upon an eternal and unerring law of nature" (§ 53).

These citations should be sufficient to establish the second thesis—namely, that homœopathy is an exclusive system, that it is arbitrarily devised, that it is inflexible, and that it claims to be infallible. "An eternal and unerring law of nature" can admit of no exception and no failure. Upon the surface of the earth, at the centre of the sun, or at the extremest limit of the orbit of Neptune, gravitation acts with a force proportional to mass and inversely as the square of distance. In the tropics, as in the arctic regions, like poles of magnets repel and unlike poles attract. The atomic weight of carbon, the valence of hydrogen, differ not in the brain of man, or in the fossil leaf. These are matters governed by "eternal and unerring laws of nature." If the "law of homœopathic cure" is entitled to be called a law, it must be equally infallible and exclusive to-day, as when Hahnemann penned his sweeping claim. Maintenance of that claim precludes any modification in principle or practice; "More than one straight line *cannot* be described between two given points." Abandonment of the claim is abandonment of homœopathy.[1]

III. Homœopathy forbids diagnosis[2] and condemns the attempt to direct treatment to definite ends, etc.

It follows from what has been quoted, and is repeatedly, explicitly, and elaborately stated by Hahnemann, that the sole function of the homœopathic practitioner, after having inquired minutely into the symptoms of the case before him, is to select from among the various medicines known to him, that one the "disease-producing power" of which most closely corresponds to the "natural disease" (§§ 83 et seq., 146 et seq.). This is the sole and infallible method (§ 109). If additional evidence is required on this head, the following should suffice:

"There is nothing for the physician to cure in disease but the sufferings of his patient, and the changes in his state of health which are perceptible to the senses—that is to say, the totality or mass of the symptoms by which the disease points out the remedy it stands in need of; every internal cause that could be attributed to it, every occult character that man might be tempted to bestow, are nothing more than so many silly dreams and vain imaginings" (§ 70). "Just as little as we can witness what is passing in the interior of our bodies in a healthy condition—and as certainly these processes remain concealed from us as they lie open to the sight of Omniscience—just so little can we perceive the internal operations of the animal frame, when life is disturbed by disease."[3]

"They" (physicians) "likewise suppose that by removing a polypus by ligature, extirpating a tumefied gland . . . dissecting out the insulated cyst of a steatomatous or meliceretous tumor, operating for aneurism, fistula lachrymalis, or fistula in ano, amputating a cancerous breast . . . etc., to have cured the maladies in a radical manner and destroyed their cause. . . . *But mark what follows.* New forms of disease . . . infallibly manifest themselves sooner or later . . . being always worse than the primitive affection. . . .

---

[1] See Declaration of Homœopathic Principles; with Comments by Adolph Lippe, dated Philadelphia, Feb. 4, 1878; and Protest against a certain Resolution adopted by the Homœopathic Medical Society of the County of New York; signed by C. Lippe, E. Carleton, Jr., S. Baruch, et al. Reprinted from *The Organon*, Liverpool, April, 1878. The resolution, *which was afterward rescinded*, declared that belief in the principle *similia similibus curantur* "does not debar us from recognizing and making use of the results of any experience;" and it is protested against, because, "*not being in accordance with the teachings of Hahnemann*, [*it*] *cannot be accepted by Homœopaths.*"

[2] See especially § 100.

[3] Introduction, foot-note, ed. cit., p. 42.

These ought to undeceive them and prove that the evil has an immaterial cause, the deeper concealed because its origin is dynamic, and it cannot be destroyed but by dynamic power."[1]

If such obvious procedures as tying an artery for aneurism, dissecting out a sebaceous cyst, or amputating a cancerous breast, are thus condemned, what shall we think of such impious attempts to pry into the processes going on in the interior of our bodies —"as surely concealed from us as they are open to the sight of Omniscience"—as are involved in the diagnosis of consolidation of a lung, stenosis of a cardiac orifice, or tumor of the brain? And what of measures that disregard symptoms *in toto* and endeavor to attack the pathological process underlying them?

IV. The doctrine of "homœopathia" is inextricably bound up with the practice of infinitesimal dosage.

"The appropriation of a medicine to any given case of disease does not depend solely upon the circumstance of its being perfectly homœopathic, but also upon the minute quantity of the dose in which it is administered. If too strong a dose be given, it will infallibly injure the patient. The impression it makes is felt more sensibly because in virtue of its homœopathic character the remedy acts precisely on those parts of the organism which have already been most exposed to the attacks of the natural disease" (§ 275). "A strong dose of homœopathic medicine would do more harm than the dose of an allœopathic medicine of equal strength; for in that case the homœopathic aggravation—that is to say, the artificial malady excited by the remedy in the most suffering parts of the organism—is carried to a height that is injurious" (§ 276). This, of course, we should naturally imagine; that in so far as the effects of medicines do at all resemble the symptoms of diseases, the result of giving such medicines would be highly injurious. Instead of being taught by this the folly of his methods, Hahnemann, being, like Ephraim, wedded to his idols, takes refuge in a new absurdity, and concocts the doctrine of infinitesimals.

In order to determine just how far homœopathic medicines would have to be attenuated in order to be rid of their power for evil, Hahnemann had recourse to experience; and he found it necessary so to dilute the dose that it amounts to practically nothing. The well-known process is to dissolve two drops of medicine in ninety-eight of alcohol, one drop of this in ninety-nine more of alcohol, and so on until the necessary minuteness is attained, at from the tenth to the thirtieth dilution:[2] provided care be taken not to shake the containing vessels more than twice at each successive dilution, as otherwise too much "dynamic spirit" would be freed; and ten shakes might even make the medicine so powerful as to be extremely dangerous.

These directions and cautions are found in the *Organon*, beginning with Section 269, and elaborated in the succeeding twenty sections.

It is possible, however, for even the minutest dilution of homœopathic medicine to be too strong for a very sick patient. "In that case" we find[1] that "it will be sufficient to let him smell it once." In the process of smelling,[2] the patient should place a vial containing one globule of sugar the size of a mustard-seed, impregnated with a sufficiently attenuated dilution of the desired remedy, under one nostril, and take one momentary inhalation. If the dose is intended to be stronger, he may then repeat with the other nostril. The operation of the remedy continues as long as when the same drug is taken in substance, and hence the dose must not be repeated at shorter intervals. In Section 247, we are told that "the most subtile doses of the best chosen homœopathic medicines" are to be repeated at intervals of fourteen, twelve, eight, to seven days; except in acute cases, when the periods may be abridged to twenty-four, eight, or four hours, and in the most acute cases down to five minutes.

In a case of pneumonia, I suppose, the patient might safely smell the medicine once in four hours; in a case of mitral stenosis, once in a week;[3] and in a case of chronic gastric catarrh—not at all.

The citation of this nonsense is not unfair quibbling upon my part. It is the essential part of the true homœopathic practice. Any fair-minded person who reads what Hahnemann says upon this subject, his frequent strong, repeated affirmations that "the more homœopathic the medicine, the greater danger" if it be given in any but the most attenuated doses; his denunciations of the "pretended homœopathists" who give larger doses than he directs; his elaborate and minute directions as to the manner of preparation; forbidding powders, for example, to be triturated "with force"[4] for more than one out of the three hours which he considers necessary to effect liberation of the spiritual dynamic essence;—any fair-minded man, reading all this, cannot but admit that the doctrine of similars and the doctrine of infinitesimals must stand or fall together.

And that he is painfully in earnest as to the smelling business, is evidenced by the following statement

[1] Ed. cit., p. 33.

[2] Representing one grain of a medicinal substance dissolved in sufficient alcohol "to make one hundred and forty billions spherical masses extending from limit to limit of Neptune's orbit, or a quantity equal to many hundred spheres each with a radius extending from the earth to the nearest fixed star."—*Simpson.*

[1] Note to § 285. [2] Page 209.

[3] "Let the patient once strongly smell a globule as large as a mustard-seed impregnated with *hydrarg. met.* X., which is to be allowed to operate about nine days."—Page 208.

[4] Page 225.

—a statement which I certainly do not care to dispute: "All that is curable by homœopathy may with most certainty and safety be cured by this mode of receiving the medicine."[1]

Does it need comment of mine to show how utterly impossible it is for a physician to meet in consultation one who gives the slightest credence to the rot which I have quoted?[2] The physician's first course, as I have had the pleasure of observing in cases in which I have solicited aid from the special knowledge of my friend Dr. Jackson, is to make a diagnosis; the homœopathist is bound to reject diagnosis. The physician seeks out the causes of disease, that he may remove them, if possible; that he may intelligently combat their effects; that he may prevent disease in the future. The homœopathist is committed to the doctrine that disease consists only of symptoms whose cause has been concealed by an all-wise Providence. The physician may use or omit drugs; the homœopathist is bound to employ drugs, though, it is true, in such infinitesimal doses that if needless they will at least be harmless. But this negative virtue of the attenuated medication vanishes in cases in which drugs are imperatively needed, for then the homœopathist is precluded from employing them in effective quantity: because, if homœopathic, they will infallibly do harm; and, if not homœopathic, his system declares them to be murderous.

But it may be said that the homœopathist is no longer bound by the *Organon* of Hahnemann; he is open to the lessons of experience, and homœopathy is no longer to him an infallible law of nature, but an occasional guide in practice.

This brings us face to face with an exceedingly unpleasant portion of our task, that of considering our second hypothesis; namely, that men who now profess to be homœopathists are in reality something else. However, as we are merely considering it as a hypothetical, casuistical question, we may at least avoid direct personal reference.

Can one remove the foundation and expect the building to stand? Considering the origin of homœopathy, its claims to universal and infallible application, the explicit declaration of its founder that no other system could be true, even as more than one straight line could not be described between two given points; it must be much more than an occasional guide in practice, or it must be what scientific men regard it, a baseless fabric of assumptions. As has been well said by Prof. Gairdner, the vigorous imagination which can attribute nine hundred and thirty symptoms to charcoal, and ten hundred and ninety to oyster-shell, can find little difficulty in fitting a sufficient number of the confused mass of "provings" belonging to any drug, to any case in which recovery may have taken place coincidently with its use. Mere experience, then, need not take any out of the homœopathic ranks, if he be not possessed of a scientific conscience whose crying refuses to be quieted with sugar plums.

But a homœopathist cannot deliberately reject Hahnemann's *Organon* and remain entitled to the name. Hahnemann invented the name, or at least gave it its peculiar significance; Hahnemann has defined it, and no one has the right to alter Hahnemann's definition. He put forth homœopathy as a new system in medicine, differing *in toto* from all other systems, rejecting alike the methods of investigation and the methods of treatment pursued by the great body of physicians. As he formed it, so it must remain; for he claimed the authority of a divine revelation,[1] the infallibility of "an eternal and unerring law of nature."

If the barrenness of its history during the years that have been so fruitful for medical science; if the brilliant results of that patient search after material morbid agencies so derided by Hahnemann; if the triumphs of preventive medicine, in which a system founded upon drug-giving could have, and has had, no part; if the progress of physiological therapeutics, which having learned how remedies act, now joins forces with chemistry to attack the why:—if these things unite with continued experience in the sick-room, to prove the wretched inadequacy of Hahnemann's system; so that even in the temple builded to his name strange fires are burning upon the altar, so that even among his priests and votaries the light of the fires of science is breaking through and dispelling the gloom of his mystic and obscuring speculations:—if intelligent men, entering the homœopathic ranks through prejudice or force of associations, and in ignorance of the facts, have learned by study and experience the hollowness of the faith to which they profess allegiance—then there is for these men but one honorable course—the public acknowledgment of the facts. It may be unpleasant. It requires moral courage. But it is right, and it will compel respect.

But so long as a name having commercial value

[1] Note to Section 288, p. 226. It is a cheap method, too. He states that one globule will retain its virtues undiminished for twenty years, though it had been smelled during that period a thousand times. Let alienists tell us how much dependence can be placed upon the observation of a man who seriously makes such assertions.

[2] And I have by no means cited the most ridiculous passages of the *Organon*. I have said nothing of the "psoric miasm," for this is not essential to homœopathy; and, indeed, like the exceptions Hahnemann himself was compelled to make concerning "surgical diseases" and the "*causa occasionalis*," logically contradicts it.

[1] . . . "The certainty of medicine depends on the establishment of fundamental principles, based on natural laws, to guide the Healer in his Therapeutics; and . . . Samuel Hahnemann *was allowed to reveal to the world* such principles and their application for the cure of the sick, in his *Organon of the Healing Art* . . ." Declaration of Homœopathic Principles, loc. cit.

as a trademark is retained by any body of men, so long do the barest principles of trade-honor bind them to all the implications of that name. If they can reconcile it with their consciences to continue to bear a name to which they have lost the right, we at least dare not impute to them, without sufficient evidence, conduct so base and cowardly; or, if we have such evidence, then we must not, by condoning duplicity, become partakers in dishonor.

CLINICAL MEMORANDA.

HYGIENIC.

Possibility of Establishing Tolerance for the Tubercle Bacillus.—During the last summer I spent much time in bacteriological laboratories abroad, studying the different methods of manipulation and technique. The first culture given me to stain by Prof. Klein, at the College of State Medicine, London, contained tubercle bacilli. The tube had been kept in an incubator used by all the students in the College, not only for legitimate purposes, but for warming of staining materials, and, therefore, it goes without saying, that the temperature was not at all constant. The first slides prepared from this culture showed club-shaped bacilli. Suspecting a lower degree of virulent life, I permitted the tube to remain at the temperature of the room for several days, before staining a second series of slides. Upon these I found many bacilli in the forms represented in the accompanying cut.

When Prof. Klein's attention was called to the newly discovered forms of bacilli, he expressed much surprise, and was unable to account for the change in their forms, and yet was quite certain that the tube in question was inoculated with bovine tubercle bacilli after the method generally employed. From this tube I made a series of tube inoculations, and grew bacilli which in every respect corresponded to the ordinary tubercle bacillus. From the facts already given, I have seen fit to institute a series of experiments, the results of which will be published from time to time, and which lead to the following thoughts.

In considering a means for overcoming infection by tuberculosis it is probable that a condition of tolerance to the action of the tubercular bacillus must first be established. To this end two hypotheses may be suggested:

First. It is possible that, by a thorough filtering out of bacilli from tubercular material, a filtrate might be obtained and attenuated so that by systematic inoculations a change might be produced in living animal tissues that would enable them to resist virulent tubercle bacilli.

Second. To bring about a chemical or physical change in living tissues that would resist tubercular phthisis, it is possible that inoculations with the bacillus would have to be made; yet, before this could be done, the power of the virulent bacilli would have to be diminished, otherwise the result would be most disastrous.

The accompanying cut represents tubercle bacilli in other forms than those heretofore recognized, and it is possible that they represent the condition of bacilli necessary to prove the truth of the second hypothesis, particularly as animals inoculated with these organisms have survived subsequent inoculations with virulent tubercle bacilli.

Samuel G. Dixon, M.D.,
Professor of Hygiene, University of Penna.

MEDICAL PROGRESS.

Death from Chloroform.—Another case of death during the administration of chloroform is reported in the *British Medical Journal* of October 5, 1889. A lady, about twenty-five years of age, of a very nervous, excitable temperament, desired to have some teeth extracted, and insisted upon an anæsthetic. Her medical attendant administered chloroform. The patient was seated in an easy chair, and, after inhaling a few breaths of chloroform, she slipped down in the chair, and her pulse and breathing were both found to have stopped. Artificial respiration was at once resorted to, but without success. It seemed perfectly clear that the patient was not anæsthetized when she died, as she had only just commenced to inhale the chloroform, and, of course, no attempt had been made to extract her teeth. The coroner's jury returned a verdict that death was due to syncope, and that no blame whatever was to be attached to the administrator.

Syncope, as has long been known, will result from any very violent emotion, and especially from the effects of fear. In a case recorded in Germany a few years back, a female patient visited a dentist, and requested him to extract some carious teeth, demanding, at the same time, that she should be chloroformed. The dentist, very properly, explained the risks of chloroform, and suggested nitrous oxide; but his patient persisted, and he consented to humor her. Having, however, a wholesome dread of chloroform, he substituted eau-de-cologne, and bade her inhale the supposed anæsthetic from a folded towel. After two or three inspirations she suddenly fell from the chair, and died. That death occurs from fear in some cases during the earliest stage of chloroforming is unquestionable; and as it is predisposed to by the sitting posture, and by forcibly restraining the patient's voluntary movements, there can be very little doubt that in every case in which chloroform is to be administered the recumbent posture should be insisted upon, and a loose dressing-gown substituted for the usual every-day costume. There is another point of no small importance, which is, that chloroform increases the liability to death from "reflex syncope." A person partly under chloroform is more prone to die from fright than one to whom chloroform has not been administered. Nor must it be forgotten that deaths occur when only one or two inspirations of chloroform have been taken; this is liable to take place when a too-concentrated vapor (that is, one of greater strength than four per cent.) is employed. In the event of syncope occurring in one of the ways above indicated, the line of treatment which offers the greatest chance of success is

total inversion of the patient, while care is taken that the rima glottidis is maintained open for the entrance of air. Dr. Chisolm, who has strongly supported this, Nélaton's original manœuvre, has recorded some highly instructive cases in which the method of inversion, being promptly performed, effected resuscitation, and so saved the patient's life. But here a caution must be given. Nélaton's method is valuable only in primary syncope, and is absolutely dangerous in cases of heart failure consecutive upon pulmonary engorgement and overfilling of the right heart; or, in short, when respiration stops before the heart ceases to beat. Cases belonging to this last category do not occur, as a rule, until the later stages of chloroformization, and the respiratory failure is then due to overdosage with the anæsthetic.

Functions of the Stomach in Phthisis.—Simultaneously with the recent investigations regarding the prophylaxis of phthisis, the accompanying symptoms and various forms of this disease have been most actively discussed, both here and abroad. Of these, phthisical dyspepsia is perhaps the most common and most unpleasant symptom. German investigators have dealt with the subject most extensively.

DR. G. KLEMPERER,[1] after an examination of a large number of cases, places them in two categories—initial and terminal dyspepsias. The initial dyspepsia is characterized by heart-burn, eructations, nausea, a feeling of fulness of the stomach, and not infrequently vomiting, which is usually excited by violent coughing, and is independent of the ingestion of food. The appetite is variable, and varies from rejection of food to insatiable hunger. Klemperer believes dyspepsia to be frequently the first symptom of early phthisis. Terminal dyspepsia is characterized by constant loss of appetite; severe vomiting usually occurring every day or two, and the stomach frequently becoming greatly distended. Primarily, the trouble is merely a weakness of the muscles, but finally there is almost total cessation of the secretions.

Therapeutically, Klemperer especially recommends remedies which tend to stimulate the motor power of the organ. Foremost among such drugs is creasote, and he has found that alcohol and bitter tonics are also valuable.

Another writer on this same subject, DR. O. BRIEGER, of Breslau,[2] has examined sixty-four phthisical patients in various stages of the disease with the following results: In severe phthisis only 16 per cent. of the cases had a normal condition of the stomach, in the rest a more or less complete gastric insufficiency was noted. In 9.6 per cent. an entire loss of the normal secretive power was observable. In cases where the disease was moderately severe 33 per cent. were found to be free from gastric complications, and in 6.6 per cent. an entire absence of the normal secretions was observed.

Brieger lays great stress upon the value of "overfeeding," or increased alimentation, if the stomach will permit it.

DR. C. HILDEBRAND,[3] in examining the gastric secretions of forty cases of phthisis, found free muriatic acid in some patients, while in others it was absent. He further noted that in the former fever was absent, whilst in the latter it was constant. In a third group of cases, in which the fever was intermittent, it was found that the presence and quantity of hydrochloric acid depended largely upon the condition of the temperature. Hildebrand, as well as Brieger, has obtained excellent results with forced alimentation.

Laparotomy for Hydatid of the Liver.—DR. DAVIES THOMAS, in a paper on echinococcus cysts (*The British Medical Journal*, September 28, 1889), says that it is not possible to estimate the value of tapping, parasiticide injections, and electrolysis, because the cure which often appears to follow is frequently illusory. He sees reason to believe that tapping operations fail to cure in fully 40 per cent., and probably in a larger proportion. Taking aspiratory punctures and ordinary tapping operations together, the deaths amounted to nearly 18 per cent.; but the mortality following aspiratory puncture, whether single or multiple, was only about half that of punctures with an ordinary fine trocar. Dr. Thomas believes that the greater the number of punctures required the smaller the probability of cure, and points out that, though simple puncture is generally devoid of risk, it has been known to cause sudden death, sometimes apparently from shock—sometimes, however, in the case of pulmonary hydatids, from suffocation by the fluid contents of the bladder-worm. The objection to puncture as the mode of treatment for internal hydatids, however, lies less in the occasional perils of the operation than in its frequent inefficacy.

Dr. Thomas considers that nothing can be said in favor of parasiticide injections into the sac and the employment of electrolysis that does not apply with equal force to simple puncture; and, moreover, each possesses drawbacks of its own. The statistics of abdominal section for hydatid of the liver compiled by Dr. Thomas are extraordinarily good. He has collected sixty-eight cases thus treated, with only seven deaths; in one of these seven cases the patient died suddenly during the operation from sudden arrest of the heart due to a hydatid cyst in it; in two others there were multiple hydatids in the body. Even including these three cases, the recoveries amounted to within a fraction of 90 per cent. The method by two stages, producing peritoneal adhesion by incision and packing with carbolized gauze (Volkmann's method) showed a mortality of a fraction over 19 per cent.; the operation by caustics gave a mortality of 33.68 per cent., while that by the *canule à demeure* was 26.66. The cases treated by Volkmann's method only numbered twenty-one, but even so the statistical evidence appears to be strongly in favor of abdominal section as the safer procedure. Where unruptured cysts are present on the convexity of the liver, the treatment offers greater difficulty, for Dr. Thomas states that thoracic incisions show a high rate of mortality. As to pulmonary hydatids, however, the risks and disadvantages of puncture are so great and the results of radical operations on the whole so favorable, that Dr. Thomas considers that there ought to be but little difficulty in making a choice of treatment in ordinary cases. Where a hydatid, whether of the liver or of the lung, has ruptured in the pleura, free incision into the pleura appears to be the only treatment which holds out a fair promise of success.

Medical Treatment of Ileus.—Among European investigators none, perhaps, have so carefully studied the therapeusis of ileus as Dr. Nothnagel. After an experience of many years he now bases the medical treatment of this disease on the following principles: Excitation of peristalsis by means of irrigation, and salt water enemata or ice-water injections, opium internally to guard against fatal collapse, entire abstinence from all food, and exclusion of all cathartics. Irrigation of the stomach, although practised by many, is of no particular value; still, as it is harmless, it may be tried, and may give the patient some ease. Massage is emphatically contraindicated, as is also the use of electricity.

When given early in the disease Nothnagel favors the use of mercury. His experiments upon animals have proven the fact that the drug never causes reversed peristalsis, either in the normal bowel or when stenosis exists.

He asserts that the vomiting of fecal matter is caused mechanically. When an effort is made to vomit, the abdominal muscles are forcibly contracted, and the fecal mass, being compressed, seeks the easiest outlet, which is above.

A Novel Vermifuge.—While the following advice seems to us as apt to kill the host as the guest, we quote it for the benefit of our readers from the *Journal of Pharmacy* for September:

A whole cocoanut, grated fine, mixed with milk, and taken on an empty stomach on rising, is fully as reliable a tæniafuge as male fern, kousso, or pomegranate, etc.; it is far more agreeable to the taste. No after-treatment is necessary, as a single dose usually is all-sufficient.

A New Turpentine Eruption,—Dr. Ernst Feiber, of Aix-la-Chapelle, in the *British Journal of Dermatology*, furnishes an excellent clinical example of the very rare and unique condition of an œdematous and papular erythema following the internal administration of a turpentine preparation. The patient was under treatment for subacute gonorrhœa, and was taking ten minims of the oil of turpentine twice daily. On the ninth day of the treatment—that is, after the use of nearly three fluid-drachms of the turpentine preparation—the patient complained of severe pruritus. On the following day an erythema, consisting of small, acutely pointed papules of a bright red color, some of which were excoriated by scratching, was found to cover the entire surface of the body excepting the head and face, being more pronounced on the lower than on the upper limbs, and specially intensified on the abdomen and buttocks. The pruritus and rash disappeared in three days, on the cessation of the turpentine preparation. Being desirous of ascertaining if the turpentine would again produce the erythema, Dr. Feiber again prescribed it. On the fourth day violent itching returned, accompanied by an eruption of similar papules; but in addition to these there were noticed on the abdomen and buttocks small red, slightly raised spots, with patches about the size of a florin of the same bright red color, both in their centres and in their peripheries. The urine was normal, and the patient felt well. Dr. Feiber remarks that whereas the first eruption was exclusively a pure papular erythema—roseola, the second, on the contrary, was a mixed form of œdematous and papular erythema, an eruption described now, as far as he knows, for the first time as consequent on the administration of turpentine.—*The Practitioner*, September, 1889.

Quiet Gout.—This term, says Mr. Jonathan Hutchinson, in the *Archives of Surgery*, may be suitably employed as applicable to the many cases in which those who are gouty experience no material inconvenience. The phenomena by which this condition is recognized are infinitely varied, and some of them very peculiar. A great many of them are probably caused by locally restricted attacks of peripheral neuritis. He regards the following as a case in point: A gentleman, past middle age, who had never suffered from an attack of gout, but who for many years had experienced many warnings, became the subject of a very real but almost ludicrous affection of one knee. He could walk quite well, could bear to have the knee handled any way, and there was not the slightest swelling. There was one thing, and only one, which he could not do without pain: he could not kneel on any soft substance. If he took care how the knee was placed on a hard floor, he could bear the pressure without pain for some time, but to kneel on a cushion might produce an explosion of pain which would make him cry out. He was often, so to speak, "caught" when in the act of getting into bed. The pain was of the nature of a local explosion, and was limited to an area the size of a crown piece. Very curiously, after one explosion had occurred it was difficult to produce a second which should in the least approach it in severity, and, after two or three shocks, he could kneel firmly without any pain whatever. The liability to the attacks passed away under treatment by alkalies and restricted diet, but subsequently returned and lasted a month or two. The skin on the front of the knee became for a time decidedly anæsthetic, a point which seemed to confirm the view that there was a local peripheral neuritis. —*The Practitioner*, September, 1889.

Hydrochlorate of Hyoscin as a Sedative.—Dr. Magnan, of Paris, who has lately tested hydrochlorate of hyoscin in his hospital, finds that a dose of 1 milligramme ($\frac{1}{64}$ grain) renders the patient calm in five minutes; he appears as if slightly intoxicated by alcohol, his feet seem rooted to the ground and he ceases talking. The drug is valuable in the treatment of insanity, as under its influence lunatics become calm, and remain so. In delirium tremens it induces healthy sleep. A child of thirteen suffering from tic, under its influence was cured of the spasmodic movements. A hysterical patient suffering from profuse perspiration of the hands and arms was entirely relieved by means of an injection of ½ milligramme, the perspiration was arrested in two minutes. —*The British Medical Journal*, September 28, 1889.

Treatment of Eczema, Psoriasis, and Pityriasis.—At the International Congress of Dermatology and Syphilography, Dr. Gourbault reported a number of cases of eczema, psoriasis, and pityriasis, which he had rapidly cured by the following syrup and ointment: Sixteen ounces of the syrup contain—of bicarbonate and acetate of soda two drachms each, also two drachms of extract of gentian, and a similar quantity of extract of sarsaparilla; a small amount of rhubarb and senna may be

added at the physician's discretion. The dose should be two fluidounces daily.

The formula for the ointment is as follows:

℞.—Ergotine, Perchloride of iron } . . . āā ʒss.
Vaseline . . . . . ℥j.
M. et fiat unguent.

This should be applied to the affected parts twice a day.

Antipyrin.—One of the greatest dangers which threatens the life of a new drug is the probability of its being looked upon as a panacea. Then, as a rule, after a brief period of notoriety, the drug fades away into obscurity, and even those good qualities which it does possess are looked upon with suspicion. No drug of late years, perhaps, has been so wronged in this way as antipyrin; and when one reads that in New York and elsewhere "antipyrin tippling" has become a common custom, the welfare of the drug seems indeed precarious. Yet antipyrin has held its own so far, and its sphere of usefulness seems to be broadening. The latest investigations with the drug have been probably those of DR. S. CARAVIAS, conducted under the guidance of Professor Germain Sée. He sums up the various actions of the drug in the *Centralblatt für klinische Medizin* for September 28, 1889.

Antipyrin decreases the excitability of the sensitive nerve-centres. Administered cutaneously it greatly alleviates pain of various origins. By means of a direct influence upon the vaso-motor system, it causes an enlargement of the peripheral vessels. Antipyrin in a 50 per cent. solution is a most excellent antiseptic, superior even to a 1 to 1000 solution of sublimate.

Clinical experiments have shown that antipyrin is a most excellent anodyne. It has yielded most satisfactory results in acute articular rheumatism, neuralgias, lancinating pains, etc., and its use, except in a few exceptional cases, has been unattended by any unpleasant accompanying symptoms. Good results were also observed to follow its use in gonorrhœal rheumatism, in dyspeptic troubles, and also in asthma.

The dose employed by Caravias ranged from 47 to 93 grains. In case the internal use of the drug is not tolerated by the stomach, it should be given hypodermatically. This form of administration is also preferable when a quick action is desired.

Regarding the antiseptic properties of antipyrin, Caravias has used a 10 per cent. solution as an injection, and medicated bougies containing twelve grains of the drug with great success in gonorrhœa.

The Treatment of Angioma by Electrolysis.—In the *Centralblatt für Chirurgie* for September 7th, DR. TH. GESSLER gives a report of 221 cases of angioma occurring in the Tübingen clinic. Speaking of the various methods of treatment employed, Gessler records 60 cases treated by excision; 73 by ignipuncture, and the remainder either by the galvano-cautery, ligation of their nourishing arteries, or injection of chloride of iron solution. In 10 of the most severe cases electrolysis was resorted to, and in 9 of these it proved to be successful.

Electrolysis has been rarely used in Germany, but widely employed in England and America. In France its employment has been limited.

The method of treatment employed at the Tübingen clinic was as follows: Two platinum needles were thrust into the base of the angioma, care being taken that they did not touch each other; then a constant current, of about ten to twenty milliampères, was allowed to pass through the growth for ten or fifteen minutes. A burn was caused which healed quickly when treated with iodoform. The procedure must be repeated frequently during a period of one or two months before a complete cure can be effected.

The Cause of Death from Burns.—A series of experiments recently conducted by DR. WELTI, are reported in the *Centralblatt für klinische Medicin* for September 21, 1889. The research was undertaken with a view of ascertaining the cause of death so frequently observed to follow superficial burns of a comparatively slight nature. From an etiological point of view Welti's researches are most interesting.

The first experiments consisted of holding a rabbit's ears in water, the temperature of which was gradually increased up to about 160° to 170° F. The animals all died within an hour. In the other experiments the animals' ears were merely dipped once into water of about 160° F. The majority of these died in one or two days.

In each case the cause of death was manifestly identical, as the same changes were observable in every instance. This change consisted in a degeneration of the red blood-corpuscles, and the formation of thrombi loaded with blood plaques in many vessels, especially those of the pia mater, kidneys, and intestinal tract. When the animals lived for several days after the experiments, pathological results of the above changes were noted. Owing to the obstructions, the different tissues underwent softening and the free surfaces of mucous membranes broke down. Observations in the human subject, under similar circumstances, revealed identical pathological changes.

"Amminol" for the Disinfection of Sewage.—In the issue of THE NEWS for September 14th, a new method of precipitating sewage, then being tested at Wimbledon, was referred to. The *London Times* now devotes a large amount of space to the consideration of this new disinfectant method, which was discovered by MR. WOLLHEIM, of London, and which bids fair to revolutionize the sewage question. The disinfecting power of amminol gas is such that, when introduced into sewage, it very quickly destroys the microbes of putrefaction and of many diseases. The odor of sewage is almost instantly displaced by that of the reagent, and in less than an hour the sewage thus treated is both deodorized and sterilized. It is reported that Dr. Klein has in part confirmed the claims of the discoverer in so far that one sample of sewage examined by him was found to be absolutely sterile after having been treated by the amminol method. If this alleged discovery should be verified, it will undoubtedly become one of the most useful discoveries of the present day and must materially influence the future of sanitary practice.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

Philadelphia.

SATURDAY, OCTOBER 19, 1889.

ANÆMIA AND ITS TREATMENT.

The interesting papers recently read by Dr. Henry as referee and Dr. Forchheimer as co-referee, before the Association of American Physicians, which have appeared in the columns of this journal within the last few weeks, naturally call attention to the question of the treatment of the maladies which they so fully discuss. Let us first glance at the theories held by some of the various writers on this subject, before turning to the drugs actually to be employed; and in doing this, we must of necessity study to a slight extent the failure of the absorption of iron under ordinary circumstances.

We have the theory of Bunge that sulphur in excess in the body prevents the assimilation of iron, and its endorsement by Clark. If the latter is quoted correctly, his own statement contradicts itself, for he says that in chlorosis sulphides are formed in excess, and this causes chlorosis by non-assimilation of iron. The question at once arises, How did the chlorosis come on in the first place, before the sulphides were formed? Sulphides may aid in its continuance, but it is not proved that they produce it, and it is proved that they are often present in enormous quantities where no chlorosis occurs. Again, we have no proof that the manufacture of hæmoglobin depends upon the absorption of iron alone.

Clark thinks that when we give iron to such a case the sulphides unite with it and the iron in the food escapes into the blood-making organs. Either the doses of iron must be very accurately fitted to the amount of sulphides, or excessive amounts must be used, so that no sulphide may be companionless. As all persons have sulphides present in sufficient amount to make a characteristic stool on taking iron, we should, according to this theory, all have anæmia unless we protected the iron in our food by a constant use of the free metal.

We think practical experience does not support the use of enormous doses of iron in anæmia and chlorosis, but rather the contrary. The celebrated teachers of the Dublin school years ago put forward the theory that small doses of iron were more useful than large ones in direct ratio to the severity of the disease, and we are much inclined to agree with them. There is quite as much likelihood of failure of assimilation of iron by diseased organs as of its destruction by wolf-like sulphides.

We learn from practical experience several things which science does not tell us, namely: Iron will not cure all cases of chlorosis or anæmia, even if they belong to a functional type, but other methods must be resorted to at the same time, or separately, for their cure. The insoluble salts of iron are better remedies for absorption than the soluble salts, because they are not precipitated in the stomach, and for this reason reduced iron is the best chalybeate for uncomplicated cases. Beside using iron in this form, we should employ laxatives if the bowels are confined, mineral acids, particularly nitric and nitro-muriatic, for their effect on the function of the small intestine and liver, and, in addition, bitter tonics of a more or less simple form, according to the exigencies of the case; using quinine if malaria seems lurking in the body, simple bitters if the stomach lacks in tone, aromatic bitters if, from atony of the muscular coats, the digestive tract seems sluggish, with a resulting formation and accumulation of flatus and digestive juices.

At present we may conclude that pathology has not found out the real causes of these troublesome cases, and that until physiology can put its finger upon the most intricate mechanism of blood-making with a positive, clear statement of its function and the physiological chemistry of the manufacturing of hæmoglobin, we must remain satisfied to resort to the remedies which experience or common sense tells us will be of value to our patients.

HOMŒOPATHIC VIEW OF MODERN HOMŒOPATHY.

THOSE not members of the medical profession, often assert that regular physicians are exceedingly bigoted because so many of them exhibit great feeling when the question of homœopathy is brought forward for discussion. The reason for the bitterness of many medical practitioners is, however, not far to seek. It is because their experience has taught them, that the bulk of the homœopathic practitioners owe, in great part, their success to their not practising what they preach, to their claiming that they avoid strong medicines while at the same time they use drugs in much the same manner as do other doctors.

A recent editorial in *The Journal of Homœopathics* seems worthy of being regarded as witnessing the decadence of modern homœopathy from Hahnemannism. We notice also in the same journal the query whether the American Institute of Homœopathy, having a guilty conscience, was afraid of Judge Barrett's arraignment. It seems to us odd that any legal decision should have been necessary to prove that a man who habitually does exactly what he professes most strenuously not to do is a fraud and a hypocrite, but there are many in whom the discovery, and not the crime itself, produces remorse. The editorial is as follows:

"Perhaps no stronger comparison can be presented between the methods of Hahnemannian Homœopaths and the Eclectic Homœopaths than the recommendation of President Talcott, of the American Institute of Homœopathy, in his annual address at Minnetonka Beach, and the action of the International Hahnemannian Association in 1886, in relation to the same subject, viz., specialties in medicine.

"Specialism in treatment presupposes that there are different means of producing diseased conditions than that which Hahnemann has presented—*i. e.*, something different than a 'distunement of the spirit-like Dynamis (life-force), in the invisible interior, vivifying our bodies. If this supposition is true, then there is no ground for the Institute to stand upon, as an organization separate from the allopathic school; if it is untrue, then the very suggestion places the Institute in the doubly false position as a supporter of homœopathic principles and an opponent of homœopathic practice.

"There is absolutely no place for specialists in homœopathic treatment, except the specialism of *similia*. If there is sickness presenting itself by symptoms in one particular organ or set of organs, it is not because those organs alone are sick, but because the entire individual is sick, and the cure must be effected throughout the entire individual; otherwise there is no *cure*.

"If the American Institute will take pains to study Homœopathy and Hahnemann's *Organon* for the ensuing year, there will be some hope that such absurd blunders will cease in the near future. Such matter, as this we criticise, is, however, but a mere caricature of homœopathy.

"It is only in the International Hahnemannian Association that homœopathy pure and simple is to be found—the Institute abandoned it long ago."

THORACENTESIS.

THE subject of the treatment of collections of fluid in the chest must always be of interest to the practitioner of medicine, because diseases giving rise to such effusions are so constantly met with that every physician must frequently be called upon to treat them.

In *Lyon Médical*, September 8, 1889, Leclerc and Tillier record a case of death from exhaustion following empyema, where thoracentesis had been practised with irrigation of the pleural cavity. One of the chief points of interest in the case is that the injection of a warm antiseptic solution gave rise to the most alarming symptoms, absolute instantaneous arrest of heart action and respiration, with a brachial monoplegia which remained after the more threatening symptoms had been successfully combated. That the symptoms were not due to the antiseptics used is evident from the fact that they appeared immediately, before sufficient time had elapsed for absorption. This case and others illustrate the danger attendant upon irrigation of the pleural cavities, and that such danger should exist is not to be wondered at when we consider the important structures contained in the very mobile mediastinum. That the practice of washing out the emptied pleural cavity is unnecessary, the statistics of Bowditch demonstrate very clearly.

Thoracentesis by itself is not without risk fortunately minimized by the substitution of aspiration for tapping with trocar and canula. Foremost among the dangers stands "albuminoid expectoration," or, to name the lesion instead of the symptom, the overfilling of the capillaries of the lung,

rapidly expanding to occupy the vacuum produced by withdrawal of the exudate. Beside this there is the risk of pulmonary embolism, as well as that of producing convulsive or paralytic phenomena which are usually transitory, but which may, as in the case above mentioned, persist for a longer time.

That there are dangers incident to the operation of thoracentesis is a reason not for discontinuing its use, but for extreme care in its performance. That it should not be unnecessarily performed is as certain as that it often is the means of saving life.

Past experience has taught valuable lessons in regard to the handling of pleuritic effusions. That the fluid when serous can often be speedily removed by medicaments, notably by the use of the "dry method," is undoubted. The withdrawal of even a small portion of the mass of fluid may wonderfully accelerate the complete absorption of all of the exudate. Should the amount of fluid be so large as to threaten life, or should its absorption be found (after a proper trial of non-operative measures) to be slow or imperceptible, the operation of thoracentesis by means of a *small* aspirating needle is indicated to remove either a part or all of the liquid.

Quite different is the aspect of the case when hectic appears, or when exploration with a hypodermatic needle reveals the presence of pus. Here the only means of cure is to evacuate the pus either by aspiration, or far preferably by incision and drainage with or without exsection of portions of one or more ribs. These cases run a far better course if no injections whatever are made, and we believe in the large majority of instances the use of such washes distinctly increases the danger of a fatal issue.

REVIEWS.

A Treatise on the Science and Practice of Midwifery. By W. S. Playfair, M.D., F.R.C.P. New (fifth) American from the seventh English edition; edited, with additions, by Robert P. Harris, M.D. Octavo, 670 pages. Philadelphia: Lea Brothers & Co., 1889.

After the lapse of four years a new edition of this well-known work appears, sufficiently Americanized upon the points where English and American obstetricians differ in opinion and practice, to fit it for the uses of medical students and obstetricians in this country. We find some portions of the book rewritten and several new illustrations added, but by far the greatest change is seen in the additions and notes of Dr. Harris. The pages devoted to the anatomy and physiology of the organs concerned in parturition are practically identical with those of the earlier editions. The precise mode in which the blood escapes from the vessels in producing the menstrual discharge, has been studied by Leopold upon a young girl burned to death on the third day of her menstrual period, and his observations corroborate the view of Coste—namely, that the blood transudes through the coats of the capillaries by a process of diapedesis, while the same observation rather disproves the theory that the entire mucous membrane, or even any portion of it, undergoes the fatty degeneration and extensive exfoliation as are so commonly described. Part II., in which pregnancy is considered, will give the student a clear and concise idea of conception and generation. The author is to be congratulated upon his clear elucidation of the chapter devoted to embryology, a subject which is always so obscure to the average reader. While allusion is made to the employment of abdominal palpation and the fact that it has not been generally appreciated in obstetric works, the author, we think, has not given the subject as much attention as its importance merits. An illustration and less than a page of text describe the method. There is, however, no mention of its value in diagnosticating occipito-posterior presentations, nor the possibility of ascertaining the approximate size and compressibility of the fœtal head. Dr. Herbert R. Spencer, at a recent meeting of the London Obstetrical Society, pointed out the possibility of making the diagnosis of placenta prævia by this method.

In discussing the treatment of extra-uterine pregnancy, prior to rupture, the author states that the uncertainty of diagnosis has prevented the adoption of abdominal section and, so far as electricity is concerned, says, "this practice is perfectly safe and there can be no rational objection to its being tried."

The American editor's note clearly indicates the necessity of employing the exsection method in dealing with the cyst and placenta in cases where the fœtus is living and viable.

About two hundred pages are devoted to labor, in which are ably discussed the phenomena and management of labor, the mechanism and management of normal and faulty presentations, anæsthesia, and dystocia.

The author approves of the intra-uterine applications of styptics as a *dernier ressort* in treating post-partum hemorrhage, but makes no mention of the intra-uterine tampon of iodoform gauze, as first recommended by Dührssen.

In considering obstetric surgery as applied to many causes of dystocia, Dr. Harris, in his editorial notes, has displayed again his intimate knowledge of what has been accomplished by the obstetric surgeon—a knowledge, indeed, so accurate and far-reaching as to merit the highest praise.

It is most gratifying to learn that the Porro operation has fallen in its rate of mortality since 1884 from 58 to less than 20 per cent.; that laparo-elytrotomy has given way to the conservative, or improved Cæsarean, by reason of its diminished death-rate from 45 per cent. to a general average of 20 per cent., and for Continental Europe of 12 per cent.

The chapters describing obstetric operations are admirable, particularly that on Cæsarean section.

The work concludes with ten chapters on the puerperal state, the last one on pelvic cellulitis and pelvic peritonitis, in which the author refers to the importance

of distinguishing the two classes of cases—an importance which recent abdominal work has failed to recognize.

Playfair's Midwifery has for a long time enjoyed a well-deserved place of honor among the standard works on obstetrics, and we see no reason why it should not continue to be one of the best books for the student or practitioner.

Wood's Medical and Surgical Monographs. Volume I. Number 1. Octavo, pp. 258. New York: William Wood & Co., January, 1889.

The first volume of this series of monographs opens most appropriately with the well-known lectures of Mr. Jonathan Hutchinson, delivered in 1881, on The Pedigree of Disease, which it would be supererogation on our part to review and which are above criticism. A more fitting introductory essay to a series could not well have been selected. Following these six lectures on Temperament, Idiosyncrasy, and Diathesis, are eight on Common Diseases of the Skin, by Dr. Simon, of Birmingham. In them, pruritus as a symptom, eczema, psoriasis, scabies, acne, and ringworm are ably discussed from the standpoint of the general practitioner, with much more attention to treatment than to pathology and dermatological nomenclature. Dr. Simon, in most of these diseases, rightly considers the general management of paramount importance, and devotes six pages to the constitutional treatment of eczema, adding one more protest against the indiscriminate use of arsenic in all but the most chronic cases.

Last and least in practical value are fourteen lectures of Dr. Ferrand's on The Varieties and Treatment of Bronchitis. Classification seems chiefly to have occupied this author, describing, as he does, congestive bronchitis, catarrhal bronchitis, inflammatory bronchitis, spasmodic bronchitis and infectious bronchitis, with nearly fifteen sub-varieties. On the whole, these lectures, though interesting, must often be puzzling to those accustomed to broader views and less minute classification. In treatment there is but little originality, revulsives, inhalations, and nauseant depressants all being advised. Nauseants Dr. Ferrand uses very largely, even when free secretion is established. The volume is printed on the best of paper and in the clearest type.

A Guide to Therapeutics and Materia Medica. By Robert Farquharson, M.P., M.D., etc. Fourth American from the fourth English edition. Octavo, pp. 598. Philadelphia: Lea Brothers & Co., 1889.

The existence of the classical works of Wood, Ringer, and Bartholow makes the addition of smaller and less complete works appear to us unnecessary. Dr. Farquharson has given us a book fairly up to date in regard to our knowledge of drugs and their effects, but to that knowledge he has added not an iota. The work before us partakes both of the nature of a quiz-compend and a text-book. Used as the former it would be better for the student than the average compend, which, in the present state of medical education, is perhaps a necessity. The manner of placing the physiological actions and therapeutic uses of drugs in adjacent columns, and the frequent bracketed annotations of the editor seem to us an unfortunate arrangement, and, until one is accustomed to it, decidedly distracting. The most useful sections are the introductory chapters on general rules for prescribing and the appendix containing the formulary issued by the American Pharmaceutical Association. From the latter the practitioner may glean many suggestions valuable in writing his prescriptions.

Dr. Woodbury has done his work well and thoroughly, and in no instance will the American reader be led astray by English authorship.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, September 11, 1889.

The President, W. W. Keen, M.D., in the Chair.

Dr. Ferdinand H. Gross read a paper on

HÆMATOMETRA.

The rarity of hæmatometra is so well known that, while I have nothing new to say on the subject, I have been induced to report to the Society in some detail two cases of this character, which came under my observation during the early months of the current year. Atresia of the vagina I have, of course, frequently observed, but not when it was complicated by the state of which I now speak.

In the cases to which allusion has just been made, the atresia existed in one, at the lower end of the vagina, while, in the other, it consisted in an obliteration of the cervical canal of the uterus; and thus two interesting varieties of the occlusion were exemplified.

A young girl who had been under the care of different physicians without the source of her troubles being fully recognized, was referred to me by a medical friend for treatment, with the information that a tumor occupied the vagina and filled up the lower part of the pelvis.

The patient was in her fourteenth year, and therefore at the age of puberty; but she had never menstruated—that is to say, no visible sign of the catamenial flow had been noticed. The first disturbances of her health had occurred about six months before, and although she never felt quite well afterward, her indisposition, for a time, caused no apprehension. Finally, a number of paroxysms of great severity attracted attention, and the alarming character of the exacerbations led to a physician being consulted.

When, in an advanced stage, the case was referred to me, a digital examination of the vulva revealed protruding therefrom a smooth and very tense swelling, in which the experienced touch could readily detect fluctuation, particularly by rectal exploration. Neither the examining finger nor the probe could find anywhere between this protrusion and the labia an entrance into the vagina. The hypogastrium had become prominent from a tumefaction which arose from the pelvis. This enlargement in the course of its development had been noticed to be most sensitive during the above-mentioned paroxysmal attacks, which were doubtless the regular menstrual molimina. The continuous abnormal pressure upon the pelvic organs was the occasion of vesical

and rectal tenesmus as well as constipation; and restless nights were the inseparable accompaniments of such torments. Aside from these there were symptoms of a subjective character, such as headache, giddiness, nausea and other gastric distress, a feeling of painful fulness in the abdomen, palpitation, and disturbed vision which the prescribed glasses of the oculist had failed to relieve. The presence of such distressing and long-enduring symptoms naturally led to the diagnosis of hæmatometra as a consequence upon atresia hymenalis.

It is not my purpose here to recount with exhaustive minuteness the various results of hæmatometra if relief be not given in good time, by what is usually a simple surgical operation, nor would the time allotted permit me to speak of the lesion as it occurs in double vagina, in duplex uterus, and in other malformations of the female generative organs. Greulich relates in concise form, but with sufficient clearness, the different issues of this condition, and cites an array of authors who appear in the literature of the subject. Some of the results of these blood-tumors should not remain unnoticed in this place. Much may depend upon the period of life at which the atresia has been acquired. For example, in the climacteric age the hæmatometra may eventually be tolerated (*Real Encyclopædie der gesammten Heilkunde*, vol. vi. page 180), or at least borne with less suffering or discomfort, since at this period of change the tumor may cease to enlarge because of the discontinuance of the menstrual secretion. Again, at periods prior to the menopause, the rapidity or slowness with which the liquid accumulation takes place, and consequently the degree of its evil effects upon the general organism, may depend upon the character of the patient's constitution, whether this be plethoric and robust, or weakly and anæmic. If the latter be the case, the increase of the pent-up menses may be very meagre or even *nil;* and again, if vicarious menstruation be established, the addition *in utero* would naturally be voided, affording a degree of local relief, or, at least, checking for a time the progress of serious symptoms, provided the locality of the vicarious discharge be a safe one.

Among other possible results of this bloody accumulation are enumerated hæmatosalpinx, intra-peritoneal hæmatocele, and hæmatoma of the ovarium, each with its serious consequences. The internal *ostium* of one or both Fallopian tubes may be drawn open by the expansive force of the womb's accumulating contents, which, if not met by tubal obstruction, may ooze out at the *ostium abdominale*, and give rise to an intra-peritoneal hæmatocele and peritonitis. In hæmatoma of the ovarium the formative process is likely to be different. Whether at certain periods of functional activity, when the fimbriæ of the tube are said to clasp the ovary, to receive the ovule from the Graafian vesicle; or whether, at the time of direct communication between the tube and ovary, the fluid of the hæmatometra ever escapes into the bursting vesicle or stroma of the gland, must be left to hypothetical speculation. But hæmatoma of the ovarium as well as effusion into the tube may occur by direct extravasation from congested vessels and yet hæmatometra be responsible for either occurrence, since hyperæmia of the uterine appendages is one of the accompaniments or conditions of the hæmatic tumor we are considering. If, therefore, the already engorged plexuses or network of vessels of the environment be periodically subjected to additional blood-pressure, the bleeding that follows the bursting of a Graafian follicle under normal circumstances may now become sufficiently copious to produce results of a pathological character.

Without stopping to speak of a possible rupture which would allow the secretions to flow off in a natural or harmless direction, adhesions may form with the neighboring hollow organs, and perforation take place into bladder or rectum. Septicæmia from decomposition within the womb is also a great danger. The entrance of urine on the one hand, or of fecal matter or intestinal gases on the other, would be favored by the womb's enfeebled contractile power, as that organ could not empty itself with promptness nor with that degree of force of which it is possessed when developed for a physiological purpose. The pressure of tumors is recognized as a cause of uterine atrophy, and we can readily conceive in hæmatometra that an attenuated condition of the muscular coat might ensue. Another danger of infection may be a vaginal *cul-de-sac* below the point of perforation into either of the hollow viscera mentioned, which would serve as a reservoir for decomposed matter.

Considering the possible results of this condition, no time is to be lost in providing for the escape of the accumulated secretions.

Hymen imperforatum in a large majority of the cases is not discovered before the age of puberty, and the one referred to was doubtless of the congenital variety.

The operation can hardly be called a painful one, but the girl had become so irritable and sensitive from long suffering and repeated examinations, that the puncture by trocar was made under ether. Thirty-two ounces of reddish-brown, chocolate-colored fluid were drawn off without interruption of flow. The canula being removed, a crucial incision with a probe-pointed bistoury enlarged the opening, from which a little fluid oozed. Ergot was administered, but only gentle pressure was applied externally by an abdominal binder. The vagina was gently washed out with a weak solution of the bichloride. The uterus remained too high to be reached by the finger, and an examination by force was uncalled for. The vaginal surface was smooth and devoid of rugæ. As an additional precaution, the external parts were covered with compresses of antiseptic gauze.

It is to be remembered that the imperforate hymen is not a normal but a patho-anatomical structure. On the inner side its mucosa is continuous in cul-de-sac form with that of the vagina, and externally the mucous membrane is continuous with that of the vulva, while between these layers lies a fold of connective tissue. The membranous barrier in this case was found thick and tough beyond expectation, imparting the sensation of soaked leather to the fingers.

The relief was prompt and decided; on the second day there was some pain in the hypogastrium, but no significant rise in the patient's temperature. In four weeks the menses were discharged in a normal manner, and this has recurred at regular intervals ever since.

In the second case alluded to, the woman is close upon forty years of age, and has lived in the marriage relation for half that period, but remains childless. The evidence she relates as pointing to a miscarriage in the third year of her married life, is not conclusive. After that time she enjoyed good health until thirteen years

ago, when she "had a severe fall backward," after which she endured so much pain in trying to void her urine that she fainted. Her physician said she had "dislocated her womb," and used instruments to replace it. She was confined to bed for three weeks and then treated in a hospital in this city; whence she returned home, still in a feeble condition, and remained in poor health for several years. These early troubles are briefly mentioned since they concern the genito-urinary organs, and I will not tax your patience with a history of subsequent maladies which had but doubtful or no connection with the patient's later complaint. Suffice it to say, that after an attack of typhoid fever as far back as 1883, she regained her former good health, and in all the years that followed until the month of May, 1888, the menstrual function was regularly performed. It was then, however, that the lesion which concerns us here appears to have had its beginning. The monthly discharge of blood became scanty, and to the patient it appeared as though "a stringy leucorrhœal discharge had replaced the regular flow." Nor was she as free from pain as she had formerly been during her regular periods. In the following August her menses failed to appear, and the amenorrhœa continued for eight months; that is to say, until she was relieved by the operation mentioned further on. As regular as had been her monthly periods when in health, just so regular were they during these eight months when the attacks of lumbar pains and uterine cramps presented themselves, the severity of which increased with each returning molimen. In vain she now applied for relief both to regular and irregular practitioners. The latter advised her to enter their hospital and submit to a laparotomy for the removal of what they pronounced to be a "fibroid tumor attached to the uterus and left ovary." This advice was not followed, and it need hardly be said that the diagnosis was as incorrect as the laparotomy would have been unwarrantable. The condition grew from bad to worse. From dire necessity the woman had learned to catheterize herself and was enabled by that means to obtain frequent relief from one of her greatest torments.

On the 30th of last March she entered the German Hospital, where she became my patient. On examination the next day, I found a large, smooth, very hard and firm tumefaction pressing low in the pelvis. The os could not be found and there was no discernible discharge from the vagina. No fluctuation was perceptible, either by vaginal or rectal examination. The mass had repeatedly been held by others to be a fibroid; but on hearing the patient's own account of the case, from which the above is a condensed statement, I concluded it to be a hæmatometra, at once verified the diagnosis with an aspirating needle, and on April 2d introduced an ordinary sized trocar and drew off the long pent-up secretions. In penetrating at the indistinct but supposed point of the former os, the instrument imparted the sensation of passing through a wall of considerable thickness before reaching the cavity, showing the obstruction to be something more than membranous. This was probably brought about by a stenosis of the inner os, combined with an endocervicitis and adhesions of the entire cervical canal.

The mahogany-colored, jelly-like fluid, or semi-fluid, could not flow freely through the canula, but came only drop by drop. The cervix dilator therefore replaced the canula, and being used as a director for making a shallow crucial incision, a quart of the tarry substance was drawn off. The cavity of the womb was freely washed out with a continuous stream of the mercuric solution. Ether was not administered. The after-treatment was in the main similar to that instituted in the other case. Recovery was complete, and the patient has menstruated at regular periods several times since the operation.

Dr. John C. Da Costa asked Dr. Gross where he punctured the uterus in the second case? Did he attempt to follow the cervical canal, or did he put the trocar directly into the mass? He congratulated both patients on having fallen into the hands of Dr. Gross, and out of the hands of their previous advisers. Hæmatometra is not of common occurrence, and when we have it, it is usually due to closure of the os, or atresia, so called. The first case reported would, he thought, be found described in the books rather under the head of atresia of the vagina than of hæmatometra; neither could he understand how those who had previously examined and treated the case could have overlooked the nature of the difficulty. They would not have done so if they had heard the late Professor Wallace lecture on atresia vagina, as he used to describe it, with "the bulging membrane looking like a child's head coming out." If they could not have made a vaginal examination, an examination by the rectum would have shown the uterus above and the soft fluctuating mass below, and made the diagnosis for them.

The second case seemed to be due to closure of the cervical canal. This is more common after the application of solid nitrate of silver than people generally are aware. There is apparently something particularly vicious about the application of solid nitrate of silver to the cervical canal. Stronger agents may often be used without producing the trouble it does. The speaker was unable to see how in this case a practitioner could mistake the nature of the trouble. The gravity of such cases often arises from imperfect examination of the parts, and, therefore, ignorance of the condition, and as a result of this—want of timely treatment.

Dr. Lawrence Wolff had had the pleasure of examining the second case with Dr. Gross. He had assisted him in emptying the uterus, and his curiosity having been aroused as to the nature of the chemical changes that had taken place, he secured some of the contents for examination. The microscope showed that there were no corpuscles present. He made the blood test, and secured Teichmann's hæmatin hydrochloride crystals. While there was undoubtedly blood, there was no hæmoglobin, but hæmatin. He thought the question is not altogether solved as to what becomes of the serum-albumin in such conditions. The uterus is not prone to take up serum-albumin, but here it had evidently been absorbed, and nothing but globulin and hæmatin remained, as was found to be the case when the mass was mixed with water, which rendered it turbid, the globulin being insoluble in water. The fact that globulin is not taken up is not generally known. We know that the corpuscles, as a result of pressure, poisons, and other conditions, will break down, and that hæmoglobin will be changed to hæmatin, but it is not generally understood that in hæmatometra serum-albumin, which is diffusible, is reabsorbed and globulin retained. These facts have a bearing upon various pathological conditions, especially

some forms of nephritis, and that is one reason why he had brought up these points in regard to the condition of the blood in these cases.

Dr. Joseph Price said that these congenital forms of atresia were quite common. In the last few years a great many operations have been performed for infantile forms of the female generative organs, and in many of these cases we find atresia. In the last year he had done two sections for regular menstrual molimen without visible flow. The patients had suffered from the age of thirteen or fifteen years to thirty-five, without any menstrual fluid showing itself. In these cases atresia with infantile uteri was found. The appendages were rudimentary. There was no accumulation. In both instances the results have been quite happy.

A few years ago, a lady asked Dr. Price to attend her in her confinement. Conception had immediately followed an operation upon the cervix uteri done by an estimable operator. She had been sterile for five years before the operation. Previous to this she had borne three children. She sent for him after she had been in labor for some time. There had, however, been no show. On examination he found a supra-vaginal diaphragm, without the semblance of os or cervix. He made a careful speculum examination, and sent for a friend, a man of good judgment and experience. The head was engaging, but no os could be found. A crucial incision was made in this diaphragm, and she was delivered of a healthy child without trouble. She made a good recovery, and has since borne children. In this case, although a canal had been left, there were probably some granulations which subsequently closed the channel.

Ten days ago he operated upon a cicatricial case. The woman had borne four healthy children, but had not menstruated for some years. He found but little accumulation. There had been extensive sloughing, and he had to make a vagina throughout. A portion of the blood had apparently been absorbed. The material found in these cases is usually of a hard character similar to that found in hæmato-salpinx. It will make a black mark, and can be used as a crayon.

The discharges from the tubes of which Dr. Gross spoke, he was satisfied last only a short time. The irritation is sufficient to provoke occlusion of the tube, and we have the clubbed condition of the tubes seen in accumulation of fluid in the tubes. The tubes look like the end of an amputated finger. I have here two specimens illustrating this point. The woman from whom this was removed never conceived. There have been salpingitis and local peritonitis, causing closure of the pavilion. Here we have a broad ligament cyst, an occluded tube, and a typical hydrosalpinx. Schœder gives an interesting discussion of this entire subject, and cautions care in the examination that leakage or rupture may not occur. It is evident from his remarks that this accident had occurred in his hands.

Dr. Gross, in reply to the question of Dr. Da Costa, stated that there was only a point indicating where the os might have been. He followed this in the direction one would suppose that the canal would take. It was some time before the trocar reached the cavity.

In regard to the first case, an examination *per rectum* might have revealed a small uterus if the fluid had been contained only in the vagina. This case was, however, of six or seven months' standing, and the secretions, after filling the vagina, had also dilated the cervix and uterus. Here the term hæmatometra is also used. When the vagina only is filled, it is an hæmatocolpos. To be more exact, unless we object to long names, the term hæmatometrocolpos would express the condition when both vagina and uterus are involved.

Dr. Gross was obliged to Dr. Wolff for his interesting remarks in regard to the character of the fluid, which made the report of the case more complete.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting September 5, 1889.

John C. Da Costa, M.D., in the Chair.

Dr. John C. Da Costa read a paper entitled,

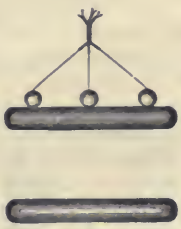
AN EASY METHOD OF REPAIRING THE PERINEUM.

He did not claim anything new, the operation being the result of a combination of old ideas, and an easy and simple method, answering equally well whether the tear is long or short.

Mr. Lane, of London, in 1860, used ivory bars with small perforations for approximating the edges of the perineal tear, and reported thirty consecutive cases without a failure. Dr. Thompson, of Washington, used flat rubber bars with small holes in them, and has reported fifty-three consecutive cases, all cured. Dr. Thomas, after speaking of the quill suture, leads us to infer that he uses perforated bars, and states that he does not recall a failure in his experience.

The operation which Dr. Da Costa recommended is very simple and the instruments are few: a pair of blunt-pointed scissors, a perineal needle, a little silver wire and a few shot, a shot-compressor, and two bars shaped like the accompanying cut:

Fig. 1.

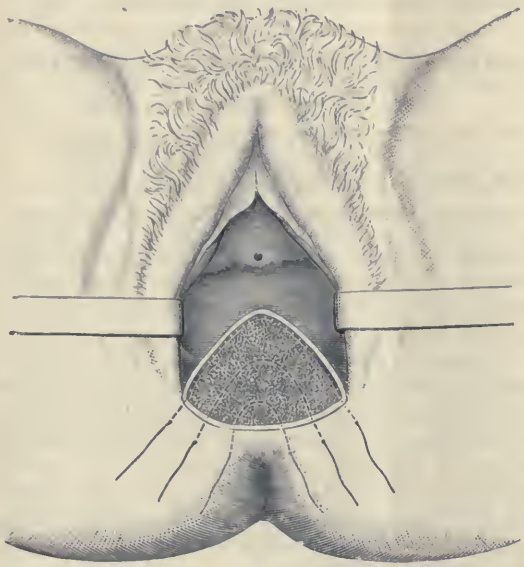


Bar, ½ size.

The operation is begun at the bottom ot the tear in the vagina. With one or two fingers in the rectum, a little slit is made at the lowest point and the torn tissue is denuded. It is important to get rid of all scar tissue, for unless this is done good union will not be secured. After freshening the bottom of the tear, the scissors are turned to the right and to the left, and each side is denuded. Then, with four cuts of the scissors, the loosened cicatricial tissue is removed. The first stitch is made near the bottom of the raw surface and is passed three-fourths of an inch from the edge of the cut portion, buried the entire distance, and comes out on the other side equally far from the border of the wound. The needle is then threaded with silver wire and withdrawn. The second stitch is put in in the same way. The third stitch is started in the skin like the others, three-fourths of an

inch from the edge of the cut, and carried along just under the edge of the freshened surface the whole way around. This is the most important stitch of all, and was introduced by the late Albert H. Smith, when one of the physicians-in-chief at the Nurses' Home some years ago. The stitches are buried throughout, and only three are used in the operation. All that is necessary is to bring them out in a straight line.

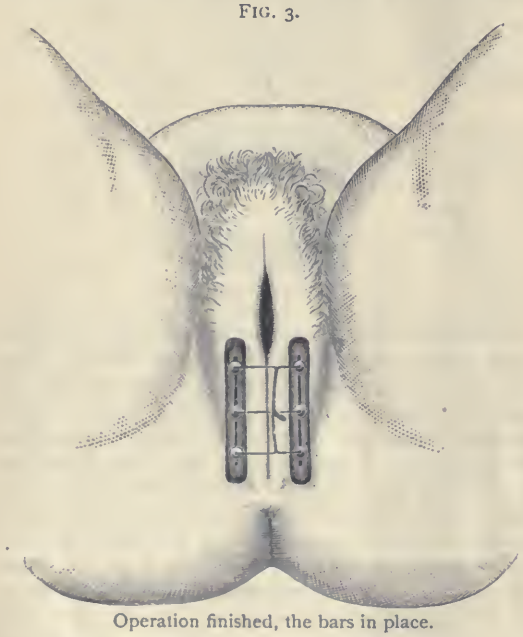
FIG. 2.



Surface denuded, and stitches in place.

After this, the wires are slipped through slotted rubber bars, on each side, and shot clamped on them. After the shot are clamped, the ends of the wires are twisted

FIG. 3.



Operation finished, the bars in place.

over the median line, and passed through a piece of catheter. Any dressing may then be applied.

The advantages of this operation are many. In the first place, but three stitches are used. Probably every gynecologist has seen cases where there has been deep quilting, and where the tissue has sloughed out because the circulation has been so interfered with that nutrition could not be maintained. These three sutures interfere very little with the circulation, and they hold together the deep parts of the wound. When inflammation takes place, the wires over the shot are cut; the bars spread and relieve the tension and prevent any tendency to sloughing, while still supporting the parts.

This is a different operation from that in which the denudation is made in curved lines, and where another operation is required for any existing rectocele. The operation described above will include a rectocele. It is better than another popular operation, which does not restore the triangle which nature made, but makes a beautiful skin-flap, which looks well from the outside, but affords no support.

DR. JOSEPH PRICE said that there were a few points about which he would like to speak in connection with this operation. As Dr. Da Costa had pointed out, this is an old operation, and can be found in all the text-books. It is the old operation upon the posterior wall, and has the merit referred to, of, in many cases, making a superficial or skin perineum. The principle of suturing described is not adopted in any other branch of surgery, and he was sure Dr. Da Costa would not apply this principle to any other portion of the body. He said that sometimes he denudes a distance of three inches. In no other part would he approximate such a surface with three sutures, as three sutures will not close it.

One of the illustrations shows what takes place in many perineal tears. The skin-perineum side is not harmed; but if a finger is placed in the sulcus on one side, a sense of resistance is found which is absent on the other side. The sulcus is a deep one, and is a lateral tear. As has been remarked by Dr. Deaver, "It is like the lateral cut for stone." In such a case the operation is almost a unilateral one. It is just such a state of affairs that Emmet had in view in his classical operation for the restoration of the pelvic floor, and he has been wonderfully successful. The needle used should be very small.

DR. DA COSTA, in reply to Dr. Price, said that the criticism made in regard to one of the illustrations had nothing to do with the subject under discussion. If there is a line of cicatricial tissue on one side, we do not need to denude both sides to repair the condition, for it is a simple matter to remove the scar tissue and sew it up, as in any other surgical operation.

DR. JOSEPH HOFFMAN made a

REPORT OF A SERIES OF ABDOMINAL SECTIONS, WITH SPECIAL REFERENCE TO COMPLICATIONS.

The list of operations may be classified as follows: one strangulated ventral hernia; one appendicitis and hæmatocele; sixteen cases of ovarian and tubal disease with adhesions, inflammation, and occlusion of the tubes, with one death, the result of sepsis from a miscarriage brought on instrumentally. In other words, he believed the tubes were in a septic state, and gave rise to the peritonitis.

In two cases the gonorrhœal origin of the pyosalpinx was well established; in two the history pointed to a post-puerperal origin; in the remaining two the origin was

doubtful, though in one of the cases specific trouble was strongly suspected.

One case died of shock—never coming out of the anæsthetic. She was a hard drinker.

In two cases the tumor removed was a dermoid cyst, both of which were small. In one of these cases the uterus was rudimentary, though the woman had for a long time worn a pessary for a so-called displacement, introduced by a specialist in gynecology.

In two cases exploratory incision was made, and the women recovered quickly. One of these died soon after tapping; from what cause he did not know. The second exploratory incision was due to an error in diagnosis. The uterus was retroverted, a miscarriage having occurred a short time previously. There was a peculiar thickening of the right broad ligament, which led to the blunder.

In the thirty-three operations recorded, two deaths have occurred. The first occurred early in the series. In the last twenty-six cases there has been but one death, and the last eighteen cases have been without a death.

Dr. J. Price said that the mortality of this group of cases was exceptionally low. The pus cases and the extra-uterine cases interested him the most.

Dr. Joseph Price reported

TWO OPERATIONS FOR EXTRA-UTERINE PREGNANCY.

The first case was that of a white woman, aged thirty-five, nursing a child of thirteen months. The menses appeared on the fourth month of lactation, and remained perfectly regular at intervals of twenty-seven days with four days' duration; finally, they were absent two periods, and paroxysms of pain and collapse asserted themselves. He immediately operated for ruptured tubal pregnancy, and found about a quart of clotted blood in the peritoneal cavity; tubal rupture on the left side, and hydrosalpinx on the right side. These were removed, and recovery occurred.

The second case occurred in a negress, and is of great interest, as ovarian cysts are very rare in true Africans, and microscopical examination gave a doubtful result, although the growth resembled one very closely. One point of great interest in connection with these cases that survive the rupture and go into the hands of the surgeon, is the marked difference in the character of the hemorrhage from those that go into the hands of the coroner—and they are numerous. In the latter cases the hemorrhage is overwhelming, and the abdomen is found full of blood. The surgeon finds probably one-fourth that amount of blood. Dr. Formad, the coroner's physician, states that in one case he found the peritoneum deluged with blood, and the fœtus washed up on the pancreas.

Dr. J. M. Baldy said, though Dr. Price had stated that ectopic gestation is rare in the full-blooded negro, that he should like to place on record such a case. The woman had been having children at regular intervals of two years for eight or ten years. The last time, when her time came to become pregnant, it proved to be a pregnancy of the tube. She was operated on and saved.

Dr. J. M. Baldy reported a case of

FIBRO-CYSTIC TUMOR OF THE UTERUS.

Mrs. A., aged thirty-five years, married, no children. She had a lump in her abdomen for fifteen years, which remained quiescent until within the last two years, since which time it has grown rapidly. The menses gradually became irregular and profuse; bowel and bladder symptoms were severe; pus appeared in the urine; the abdomen was constantly swollen, and very painful; and the general health had begun to suffer severely. Examination showed a uterine tumor, and its removal was advised, the dangers of the operation being fully explained. The operation was eagerly accepted. The tumor was removed, and proved to be an extremely nodular fibroid, which had undergone cystic degeneration in part, and in other parts was quite œdematous. The mass was firmly wedged into the pelvis, and was delivered with the greatest difficulty, leaving practically no pedicle at all. The case was treated by supra-vaginal amputation, a wire nœud being first placed around the lower portion. The stump was treated by the extra-peritoneal method, as advocated by Bantock. After the tumor had been cut away, there was left a stump with a diameter of over three inches; this was gradually trimmed away until it was reduced to about an inch and a half in diameter.

This case presents the opportunity for a few remarks on the method of treating the pedicle in hysterectomy, and on the use of electricity in fibroid tumor of the uterus.

There are two methods of treating the stump — the intra-peritoneal, as advocated by Martin, and the extra-peritoneal, as advocated by Bantock. All other methods devised or proposed are simply modifications of these two, and are far from being as good as the originals.

What is wanted are results, and in questioning different gentlemen who are experimenting with the so-called improvements in hysterectomy, it has been found almost universally that their losses amount to from thirty per cent. to fifty per cent. The patients who get well may do so quickly, and the operations may be very beautiful, theoretically, but the results are murderous! The results obtained by the extra-peritoneal method are, at present, very decidedly the best, and have proven eminently satisfactory in his hands.

Martin, by the intra-peritoneal method, reports a series of eighty-four cases, with twenty-five deaths. Later, he had thirty cases, with three deaths; and still later he had "another series with good results;" and last, "a series with bad results." And so, after an experience of over 125 cases, he ends up with a series which is so bad that he does not publish it. In contrast with this stands Bantock's record, by the extra-peritoneal method, of fifty-seven cases with only twelve deaths, and his results continually getting better to the end. He now has had a run of thirty or forty cases without a death. These figures speak for themselves. After all his experience, Martin says "we must wait for a larger number of cases before deciding this question."

Of the twenty-five deaths met with by Martin in his first eighty-four cases, fifteen died of "bleeding, embolism, and collapse," all of which, of course, means hemorrhage. By the extra-peritoneal method, these would all have been saved, as bleeding cannot possibly occur if the wire does not slip or break. Again, ten of Martin's cases died of sepsis; this also is much less likely to happen by the extra-peritoneal method, as all cut surfaces are outside the peritoneal cavity, in plain sight, and under perfect control.

When Martin has finished his operation and drops the

stump, the appearance to the naked eye is simply perfection. On the other hand, when the stump is left outside, as is taught by Bantock, the after-treatment is often tedious, and the convalescence prolonged. If the stump is not perfectly dry, it is apt to suppurate, and, at best, it is an unsightly affair. But when we contrast the results, there can be but one choice, if we give proper consideration to the safety of our patients. Not only are Martin's own results bad, but in the hands of less expert and experienced operators the mortality is very high. Even Bantock has lost four out of five cases by the intra-peritoneal method.

CORRESPONDENCE.

A SIMPLE METHOD OF TREATING UMBILICAL HERNIA IN INFANTS.

To the Editor of THE MEDICAL NEWS,

SIR: The appliance described under this heading in the number of THE NEWS for October 5th is very similar to one which I have successfully used for twenty-five years past, and which originated with myself. It fulfils the requirements stated to be essential—it is "non-absorbent, non-irritating, and of such material that it will remain in place for at least a week, notwithstanding daily bathing." It has one great advantage over the "hard-rubber, slightly oval, plano-convex lens with two wire loops," and is readily attainable everywhere and at all times. I use the large removable head of a common picture-nail. This is applied to the hernia and fixed in place by a strip of adhesive plaster. My first attempt was with the half of a toy marble. The nail-head is better because larger and less convex. This simple appliance is at command everywhere, and I only thought it worthy of presentation to the profession when I read the article alluded to above.

Very truly yours, J. C. REEVE.

DAYTON, OHIO.

NEWS ITEMS.

The Moral Sense of a Physician.—Those members of the profession who believe in the condition known as "moral imbecility," will have their opinions greatly strengthened by the following letter received by the London *Lancet* in reply to an indignant protest made by that journal concerning Dr. Allwright's plagiarism of Dr. Reeve's article in Hirst's *System of Obstetrics*:

"*To the Editors of The Lancet*—SIRS: In answer to your favor, the article mentioned obtained its foundation from the American *System of Obstetrics*, but it was not intended to be a copy, nor, I think, is it. An article in Buck's *Hand-book of the Medical Sciences* contains similar facts upon the same subject, as, indeed, must any other history on the same subject. I am very sorry if an objection has been raised to the article appearing in print. I have practised both the method of administering chloroform and also that of ether, which are suggested in the article, for some time. Perhaps you will offer my apology, and that any offence against Dr. Hirst was unintentional. I am, sirs, yours obediently,

"FRED. W. ALLWRIGHT."

"BRIGHTON, Sept. 29, 1889."

College of Pharmacy.—Another college of pharmacy is to be located at Brooklyn, New York, controlled by the Pharmaceutical Society of King's County, which has held the matter under advisement for some time in the hands of an influential special committee. It has been satisfactorily demonstrated that there are enough young druggists from Brooklyn attending the New York colleges to form a strong class, if they can be shown that a home institution has been founded that is worthy of their support.

A Maritime Medical Association.—At the last annual meeting of the New Brunswick Medical Society, held at St. John, a plan was favorably considered for the bringing about of a union between the societies of the provinces of Great Britain lying eastward from Quebec Province. A committee of conference was appointed, and another year will probably see the formation of a strong and influential Maritime Medical Society, combining the membership in Nova Scotia and New Brunswick, and attracting to it many physicians who have not hitherto associated themselves with any organization.

The Dedication of Clark University.—The dedication of the new university at Worcester took place on the 2d instant, and was a memorable occasion. It marked the landing of a puritanical group of educators in the Bay State, and yet "Severe Science" is the inscription on the standard set up by Dr. Stanley Hall, the president and inspirer of the new departure. It is the first University of the Basal Sciences which has made its appearance in America: these basal subjects being five in number, namely, Psychology, Biology, Physics, Chemistry, and Mathematics. To medical students who intend to obtain a good foundation, this will prove attractive by reason of the advantages to be found here in biology, physiology, neurology, anatomy, and chemistry. Dr. Stanley Hall, in his inaugural address, quoted an eminent European physician as his authority for the opinion that the young man who hurries on to the more attractive fields of the clinic and the amphitheatre, to the neglect of the more abstruse studies, is in the position of the prodigal who becomes prematurely old and impotent. Dr. Hall uses the time-worn adage, "Godlike is the physician who is also a philosopher," and claims that this proverb is far more true to-day than when Hippocrates framed it.

The Continental Anglo-American Society.—The Continental Anglo-American Society, which has recently been formed, held its first meeting in Paris on the 30th of September, Sir Spencer Wells occupying the chair as one of the Honorary Presidents. Among those present were Drs. Alan Herbert, Faure-Miller, Thomas Linn, and others, of Paris; Dr. Sandwik, of Cairo; Dr. Stanley M. Rendall, of Aix-les-Bain, and many others. In the evening a dinner was given at the Grand Hotel. Among the guests were Dr. Norris, of New York, and Dr. Rodgers, of Illinois.

The Society has been organized chiefly through the endeavors of Dr. Thomas Linn, the Honorary Secretary, and already has about seventy-five members.

THE DIAGNOSIS AND TREATMENT OF FUNCTIONAL DISORDERS OF THE STOMACH.[1]

BY FREDERICK P. HENRY, M.D.,

PHYSICIAN TO THE PHILADELPHIA AND TO THE JEFFERSON MEDICAL COLLEGE HOSPITALS.

THE distinction between functional and organic affections is by no means sharp. They encroach on each other in such a manner that the imaginary line which separates them is remarkable for its sinuosities, and here and there is so faint as scarcely to be traced. In both these respects it resembles the lines of demarcation, the so-called sutures, which both separate and unite certain cranial bones. These statements, while true in general, are of particular application to the diseases of the stomach, of which the disorders of function are generally, sooner or later, associated with some organic defect. Thus, disorders of secretion are frequently accompanied with some impairment of motor power, or even with some alteration in the secretory tissue.

Bearing in mind the difficulties inherent in the subject of functional disorders of the stomach, I will begin by stating that they are all included under the heads of disordered secretion, disordered motion, and impaired innervation. It is self-evident that these three classes of affections are not only closely associated, but interdependent. Like the three primary colors, they give rise, by their blending, to various affections in reality composite or secondary, but yet of primary importance.

My remarks upon these three modes of disordered function must be very brief and imperfect, for an elaborate discussion of either one of them would occupy more than the time allotted me.

To make myself thoroughly understood, I am obliged to make some preliminary remarks on the chemistry of normal digestion. It is well known that pepsin will not manifest its digestive power except in the presence of an acid concerning the nature of which there has been great difference of opinion. It has been variously regarded by men of the highest attainments in chemistry and physiology, as phosphoric, sarco-lactic, lactic, and hydrochloric; but, little by little, the first two were positively excluded from the discussion, which became limited to lactic and hydrochloric acids. For many years physiologists were at variance concerning these two acids, one set regarding lactic as undoubtedly the acid of the gastric juice, while another was equally positive that this acid could be no other than hydrochloric. For example, I myself was taught, by so great a physiologist as the late Professor John C. Dalton, that the acid of the gastric juice was lactic. The cause of these discrepancies is now plainly manifest, for during gastric digestion the reaction of the gastric contents is at one stage due to lactic, at another to hydrochloric acid. In fact, normal digestion, considered with reference to the presence of these acids, may be divided into three stages. During the first, which lasts about half an hour, lactic acid is present alone; later, lactic and hydrochloric acids are present simultaneously; and, finally, there comes a stage when the only acid present is hydrochloric. The last stage may begin half an hour after eating, or, at the latest, an hour thereafter—*i. e.*, in health, for in disease the duration of these three stages may be variously modified. The most important period of digestion is undoubtedly the last, for it is well established that pepsin acidified with hydrochloric acid digests more actively than when acidified with lactic. In fact, lactic acid is an adventitious product of the fermentation of carbohydrates, and is always found in the first stages of the digestion of a mixed diet—meat, bread, potatoes, etc.—but if egg albumen alone be administered to a fasting animal, and the contents of the stomach examined shortly afterward, hydrochloric will be the only acid detected.

The examination of the contents of the fasting stomach, which would long ago have settled this important physiological question, has only recently been undertaken. In the first place, it disproved the prevalent medical belief that the fasting stomach is empty. Rosin[1] introduced a soft-rubber tube into the stomachs of a number of individuals free from gastric disease, the time chosen for the experiments being the early morning hours before breakfast. In only two out of forty-four such experiments did he fail to obtain a sample of gastric juice, the amount of which in the forty-two positive cases varied between three and ten cubic centimetres. In thirty-one of these forty-two cases the fluid thus obtained contained free hydrochloric acid. The question whether the fasting stomach contains pepsin received

[1] Read before the Philadelphia County Medical Society, October 9, 1889.

[1] Dr. Heinrich Rosin: Deutsche med. Wochenschrift, November 22, 1888.

a positive answer in all the cases, six in number, in which the secretion was submitted to the digestive test. The important question whether lactic acid is present in the juice of the fasting stomach received a negative answer. In nearly all the cases the secretion gave the well-known biuret reaction, indicating the presence of peptone; but as this reaction is also given by the saliva, as well as by the nasal and pharyngeal mucus, it is reasonable to suppose that the peptone was swallowed with these secretions.

Now let us pause and consider what light these physiological facts throw on the disorders of gastric function.

In the first place, it is readily understood how the first, or lactic acid, stage of digestion may encroach upon the second and third stages of that process; but the question with which we are now concerned is whether this excessive lactic acidity gives rise to symptoms. There can, I think, be no doubt that such a condition is the chief cause of *pyrosis*. I do not go as far as Bourget,[1] who considers it the sole cause of that annoying symptom. He was led to this conclusion by finding that he could not produce pyrosis in his own person by swallowing two glasses of water containing 5 per cent. of HCl, but that it was experienced a few minutes after taking the same amount of water containing 1 per cent. of lactic acid with a trace of butyric acid. Pyrosis is undoubtedly a symptom of excessive lactic acid fermentation, and the earlier it appears after the ingestion of food the more certainly is it due to this cause. It is also a symptom of undue acidity of the gastric juice, or hyperacidity, it being always understood where this term is used that the acid in excess is HCl. The term *pyrosis hydrochlorica* has been applied to this condition. Finally, pyrosis is not necessarily due to an excess either of HCl or lactic acid, but may even make its appearance when the gastric juice is of subnormal acidity. It may be, in short, one of the symptoms of nervous dyspepsia, in which affection the gastric nerves are so hypersensitive as to suffer during a digestion which is, in all other respects, normal.

By hyperacidity is meant, as the term implies, that the gastric juice, which may be of normal or increased amount, contains an excessive amount of HCl. This condition is not to be confounded with hypersecretion, which means that the gastric juice is secreted in excessive amount during the intervals of digestion. As I have stated elsewhere, the former consists in a too liberal response to a physiological summons, while the latter is gratuitous. Hyperacidity occurs most frequently in connection with gastric ulcer, and, therefore, scarcely comes within the range of our subject. Hypersecretion, on the other hand, is a mere exaggeration of the normal processes, for—as demonstrated by the researches of Rosin, to which I have already alluded—the fasting stomach contains an appreciable amount of gastric juice. The limits within which the secretion of gastric juice, by a fasting stomach, may be considered physiological, are as yet unknown. It is certain, however, that the functional gastric disorder known as hypersecretion constitutes a well-marked pathological condition. Its principal symptoms are increased thirst, acid eructations, nocturnal attacks of epigastric pain, and dilatation of the stomach. The digestion of carbohydrates is greatly impaired, while that of the albuminous substances proceeds with abnormal vigor. Positive proof of this condition is afforded by the sound employed in the following manner: The stomach is thoroughly washed out in the evening and the patient directed to fast until the following morning, when the sound is again introduced. If hypersecretion exists, a quantity of fluid, varying from eight ounces to a pint, may be withdrawn: This fluid is colorless or slightly greenish, of viscid consistence, strongly acid, the acid being hydrochloric, and digests albumen rapidly. In a word, it is gastric juice.

Hypersecretion is probably always caused by disordered gastric innervation. It occurs in two forms, the one continuous, the other paroxysmal. The latter often coincides with the *crises gastrique* of tabes, and in such cases the neurotic character of the affection is plainly evident.

A knowledge of the absorbent power of the stomach is of diagnostic value, and may be obtained by the following test, first employed by Penzoldt and Faber[1] in 1882. Three grains of potassium iodide are administered in a gelatine capsule, and the saliva, which has been previously shown to be free from iodine, is tested every minute for this substance. In dealing with a healthy and empty stomach, the first iodine reaction will be obtained in from six and one-half minutes to eleven minutes. If the drug be administered immediately after a meal, the iodine reaction will not appear until from twenty to thirty, and may even be delayed until forty-five minutes have elapsed. By this means it has been shown that in various pathological conditions, such as cancer, ulcer, and chronic catarrh, absorption from the gastric mucosa is retarded. It can be readily understood that, in certain cases, a diminished absorption from this mucous membrane may be highly conservative. Litten[2] has demonstrated by the test just described, a diminished power of absorption in cases of atrophy of the mucous membrane of the stomach. Now, in many such cases, especially in the forms associated with pyloric stenosis and consecutive dilatation, the stomach may contain in its fermenting

[2] Deutsche med. Wochenschrift, Nov. 22, 1888.

and putrefying contents an amount of ptomaines sufficient, if absorbed, to cause death by acute poisoning.

The usual precautions are to be taken in the administration of gelatine capsules; *i. e.*, they should not be given to a patient who is taking either alcohol or tannic acid, as both these substances render the gelatine insoluble.

It is often of diagnostic value to obtain some idea of the motor power of the stomach, which some authorities are inclined to regard as the most important function of that viscus. Until quite recently, the only method of acquiring such information was that introduced by Leube, and consisted in the introduction of the stomach-tube seven hours after a meal; *i. e.*, at a time when the food should have passed into the intestine. The presence of food at such a time would indicate an impairment of motor power, and the degree of the latter would be in direct ratio to the quantity of the former. This method is crude, and inapplicable to most clinical purposes.

The peculiar properties of salol led Ewald and Sievers to employ it for testing the motor function of the stomach. This drug remains insoluble and undecomposed in the stomach, but splits up into carbolic and salicylic acids when it comes in contact with the alkaline secretions of the intestine. The salicylic acid is excreted with the urine, in which it may be detected by suitable reagents, and the time between the administration of the drug and the detection of the salicylic acid in the urine is indicative of the motor power of the stomach. These properties of salol seem to render it peculiarly suitable for testing this function. With this object in view, fifteen grains of the drug are administered in capsules or pills, and the urine examined at frequent intervals. The first appearance of salicylic acid in that fluid shows that the salol has passed into the duodenum, and has been absorbed and excreted. I mention this ingenious test, for the purpose of showing the direction of present research in the diagnosis of disorders of the stomach, although I believe it can never come into general use. In the first place, the chemical test for salicylic acid in the urine is, as Stintzing[1] points out, an elaborate one, and, in the next, it is impossible for most persons to urinate at such short intervals as it demands. Again, Bourget[2] has shown by experiments on his own person that the diet is of great importance in determining the time in which salicylic acid appears in the urine. After eating nothing but meat and a glass of water containing 2 per cent. of HCl, the salol test was applied and salicylic acid detected in the urine in from one hour and a quarter to one hour and a half after the repast, whereas when fruit was eaten two hours before a meal consisting of meat and vegetables, the salicylic reaction was obtained in from fifteen minutes to half an hour. These discrepancies are explained in the following manner. The fluid contained in the first portion of the small intestine is not always alkaline. On the contrary it is often acid, its reaction depending to a large extent on the quantity of acid poured into the duodenum by the stomach. If to the gastric juice, already acid, there be added an additional quantity of HCl, as in the first experiment of Bourget, the chyme will have to traverse an unusually long section of intestine before it is neutralized, and the salol contained in it will be longer than usual in finding the alkaline medium in which alone it can be decomposed. On the other hand, by rendering the intestinal juice unusually alkaline, for example by eating fruit, of which the organic acids are decomposed into alkaline products, the chyme will be rapidly neutralized in the intestine and the salol speedily decomposed.

Huber[1] proposes the following modification of the salol test: The patient takes a dose of salol, and his urine is examined on the following day at stated periods. The longer the time during which the salicylic acid is detected in the urine, the weaker is the motor power of the stomach. In certain cases of undoubted motor insufficiency, the salicylic acid reaction could be obtained on the second day after the drug had been swallowed.

Klemperer[2] recommends the following test of the motor power of the stomach, on the score of greater accuracy. He injects a certain amount (100 grammes) of olive oil into the stomach, and at the end of two hours withdraws what is left. Oil being a substance that is not absorbed by the stomach, the difference between the amount injected and that withdrawn indicates the motor power. A number of experiments proved that a healthy stomach will discharge between 70 and 80 grammes of oil out of 100 in the course of two hours. In thirteen cases of gastric catarrh, this test showed a decided diminution of motor power, the amount of oil expelled in two hours varying between 23 and 44 grammes, just about half the quantity discharged in the same time in health. For obvious reasons this test is difficult of application, and Klemperer himself admits that it is not applicable in private practice.

I have now briefly alluded to the principal disorders of secretion, and have mentioned the most approved modern methods for detecting those of motor function. The third division of my subject is disorders of innervation, which can only be dealt with in the most cursory manner.

Nervous dyspepsia has acquired a permanent position in nosology since its introduction by Leube,[1] in 1879, although his conception of the affection has undergone some decided modifications. Leube supposed the chemistry of digestion to be always normal in nervous dyspepsia, whereas numerous exceptions to this rule are now recognized. He also supposed the affection to be an independent or idiopathic one, whereas it is now regarded as a neurosis which seldom finds its sole expression in the gastric and intestinal nerves, but is, in most instances, a part of a general state of neurasthenia. For the latter reason, the terms neurasthenia gastrica and neurasthenia vago-sympathica have been applied to it, but nervous dyspepsia is, and doubtless will continue to be, the one most commonly employed.

The chief symptoms of nervous dyspepsia are eructations which, unlike those of gastric catarrh, are mostly tasteless and odorless, a sense of pressure and fulness in the epigastrium, and pain which is often independent of the quality of the food. A mouthful of water, for instance, will often give rise to severe pain, as is the case with a patient now under my care at the Jefferson Medical College Hospital. As a rule, however, pain is most readily induced by fatty and acid articles of food. Pyrosis is, as already stated, a symptom of this affection, and is sometimes peculiar in being associated with a subacid condition of the secretions. A capricious appetite is a characteristic feature of many of these cases. There may be complete anorexia alternating with periods of hyperorexia or bulimia. This morbid appetite may suddenly manifest itself at the most unseasonable hours, as in a case mentioned by Decker[1] in his excellent article on nervous dyspepsia. The individual in question was constantly roused from sleep by a sense of hunger, which he was oblige to appease with a hearty meal, composed of soup, eggs, cold beef, etc.

Insomnia is a frequent symptom of this disorder, whereas, on the contrary, in quite as many cases the patient is habitually drowsy. With reference to the stools there is nothing characteristic, except that they are not regular, a state of constipation often alternating with one of diarrhœa. The diagnosis is made by the exclusion of cancer, ulcer, and catarrh. The chief difficulty consists in distinguishing this condition of neurasthenia from one of chronic catarrh; but there are certain points which, if borne in mind, will prove of great value in this differential diagnosis. In catarrh the feelings of pressure and fulness are experienced directly after eating, and reach their maximum when digestion is at its height; whereas in nervous dyspepsia these symptoms are very variable with reference to the time of their appearance, and are often relieved by eating. They may also disappear for weeks or even months. The appetite in nervous dyspepsia is, as already stated, capricious, whereas in catarrh it is permanently absent. Valuable diagnostic aid may sometimes be derived from the effects of treatment. For example, it is said by Decker[1] that the Carlsbad cure, which is so beneficial in cases of gastric catarrh, is invariably injurious in nervous dyspepsia.

I have now reached the last and most important part of my subject, viz., the treatment of functional disorders of the stomach; and here I must repeat what I stated with reference to their diagnosis, that the time suffices for nothing more than a few therapeutic suggestions. I will first consider the treatment of pyrosis, a symptom to which I called your attention in an early part of this paper, and I do this, not only because it comes first in order, but also because its consideration will furnish some useful therapeutic hints. There are, as I stated, at least two kinds of pyrosis, one due to an excess of lactic acid and the other to an excess of hydrochloric; and the time-honored treatment of this symptom, without reference to its cause, has been the administration of sodium bicarbonate. The following experiment of Bourget shows that this drug, in the commonest form of pyrosis—that caused by an excess of lactic acid—is, at most, an evanescent palliative. To a patient with chronic gastric catarrh and dilated stomach, was given a certain amount of soup, some of which was withdrawn two hours later, and found to contain 1.68 per cent. of lactic acid and no HCl. It was then exactly neutralized with sodium bicarbonate and placed in an incubator. At the end of half an hour it contained 4 per cent. of lactic acid. It was again neutralized and about eight grains of sodium bicarbonate added in excess. At the end of an hour free lactic acid was found. On the other hand, HCl given during a meal was found to prevent the formation of lactic acid. This corresponds with the physiological fact that the lactic acid formed during the first half hour of digestion is speedily suppressed by HCl. Bicarbonate of sodium undoubtedly neutralizes any lactic acid that may be present in the stomach, but instead of preventing its further formation, seems to increase it by creating an alkaline medium favorable to the growth of the organism of the lactic acid fermentation. Lactic acid pyrosis, therefore, is to be treated by the administration of HCl during, or immediately after, a meal.

Pyrosis hydrochlorica may be due to hyperacidity or hypersecretion. In the first instance, it is to be treated by the administration of an alkali several hours, from four to six, after a meal. In hyperacidity the gastric juice is abnormally active, its physiological work is soon performed, and then it expends its

[1] Deutsches Archiv für klin. Med., Bd. xxiii., 1879.
[2] Münchener med. Wochenschrift, May 28, 1889.

[1] Loc. cit.

superfluous energies upon the unfortunate patient. Having waited until its work is done, it is rendered powerless for mischief by the administration of an alkali, just as in peptonizing milk we boil the mixture or place it on ice to prevent the process from going too far.

The most successful treatment of hypersecretion consists in the methodical washing out of the stomach, preferably just before the principal meal, and the administration of alkalies. The latter should be given in large doses, for, as is well known, the administration of a small dose of an alkali will be followed by an increased secretion of gastric juice. Thirst is often excessive in these cases, but water should not be allowed except in small quantities, as it tends to increase the dilatation which is usually present. When the sense of thirst becomes unbearable, it is better to obtund it, as Riegel suggests, by the administration of small doses of opium than to permit the ingestion of large quantities of water. The diet should, at first, consist exclusively of albuminous substances, as carbohydrates are only partially digested, and by their fermentation aggravate the disease. Dr. Roberts, of Manchester, observing a profuse flow of saliva in cases of acid dyspepsia, and believing it to be a provision of nature for relieving the surplus acidity of the stomach, recommends the use of substances that will provoke its secretion, such as gum lozenges containing a small amount of ginger, cayenne pepper, or pyrethrum. He has thus experienced relief in his own person and given it to others.

In cases of motor insufficiency, in addition to general hygienic measures, the vegetable bitters, especially strychnia, and alcoholic stimulants may be used with advantage. Klemperer[1] found that both substances hastened the exit of food from the stomach.

The treatment of nervous dyspepsia must vary with the cause producing it. One case will be cured by restoring the uterus to its normal position; another by curing a chronic constipation or expelling a tape-worm; still another by allaying an irritation of the spine. A restricted diet, or one of milk only, which is always beneficial in catarrh, is of little or no benefit in cases of nervous dyspepsia. General supporting measures, massage, electricity, the bromide salts, and, if anæmia exists, arsenic and a mild non-constipating preparation of iron, such as the potassio-tartrate, are the chief indications. I believe also, from a limited experience of the measure, that lavage may sometimes be of decided service in soothing a hyperæsthetic mucosa.

Dr. John Guitéras delivered the address before the semi-annual meeting of the Pathological Society of Philadelphia, on Thursday evening, October 24, 1889.

[1] Loc. cit.

EXPERIMENTAL STUDIES ON THE ETIOLOGY OF TYPHOID FEVER.[1]

By B. K. RACHFORD, M.D.,
DEMONSTRATOR OF BACTERIOLOGY IN THE MEDICAL COLLEGE OF OHIO.

In a discussion[2] before the Cincinnati Academy of Medicine, November 5, 1888, I called attention to the fact that experimental ptomaine poisoning, as well as clinical evidence, justified the belief that not only the fever, but all other constitutional symptoms of typhoid fever are caused by ptomaines. If this be true, then why are the nervous and other constitutional symptoms not in accord with the fever? Why, if poisonous alkaloids produce both fever and nervous symptoms, is there not a closer correspondence between the two?

The following explanation, founded on the ptomaine observations of Brieger, was offered: Brieger found that the ptomaine formed depended, to a great extent, on the kind of albuminous material in which the microörganisms were growing. The ordinary germs of putrefaction produce alkaloids differing in chemical, physiological, and poisonous properties when they are decomposing different materials, as fish, cheese, muscle, and brain. Is it not altogether probable, then, that the typhoid bacillus will produce different ptomaines according to the composition of the food material in the intestinal tract? In a certain form of nitrogenous food it may produce a ptomaine the characteristic symptom of which is fever; in another kind, a ptomaine which produces profound nervous symptoms.

It was not my belief then, nor is it now, that all the symptoms of typhoid fever are produced by ptomaines formed in the intestinal canal, since these poisonous bodies are undoubtedly produced in all parts of the body where the bacilli find a lodgement and multiply. It is also probable that certain symptoms may be due to a local irritating effect of the ptomaines on the part in which they are produced. While this is probably true, it is, nevertheless, a belief supported by much clinical evidence that the intestinal canal is the great manufactory and storehouse for these poisons, and that most of the constitutional symptoms throughout the disease are due to their absorption from this source.

Shortly after this discussion I began an experimental study of these questions, hoping to find physiological differences in typhoid ptomaines produced in various food-stuffs, and in that way to throw some tight on the dietetic management of the disease.

In the following experiments I injected into a rabbit's stomach the whole culture containing the

[1] Read before the Cincinnati Academy of Medicine, September 30, 1889. I am indebted to Drs. A. R. Chapin, Otis Cameron, and Leonard Freeman for assistance in this work.

[2] See Cincinnati Lancet and Clinic, December 8, 1888.

active bacilli as well as the products of their growth, because I feared that in attempting the destruction of the germs by heat or otherwise I might also destroy or change the character of their ptomaines. This course was decided upon because it was my belief that rabbits were not susceptible to typhoid fever, and for this reason I concluded that the introduction of the typhoid bacilli could have no appreciable effect on the symptoms, and that the result would, therefore, be either directly or indirectly due to the chemical products introduced with the culture. These experiments are, I think, of some interest in the direction anticipated, but their chief value lies in the fact that one of the rabbits died from typhoid fever, and not from poisoning by the ptomaines introduced into its stomach.

The bacilli used in these experiments were from the stock cultures of the bacteriological laboratory of the Medical College of Ohio, and were from two different sources.

One-half the cultures used were descended from a culture received from Johns Hopkins University six months before. The other half were descendants from a culture made one year before, by Dr. Otis Cameron, from the spleen of a man who died from typhoid fever in the Cincinnati Hospital. The culture materials used were:

1. Peptonized milk.

2. Peptonized beef. This was made by mashing into a fine pulp the coagulate resulting from making beef-tea, adding it to the tea and peptonizing the whole.

3. Peptonized brain, made in same manner as the beef.

4. Bouillon and beef peptonoids.

These materials were put in test-tubes and sterilized in the ordinary way. Only tubes which more than three weeks' time had proved to be sterile were used. After inoculation these tubes were placed in a crate, wrapped in paper to exclude the light, and kept in a temperature of 94° to 98° F. My object was to furnish conditions as nearly resembling those found in the intestinal tract as possible.

The rabbits were inoculated as follows: From sixty to eighty minims of tincture of opium were injected into the peritoneal cavity. As soon as the rabbit became drowsy from the opium, four drachms of a five per cent. solution of bicarbonate of soda were injected through a stomach-tube into the rabbit's stomach, and in the same manner, directly afterward, the contents of a typhoid culture tube were thrown into the stomach. The rabbits were then placed in separate cages, and given plenty of cabbage and moist bread.

The purity of the cultures used was tested in each instance, by inoculating potatoes, just prior to their use. In this manner it was learned that all the cultures used were pure typhoid.

The histories are arranged not in the order in which the rabbits were inoculated, but for convenience of reference, according to the character of the culture material.

The average normal temperature of the rabbits experimented upon was 101° F.

No. 1.—Age ten weeks. Inoculated July 31, 1889, with a pure culture in bouillon and beef peptonoids three and a half months old. Germs descended from spleen culture. August 1st, stupid; temp. 103°. 2d, very dull; temp. 102°. 3d, very dull; temp. 102°—died during the night. Post-mortem showed no cause of death; small intestine deeply injected.

No. 2.—Age ten weeks. Inoculated July 31, 1889, with a pure culture in bouillon and beef peptonoids three and a half months old. Germs descended from spleen culture. August 1st, temp. 102.4°; not active. 2d, dull; temp. 102.4°. 3d, temp. 102°; very stupid. 4th, died this morning. Post-mortem showed no cause of death; small intestine deeply injected.

No. 3.—Age twelve weeks. Inoculated July 31, 1889, with a pure culture in bouillon and beef peptonoids three and a half months old. Germs descended from spleen culture. August 1st, temp. 102.8°; not active. 2d, temp. 102.6°; dull. 3d, temp. 102.6°; dull. 4th, temp. 102.2°; very dull. 5th, died last night. Post-mortem showed no cause of death; small intestine deeply injected.

No. 4.—Age twelve weeks. Inoculated July 31, 1889, with a pure culture in bouillon and beef peptonoids three and a half months old. Germs descended from culture from Johns Hopkins University. August 1st, temp. 102.8°; dull. 2d, 102.4°; dull. 3d, 102.8°; dull. 4th, temp. 102.6°; dull. 5th, temp. 102.4°; not active. 6th, no notes taken. 7th, temp. 103°; active. 8th, temp. 99.8°; diarrhœa. 9th, temp. 99.6°; active, profuse diarrhœa. 11th, temp. 96°; profuse diarrhœa, much emaciated, very weak. 12th, temp. 95.6°; very weak and stupid, appetite good all the time; diarrhœa continues. 13th, died this morning. Post-mortem: great emaciation; no evidence of disease, except in small intestine, which was deeply injected. This injection was especially marked in the ileum, about Peyer's glands. Four small follicular ulcers were found in the ileum opposite the mesenteric attachment, while deeply injected bloodvessels radiated from these ulcers.

These cases were treated exactly alike. Each one was inoculated with the same quantity of pure culture three and a half months old in bouillon to which beef peptonoids had been added. A glance will show that the clinical histories of these rabbits correspond very closely. All of them had a slight increase in temperature, and were dull and stupid from the beginning. One lived three, one three and a half, one four, and one twelve days. In the rabbit that lived twelve days the stupor disappeared on the fifth day, and the temperature fell below normal on the eighth day, and remained so until death. That the symptoms in this group of cases

were not due to the opium injected, is, I think, quite evident from a comparison of these cases with those related below. It seems, therefore, a rational conclusion that the fever and the nervous symptom of stupor, coming on immediately, were produced by ptomaines formed in the beef peptonoids previous to the introduction of the cultures into the stomachs of the rabbits. We may at least claim that the above histories *indicate* that typhoid bacilli, when grown in beef peptonoids, will produce ptomaines capable of producing fever and profound nervous symptoms.

No. 5.—Age six weeks. Inoculated March 24, 1889, with a pure culture in peptonized brain two months old. Germs descended from culture from Johns Hopkins University. March 25th and 26th, temp. not taken; quite dull, eats little. 27th, temp. 98.8°. 28th, temp. 99.4°. 29th, temp. 96.2°. 30th, temp. 97°. 31st, died last night. This rabbit was dull and stupid all the time, and ate very little. Post-mortem: great emaciation; bladder distended. The small intestine, and especially the ileum, was hyperæmic.

No. 6.—Age six weeks. Inoculated March 24, 1889, with a pure culture in peptonized brain two months old. Germs descended from spleen culture. March 25th and 26th, temp. not taken; stupid, no appetite. 27th, temp. 96.2°; very dull, eats nothing. 28th, temp. 99.8°; dull. 29th, temp. 98°; dull. 30th, temp. 99.2°; no appetite. 31st, temp. 99.2°. April 1st, temp. 96.8°; dull, eats better. 2d, temp. 97.8°. 3d, dead. Post-mortem: great emaciation; bladder distended; small intestine injected. In the ileum three small follicular ulcers were found; spleen, liver, and kidneys were apparently normal. A plate culture was made from the spleen, but no typhoid bacilli were found.

No. 7.—Age six weeks. Inoculated March 24, 1889, with a pure culture in peptonized beef two months old. Germs descended from spleen culture. March 25th and 26th, temp. not taken; dull; eats little. 27th, temp. 99.6°; dull; no appetite. 28th, temp. 98°; dull. 29th, temp. 96°; dull; eats better. 30th, temp. 96°; stupid. 31st, dead. Post-mortem: much emaciated; bladder distended; ileum hyperæmic, especially about the large Peyer's patch near the cæcum and about another Peyer's patch six inches above.

No. 8.—Age six weeks. Inoculated March 24, 1889, with a culture two months old in peptonized beef. Germs descended from culture from Johns Hopkins University. March 25th and 26th, temp. not taken; dull. 27th, temp. 99.4°. 28th, temp. 101.7°; active; eats well. 29th, temp. 98.4°; active. 30th, temp. 99.5°; active. 31st, temp. 98.4°; eats well; not so active. April 1st, temp. 99.5°; rather dull. 2d, temp. 97.2°; dull. 3d, dead. Post-mortem: bladder distended; marked hyperæmia throughout ileum.

It will be noticed that there is a marked similarity in the clinical histories of these cases; there being no marked difference in the symptoms of those treated with a culture in peptonized brain and those treated with a culture in peptonized beef. All were quite stupid from the first day and all had subnormal temperatures on the third day, this being the first day upon which their temperatures were taken. Two of these rabbits lived seven and two nine days.

Im comparing the clinical histories of groups 1 and 2, the following points are worthy of note:

1st. The nervous symptom of stupor was the same in both groups.

2d. The temperature on the third day in group 1 was increased, while in group 2 it was subnormal.

3d. The rabbits in group 1, with a single exception, died much sooner than those in group 2.

From these facts we may infer:

1st. That typhoid ptomaines may be formed in peptonized beef and brain which are capable of producing just as profound nervous symptoms as those formed in the beef peptonoids of the shops.

2d. That the former produce no fever, while the latter produce fever.

3d. That the beef and brain ptomaines are less virulent than the peptonoid ptomaines.

It must also be borne in mind that there may be a possible error in the above inference dependent on the fact that the cultures used in the two groups differed in age. Those used in group No. 1 were three and a half months old, while those used in group No. 2 were two months old. This may account for the difference in severity but probably does not account for the difference in character of the symptoms produced.

No. 9.—Age twelve weeks. Inoculated March 24, 1889, with a pure culture two months old in peptonized milk. March 25th and 26th, apparently well; temp. not taken. 27th, temp. 99°; active; eats ravenously. 28th, temp. 100.2°; eats. 29th, temp. 96.4°; not active. 30th, temp. 98°; dull. 31st, dead.

No. 10.—Age twelve weeks. Inoculated March 24, 1889, with a pure culture two months old in peptonized milk. Germs descended from spleen culture. March 25th and 26th, temp. not taken; apparently well. 27th, temp. 102°; very active; eats well. 28th, temp. 101.6°; active; out of box; eats well. 29th, temp. 97.2°; not active. 30th, temp. 99.4°; active; good appetite. 31st, temp. 95.4°; not active. April 1st, temp. 99°; active; good appetite. 2d, temp. 98.6°; diarrhœa; not active; eats well. 3d, temp. 96.4°; diarrhœa; eats well; dulness and stupidity apparently due to weakness. 4th, temp. 95°; very weak and stupid; diarrhœa. 5th, temp. 95°; cannot stand alone. 6th, died this morning. Post-mortem[1] (present Drs. Chapin, Cameron, and Freeman and laboratory class, twelve hours after death.): Extreme emacia-

[1] Post mortem and bacteriological work done in the bacteriological laboratory of the Medical College of Ohio.

tion. Lungs and liver showed no evidence of disease; spleen normal in size; kidneys enlarged and congested. The small intestine was carefully removed and thoroughly washed by allowing a stream of water to run through it; when distended with water and held before the gaslight points of pronounced hyperæmia were seen at intervals of a few inches throughout its length. These points were more numerous and better marked in the ileum than elsewhere, and marked the location of follicular ulcers and of Peyer's patches.

Section of the gut showed that Peyer's glands throughout the ileum projected abnormally above the surface of the mucous membrane, and were much injected, one patch, about six inches from the cæcum, was slightly broken down in its centre, apparently a beginning ulceration. Some twelve or fifteen ulcers were found in the small intestine. They were chiefly located in the ileum. These ulcers were clearly defined, circular, deeply injected, about one sixth to one-eighth of an inch in diameter, and situated opposite the mesenteric attachment.

From a plate culture made from the spleen there was obtained a culture of bacillus, which in drop culture and stained cover-glass preparation was morphologically identical with the typhoid bacillus. This bacillus on potato gave a moist colorless growth, covering the whole surface of the potato.

Sections of kidney and spleen were stained and found to contain bacilli which corresponded in size and shape to the typhoid bacilli.

These experiments were begun for the sole purpose of observing the physiological effects of typhoid ptomaines formed in various food-stuffs, and not at all with the idea of producing typhoid fever in animals experimented upon. For this reason a biological examination of the organs of the dead animals was not thought of or attempted till the clinical history of rabbit No. 10 began to indicate that it was suffering from a progressive disease and not alone from the effects of the chemical poison which had been introduced into its stomach.

The rabbit (No. 10) did not show the slightest evidence of ptomaine poisoning. It remained apparently well for four days—during this time being quite active, eating well, and having a normal temperature. On the fifth day it showed evidence of sickness and from this time grew gradually weaker, dying on the tenth day of its sickness and fourteen days after inoculation. The symptoms were: subnormal temperature, gradual emaciation, diarrhœa, failing strength, and dulness. When this clinical history is taken in connection with the post-mortem lesions and biological examination it seems reasonable to conclude that this rabbit died from typhoid fever. The only way to avoid this conclusion is to argue an error in the technique.

In the study of the physiological action of typhoid ptomaines introduced with the cultures, it is quite evident that the early symptoms are all-important, since the symptoms which occurred after the third or fourth day could not have been due to the direct action of chemical poisons introduced with the culture. In the comparison, therefore, of group 3 with groups 1 and 2, it will be necessary to consider only the early symptoms.

The rabbits Nos. 9 and 10, composing group 3, were inoculated wirh cultures in milk. These two histories are, like those in the other groups, strikingly similar. They were apparently well till the third or fourth day, not showing the slightest evidence of ptomaine poisoning.

In comparing the clinical histories of groups No. 1 and 2, with those of group No. 3, the following points are worthy of note:

The stupor, which is the most prominent symptom in groups 1 and 2, is entirely absent in group 3. The fever in group 1 was increased, in group 2 the temperature was subnormal, and in group 3 it was normal. In short, all the early symptoms which characterized the cases in groups 1 and 2 were absent in group 3. These facts would indicate that the typhoid bacillus, when grown in milk, does not produce ptomaines capable of producing either fever or nervous symptoms, and that if the ptomaines thus formed are at all poisonous, they are much less so than those formed in beef peptonoids.

Now, in conclusion, let us note that there are three important propositions to which these histories bear witness:

1st. The bacillus typhosus of Koch and Eberth is the cause of typhoid fever.

2d. The physiological and poisonous properties of the ptomaines formed by this bacillus will depend in great part on the character of the food material in which it is growing.

3d. Milk is the best diet in typhoid fever, since the ptomaines produced in it do not cause either fever or nervous symptoms.

OBSERVATIONS ON INTRA-CRANIAL HEMORRHAGE AND SOFTENING.[1]

BY JAMES HENDRIE LLOYD, M.D.,
VISITING PHYSICIAN TO THE NERVOUS AND INSANE DEPARTMENT OF THE PHILADELPHIA HOSPITAL.

THE very lively interest manifested during the last few years in the pathology and surgery of the brain, has been especially sustained by the success obtained not infrequently in locating lesions in very narrow areas. Much of this success has been due to the work of the experimental physiologists, but a certain proportion of it is also due to accurate clinical observations with subsequent autopsies, which have utilized the experiments which disease has made in the brain, and have often either confirmed the results or even guided the researches of

[1] Read by title at the Annual Meeting of the American Neurological Association, Long Branch, June, 1889.

the laboratories. In these pathological studies comparatively little use has been made of the various lesions made by hemorrhages from and emboli of the encephalic bloodvessels. I say *comparatively* little, considering the large relative number of these cases. The reasons for this are probably several in number. The so-called apoplectic stroke when once declared and recognized does not appear to have further interest for the majority than is involved in the prognosis and duration of the case. Fine points of diagnosis and localization appear superfluous in the case of a man who is, perhaps, stertorous, or who, even if he survives, will probably be hopelessly hemiplegic, even aphasic, for the rest of his life. Again, there is a sameness about the vast majority of these cases which has probably inspired the feeling that there is not much new to be observed in any of them. The drowsy, hemiplegic patient, with distorted face and tongue and conjugate deviation of the eyes and head, presents a clinical picture recognized by all, any slight variations from which are not seen or thought noteworthy. Finally, hemorrhages into the substance of the brain are usually not good localizing lesions; they are apt to commit extensive ravages and to involve much contiguous territory by pressure, so that they often present symptoms which are exceedingly difficult to interpret for even the most expert diagnostician. This is not true to the same extent of emboli, which when lodged in small vessels sometimes give very exact indications of their whereabouts; nor is it always true to the same extent of traumatic meningeal hemorrhages, which may sometimes be successfully localized. With the latter I shall not deal in this paper.

In an experience during the last few months which has been unusually rich in cases of intra-cranial endarteritis, I have endeavored, as far as possible, to apply the principles of localization in the diagnosis, and to observe accurately in the autopsy the position of the lesion. I cannot claim much success; but I have been struck with the fact that when studied attentively this series of sixteen cases presents no two instances very nearly alike; that, in fact, there is much more variety and hence much more of clinical and pathological interest than any person would be led to expect in a series of successive cases happening to one observer. This interest, however, is not altogether in the localizing symptoms, but in some other clinical phenomena, as may be seen.

The enthusiasm which has been excited by recent work in cerebral surgery is, perhaps, shown in no more remarkable way than by the guarded suggestion which some have thrown out, that some cases of cerebral hemorrhage may yet be subject to operative interference. This appears as yet to be little more than a surgical dream, so far as it concerns hemorrhage due to diseased bloodvessels. The damage to the brain-tissue, the deep seat of the lesion, and the advanced deterioration of other vessels than the one which has ruptured, are a few of the conditions which cause this suggestion to appear Utopian in the extreme. It is not my purpose to discuss it at length here. Tapping and drainage of the lateral ventricles, as a mere surgical feat, has been proved to be practicable; but as a successful remedial measure in a brain whose vascular system is in advanced degeneration it must still be of very doubtful propriety. Multiple hemorrhages in the brain are not uncommon; several are recorded in this series of cases, and serve to emphasize the danger and hopelessness of evacuating a blood collection which may be one of several, or the precursor of others.

Extensive Disease of the Intra-cranial Bloodvessel System.

A case of hemorrhage into the pons, which has already been reported in detail elsewhere,[1] was an illustration of the fact just referred to.

The woman had had two intra-cranial hemorrhages, an old one into the lenticular nucleus with the usual hemiplegia, and a recent fatal one into the pons. This case was notable also for the facts that (1) the paralysis was not crossed, *i. e.*, the face and limbs were paralyzed on the same side, owing to the hemorrhage being in the upper part of the pons above the decussation of the facial nerve fibres; (2) to the absence of the contracted pupils and slow respiration which sometimes, in pons hemorrhage, simulate opium poisoning; (3) the late appearance of third nerve involvement, causing double ptosis and external deviation of the eyes; and finally (4) the strictly localized convulsive phenomena in the right arm which the patient exhibited a few days before she died, and which appeared exactly like an epileptoid seizure of focal cortical origin.

In reference to this last observation it may be stated that some have claimed that localized clonic seizures are not always of cortical origin, but may be caused by lesions at a lower level, as in the pons or medulla. This is of importance in diagnosis, because much stress is usually laid upon such local movements for fixing cortical lesions. In the above case the fit was in the sound (unparalyzed) arm, and nothing was observed post-mortem to explain it but the lesion in the pons.

It is common enough to regard a sudden hemiplegia as the first and often the only important and characteristic symptom or result of intra-cranial endarteritis. Nothing could be a greater error than this. Hemiplegia results when a large clot is thrown out and presses upon the descending motor fibres

[1] Reported by Dr. W. R. Wilson, in the University Magazine for June, 1889.

or when large vessels supplying the motor region of the cortex are plugged with a thrombus or embolus.

These accidents (except in the cases of emboli from distant parts) result from precedent disease of the bloodvessels. This disease of the bloodvessels is usually widely extended, involving many other arteries than the one which has ruptured—many arteries even outside of the head. Thus vessels accessible to pressure, as the radials and temporals, are indices of this wide degeneration, and are often found very firm, resisting, and almost like quills. At the base of the brain this arterial decay is often very extensive, and those persons who have examined many brains of hemiplegics must often have been impressed with the truth of the statement that a man's life is only as long as the life of his bloodvessels. It must also appear to them in the highest degree probable, that a brain which has had to depend, perhaps for years, for its nourishment upon such stiff and narrowed tubes cannot have been always in the best working condition, and that it must frequently, even long before the final and fatal break, have given evidence of the progressive decay which was undermining it. These *prehemiplegic* symptoms have not been recognized as fully as they ought to be. They are difficult to identify, and are still more difficult to verify. These symptoms are (1) mental, as loss of memory, sluggish intellectual processes, and inability to concentrate the thoughts: the signs of advancing senility are, no doubt, often due primarily to this cause. (2) Motor, as vertiginous attacks, possibly rarely convulsive phenomena, and conditions of more or less transient paresis. (3) Sensory symptoms, often very characteristic, as numbness or paræsthesia of a part or the whole of a limb, sometimes quite persistent. As this arterial degeneration not unfrequently accompanies kidney disease, it is a question whether some of the so-called uræmic brain-states may not be due to this mechanical cause.

A man prematurely aged at sixty, and whose appearance was that of eighty, had pipe-stem arteries at the wrists, arcus senilis, and the alligator-like skin of advanced old age. His urine was slightly albuminous and contained a very few casts: there was no œdema. He was very dull in mind, sitting about in a dazed condition, doing nothing, and responding very slowly and inadequately to questions. There was no paralysis. But when he slept or even dozed his head and both eyes deviated far to the right, and his right face also was well pulled over, leaving the left flat and smooth. His left arm was less resistant than his right; in fact, he was, while sleeping, in a partial left hemiparesis. When he awoke, this condition gradually passed away. He sank into a comatose state and died. An autopsy was refused. I believe this patient had extensive endarteritis at the base of the brain, causing partial brain starvation, especially in parts of the right hemisphere, but not advancing to hemorrhage. When he slept the blood-supply was still more diminished, and was especially cut off in the vessels on the right side.

Another patient, aged fifty-six, syphilitic, had a series of intra-cranial hemorrhages within a few months. His first symptom was a gradual hemiparesis. He did not have with these first symptoms any sudden "stroke" or loss of consciousness, but his trouble advanced to complete hemiplegia, with secondary contracture in the limbs. His last and fatal hemorrhage was in another part of his brain, and was more rapid in its effects. He had a violent convulsion with a quick-succeeding coma, and died in a few hours. After this last hemorrhage he had violent muscular contractions, sometimes called post-hemiplegic chorea, which will be referred to again. The autopsy revealed an old hemorrhagic cavity, containing brown fluid, well encapsuled, in the right external capsule and lenticular nucleus. A more recent subarachnoid hemorrhage was found over the occipital lobe on the right side, the brain substance being ploughed up by it in one spot. A similar but slight subarachnoid hemorrhage was found on the right hemisphere of the cerebellum. In addition to all this, the *left* hemisphere contained a great mass of black, tarry blood-clots in a cavity which had been made in the region of the lenticular nucleus, but which had extended far into the interior of the brain, and had broken through into the lateral ventricles. The vessels at the base of the brain were hard and quill-like, some of them containing white fibrinous masses. The gradual onset of the first paretic symptoms is very characteristic of syphilitic cases, and is explained by the gradual occlusion of the vessels. In this case, however, the lesions all appeared due to hemorrhage.

It is notable that this man's brain contained ruptured vessels on both sides. If the last hemorrhage had not been so extensive as to destroy life, he would have been one of those rare cases of *double* hemiplegia which some authors have described. The following case also was a near approach to this condition:

H. F., aged forty, had an old left-sided hemiplegia, with secondary contractures, of nine years' standing. His hemiplegia came on very suddenly without loss of consciousness. He had recovered some power in his left leg and could walk, but his left arm remained very weak. For some months before his death he had been distinctly losing power in his right leg, while his right arm remained normal. The autopsy revealed extensive degeneration of the arterial system at the base of the brain and apoplectic cysts in both lenticular nuclei, which were pigmented and softened—the right side more affected than the left. The intra-cranial arteries had undergone degeneration and rupture on both sides. The patient came the nearest I have yet seen to a double hemiplegia.

Local Asphyxia in the Distribution of Vessels.

The brain is, no doubt, often deprived of its proper blood-supply, and, hence, impaired in its functions, by vascular disease which, however, has not yet produced softening or necrosis of brain-tissue. Thus occasionally a patch, or area, of great paleness is found in the cortex in marked contrast with surrounding tissue.

In the case of a German, aged seventy-two, who died of pneumonia, the comatose condition in which he was when first seen was diagnosticated as due to intra-cranial vascular disease, especially as he had right lateral deviation of the head and eyes, and the left arm and leg were entirely flaccid and non-resistant. The autopsy showed the cerebral cortex supplied by the left anterior cerebral artery to be very pale and bloodless in contrast with the rest of the cortex of both hemispheres. The area of distribution of the anterior cerebral artery was thus beautifully mapped out. This was evidently recent, and was not attended by any necrosis of brain-tissue, nor had there been any symptoms during life to be attributed to it, except that the man's dull mental state was doubtless due to brain-starvation. No embolus was found in the main trunk of the vessel, but all the vessels at the base were much diseased and narrowed, and must have curtailed very much the blood-supply to the brain. A small hemorrhagic cyst, containing brown fluid, was found in the right optic thalamus bordering on the motor tract behind the knee of the internal capsule. It was in exact position to make pressure on the motor tract, but had not destroyed it.

Lesions of the optic thalamus are not common. They are apt to cause anæsthesia by pressure upon the posterior part of the internal capsule, as well as interesting eye-symptoms, such as blindness of the halves of both eyes on the side of the lesion (homonymous hemianopsia).

A Case of Homonymous Hemianopsia.

The occurrence of this condition as an isolated symptom—*i. e.*, without any paralytic or other anæsthetic symptoms—is rare. I have seen it in only one patient.

This man was in perfect health when one morning he was seized with giddiness and a strange feeling in his left leg. He did not lose consciousness or power. Some days afterward he discovered that he could not see to the left. This discovery was made by his almost meeting with several accidents in the street. When examined in the hospital and put to strict tests, nothing could be discovered wrong with him except a complete lateral, or homonymous, hemianopsia—that is to say, the *right* half of each eye was blind; and, consequently, he could not see in the *left* fields of vision.

This symptom is always caused by a lesion behind the chiasm, and is usually attended with other symptoms, depending on the nature and seat of the lesion. If the lesion is in the optic thalamus, pressing upon the capsule, there will likely be hemianæsthesia and perhaps also hemiplegia. The sensory fibres pass down through the capsule behind the motor. There might be a lesion in this region small enough to pick out just the visual fibres, causing no other sensory and no paretic symptoms, but such a thing is extremely improbable. The most probable region for the lesion in this case would be in that part of the cortex, or underlying white substance, which presides over vision—which receives the fibres direct from the retina. That region is probably the cuneus and the end of the occipital lobe. The lesion which could cause such results as in our patient, without other symptoms, and persisting at the end of three months, is an embolus; and while it is hazardous to express a positive opinion on such a fine point, I think this was probably the cause. The occipital lobe affected in our patient was, of course, the right.

Lesions of the Cerebellum.

The relation of lesions of the cerebellum to hemiplegic and other paralytic symptoms is not uniform or always very clear. When only one hemisphere is involved there may be no hemiplegia, or when hemiplegia occurs it is observed sometimes on the side of the lesion and sometimes on the other. Downward pressure on the motor tract in pons or medulla seems to be the most reasonable explanation, but why sensation is not always equally impaired does not appear. It will depend upon whether the downward pressure upon the motor fibres is above or below the decussation in the medulla which side is paralyzed.

In a case of large cyst of the right hemisphere of the cerebellum the hemiplegia was on the same side. This man died of typhoid fever. He had had loss of power in his right arm and leg, with a fine tremor, for three years. This had come on him with the sudden stroke of the usual apoplectic seizure. He had no anæsthesia. The case had been considered in life one of the common instances of lenticular hemorrhage. It was remembered, however, at his autopsy that he had not had paralysis of the face or tongue. The lesion found was a large cyst which occupied the whole upper third of the right hemisphere of the cerebellum. It was in the part supplied by the anterior, or superior, cerebellar artery. This vessel, however, was not occluded or diseased, as far as could be made out. The cyst may have been the result of an old hemorrhage.

Unusual Lesions of the Brain not Accounting for Hemiplegia.

The brain with degenerated vessels sometimes exhibits symptoms which cannot be explained by the *gross* lesions found post-mortem. The most common of these symptoms in my observation has been hemiplegia, which cannot always be ascribed

to the anatomical changes most apparent to the naked eye. This leads to confusion and error sometimes in applying the principles of localization in such cases.

An old woman was admitted in a semi-conscious state with hemiplegia, including the face. The case could not be distinguished from the ordinary. The autopsy revealed arteries at the base extensively diseased, and the brain was very full of venous blood. This venous congestion can probably result from the arterial obstruction. The motor regions were not different from the rest of the organ, but the cortex of the left occipital lobe was much softened, being yellow and creamy. The hemiplegia could not have been the result of the diseased occipital lobe, but it was no doubt the expression of brain starvation, caused by an impeded arterial supply, and probably appearing worse because of the patient's general dull condition. It was, hence, a coincident, not a result, of the necrosis, both being due to a common cause. The disease of the occipital lobe no doubt gave symptoms of its own, among which was probably a lateral hemianopsia, but the patient was too dull for this to be determined. So, too, of another case, in which a quite large area of softening was found in the temporal lobe. This woman had not only hemiplegia, but a rare form of post-hemiplegic motor disorder. The movement consisted of rapidly repeated shocks, very much like those produced by a rapidly interrupted faradic current. They did not resemble choreic movements, and could more properly be called unilateral *myoclonus*. The vessels of the brain were found diseased. The patch of softening involved especially the upper and middle convolutions, parts supplied by the middle cerebral artery; and the branch of that artery going to this region was found occluded with an atheromatous patch. As the middle cerebral artery supplies largely the motor regions, it is possible it was sufficiently diseased to cut off enough blood to impair, but not soften, these regions.

Lesions of the temporal lobe are of especial interest as indicating the cortical area for hearing, but this sense cannot be tested in a patient only partly conscious.

MENINGEAL HEMORRHAGES: SO-CALLED PACHYMENINGITIS HEMORRHAGICA.

Much discussion has been occasioned by the organized blood-clots, usually adherent to the dura mater, sometimes found post-mortem. The question has been, whether these new formations have originated in an inflammation of the dura mater (or other membrane), or whether they are of hemorrhagic origin. Some of these cases, at least, are the results of hemorrhages, which in turn are caused by degenerated bloodvessels, just as the hemorrhages so frequently found in the lenticular nucleus and other interior parts of the brain are produced. I have seen three cases of meningeal hemorrhage in the series of sixteen cases upon which this paper is founded. These were large bleedings, and all proved rapidly fatal, and they were all in brains whose arterial system had undergone, along with other tissue, extensive degeneration. They had one symptom in common—convulsion. If any one of these blood-clots had been very small and thin, it might have been compatible with life; it would then have become organized and adherent to the dura. One of these cases, in fact, did exhibit such a condition to a slight extent, as though the result of a former small hemorrhage. Another of these cases has already been reported;[1] in it a large tumor grew from the under surface of the temporal lobe. The skull had undergone remarkable softening and thickening, and the membranes were degenerated. The hemorrhage occurred on the vault of the hemisphere, remote from the tumor. In the third case—already reported in this paper—the hemorrhage was sub-arachnoid, and one only of several.

THE DIAGNOSIS OF OBSCURE CASES OF CEREBRAL HEMORRHAGE.

It has happened recently to the writer to be called to two fatal cases in which the diagnosis was obscure, but in which intra-cranial hemorrhage was believed to be the cause. In both cases an autopsy was refused.

These patients were women in middle life. They were seized during sleep, and both soon became so profoundly comatose that it was impossible to determine whether or no a hemiplegia was present. One had external strabismus and dilated pupil of the left eye, which would indicate possibly a lesion—as hemorrhage—of the left crus, involving the third nerve.

I refer to these cases because they are especially difficult to diagnosticate from uræmic coma, and this difficulty is, of course, increased if the patient, as in the case of one of these, has albumin and casts in the urine. The presence of albumin and casts, however, does not prove that the patient has uræmic coma, and what is equally important, it does not contraindicate cerebral hemorrhage. In both of these patients there was a total absence of precedent symptoms of kidney disease. In the one whose urine was albuminous the excretion was free, and treatment directed to a possible uræmic element did no good. The temperature was above normal in this patient, which contraindicates uræmia. The duration of these cases, almost a week in both, is also against uræmia.

DR. ORVILLE HORWITZ has been appointed Demonstrator of Surgery in the Jefferson Medical College to succeed Dr. J. Ewing Mears, who has resigned after fifteen years' service.

HOSPITAL NOTES.

TÆNIA MEDIA-CANELLATA.

Abstract of Original Lecture Delivered at the Hospital of the University of Pennsylvania, October 10, 1889.

BY JAMES TYSON, M.D.,
PROFESSOR OF CLINICAL MEDICINE.

DR. TYSON showed the class a specimen of an entire tænia media-canellata, or beef tape-worm, removed by treatment from a patient in the University Hospital. He called attention to the fact that this form of the parasite is the one most commonly seen in this country; that it generally has a length of about four yards, with a small head possessing neither snout nor hooklets, but flattened in front and provided with four prominent and powerful suckers. Attention was, also, called to the fact that two other varieties of tape-worm are frequently found in the alimentary canal of man, and are known as the tænia solium, or the pork worm, and the bothriocephalus latus, or the fish worm, as it is sometimes called. The former is very common in Germany, and is sometimes seen in this country; but the latter is much more rare, and is only seen in those countries where the people eat a large number of fish. The distinction between the tænia solium and the tænia media-canellata is marked by the former possessing, in addition to the suckers, a disk of hooklets, by which it attaches itself to the walls of the bowel, and in consequence this species of worm is the most difficult to dislodge. The bothriocephalus latus has an oval head with a slit on each side, and possesses neither hooklets nor suckers.

The treatment in the case which Dr. Tyson showed the class consisted in fasting for twenty-four hours, and in the administration at the end of twelve hours of a saline purge. On the next morning at seven o'clock two drachms of the ethereal extract of male fern were administered, and repeated in two hours. On the same afternoon another saline was given, and the worm was discharged entire.

The lecturer pointed out that failure often resulted because the treatment previous to the final purge had been imperfect. He also recommended very highly kousso in the treatment of tape-worm, and stated that an equally efficient remedy is pomegranate or its derivative, pelleterine. The kousso should be given in an infusion made of four ounces to the pint of water, all of which should be taken. Pelleterine is to be given in the dose of from two to three grains. When pomegranate itself is used, an infusion of the strength of half an ounce to the pint should be employed.

MEDICAL PROGRESS.

Scarlatina and the Puerperal State.—Can a physician who is attending cases of scarlatina take charge, at the same time, of women in labor; and if he does, are the lives of his patients endangered? This is a question of great interest to every general practitioner, since he cannot always, even if he uses the utmost care, avoid contact with scarlatina while in attendance upon labor cases. The various opinions held by medical men upon this important subject are well expressed in the discussion of a series of papers read by DR. BOXALL (*Trans. of London Obstet. Society*).

The opinion has been held by many physicians that scarlatina is especially dangerous to parturients, producing in them a very dangerous form of puerperal fever. Others, however, claim that scarlatina can produce in the parturient only scarlatina, and that the danger to the patient is little, if at all, greater than if she had not been pregnant. Do the scarlatiniform rashes, which appear upon parturient patients, indicate the presence of the scarlatinal poison, or are they simply unusual indications of non-scarlatinal septicæmia? The complete solution of this problem must evidently await more exact knowledge of the nature and cause of scarlatina, and of the peculiar characteristics of the lying-in diseases which are now grouped under the general title of "Puerperal Fever," or "Puerperal Septicæmia." In the discussion, however, some interesting points were developed. It was insisted upon, and with reason, that disinfection against scarlatina before attendance upon a case of labor, ought to embrace something more than routine cleansing of the hands—ought to include as thorough disinfection as possible of the clothing of the practitioner.

The statement was made that, while scarlatina breeds only scarlatina, yet scarlatina *plus* septic matter breeds scarlatina and septicæmia. Therefore, proper disinfection of the person and clothing of the non-parturient patient will prevent, if the physician is free from septic matter, the production of septicæmia in the parturient, although she may have scarlatina.

The suggestion was also made, that septic symptoms occurring in a patient who has acquired scarlatina during labor, may arise from decomposition of her own lochia, or from the absorption of other septic matter by the enfeebled tissues of her genital tract. If this be so, careful irrigation and cleansing of the genital canal whenever decomposition of the discharges occurs, and under other proper circumstances, would probably ward off sepsis, and limit the disease to scarlatinal fever.

One fact, which forcibly suggests that scarlatina does not of itself produce puerperal septicæmia, is, that in certain cited epidemics of scarlatina, of a very malignant form, there has been no increase of puerperal fever.

If it is true that scarlatina breeds only scarlatina, and that septic symptoms in its course, arise from a second infection of the parturient with septic matter, then it is probable that the physician may attend scarlatinal and labor cases at the same time, with comparative safety, if he practises and enforces the well-known laws of asepsis and antisepsis. Further knowledge and experience are needed before these important points can be decided.

Oxygen Inhalation.—The opinions held among medical men concerning the therapeutic value of inhalations of pure oxygen, are so various that any careful observations upon the subject are worthy of attention. In the *Practitioner* (August, 1889) DR. THOMPSON discusses the subject from a theoretical point of view, and gives also the result of experiments upon animals and of observations upon patients.

From experiment, and from consideration of the laws of physics as they bear upon the absorption of oxygen by the blood, it is quite evident that if an animal in a state of perfect health is made to breathe pure oxygen at the pressure under which this gas exists in the atmos-

phere, but very little more oxygen will be taken into the blood than if it breathed common air. In order to make any considerable amount enter the blood above that which is usually absorbed by it, a degree of pressure is necessary which causes mechanical interference with circulation and respiration.

The old idea that animals cannot live in an atmosphere of pure oxygen is erroneous. As might be expected from the foregoing statements, it is now proven that animals can live for many hours in pure oxygen, under ordinary atmospheric pressure, without any symptoms or appreciable change, provided the CO_2 exhaled and the nitrogenous waste products of the body be removed. The vague and inconstant sensations, experienced by healthy persons who inhale pure oxygen freely, may be due to impurities contained in it.

Practically, Dr. Thompson has found the inhalation of oxygen valuable in many cases. In *anæmia* and *chlorosis* he has derived no decided benefit from it. In *malignant diphtheria*, with rapid respiration, subjective dyspnœa, and cyanosis, relief was afforded only to the subjective dyspnœa, the cyanosis remaining the same, and the patient dying from pulmonary œdema and heart-failure. In a case of *illumination-gas poisoning*, with persistent unconsciousness and subsequent pneumonia, the continuous inhalation of oxygen had no effect whatever, either upon the breathing or upon the cyanosis which occurred during several attacks of pulmonary œdema.

In a case of *malignant endocarditis*, with extensive valvular disease and dilatation, oxygen failed to relieve the dyspnœa, either before or after obstruction occurred in the lungs. In *pneumonia*, with rapid breathing, dyspnœa, and cyanosis, he has often found oxygen of very great value. The dyspnœa may diminish while the cyanosis quickly vanishes, and the respiration becomes slower and more natural. So also in *capillary bronchitis* and *asthma*, especially when it is accompanied by much bronchial secretion. In *uræmic dyspnœa* he has found it of great use. In one such case, with normal lungs and very intense dyspnœa, lasting for three days, each inhalation of oxygen was followed in fifteen minutes by slowing and quieting of the breathing, slight improvement in the cyanosis, and great increase of comfort to the patient. Upon stopping the inhalation the dyspnœa always returned.

A bibliography of the subject is appended to the article.

The Dissemination of Tuberculosis.—The experiments of DR. CORNET, in the Hygienic Institute of Berlin, under the auspices of Professor Koch, have been frequently alluded to in THE NEWS, and are, indeed, so well known by the profession in general as to need no repetition. Being a Bavarian by birth, Cornet some time back sent a copy of his publications to the Bavarian Government, with the request that they test the correctness of his views. Although it was not to be expected that they should undertake an extended inquiry at the dictate of a private individual, the *Medical Press and Circular* of October 2d states they handed the articles to the Upper Board of Health. The referee on this occasion, Professor Bollinger, has decided to enter on an investigation as regards prisons.

It is notorious that a great number of prisoners, nearly one-third, die of phthisis, and Professor Bollinger has determined that they shall not die of phthisis contracted within the prison walls, if Koch's views on the etiology of the disease are correct. For the future, all cells are to be disinfected as thoroughly after occupation by phthisical patients as after cholera or smallpox. Further than this, all prisoners already phthisical, or suspected of being so, are to be removed. All the sputum is to be disposed of in the way recommended by Dr. Cornet.

The Treatment of Lupus by the Application of Ice.—DR. KLAUS HAUSSEN, in the *Centralblatt für Chirurgie*, for September 7th, reports two cases of lupus, one of the lower lip and the other of the chin, both of which had been subjected to various modes of treatment, such as cauterization, the use of the galvano-cautery, scraping, etc. In spite of this treatment healing did not occur, and the disease continued to spread. In both cases the parts affected were most sensitive, and even the application of iodoform powder caused long-continued pain, which the use of cocaine solution was unable to mitigate. Haussen scraped the parts again, and treated the disease by applications of ice. The extreme sensitiveness speedily disappeared, and in the course of a few weeks both cases were entirely cured.

Reduction of Hernia during Coughing.—It is an undoubted fact that coughing will produce or bring down a hernia; it is therefore somewhat surprising to hear that coughing may be useful in the reduction of such a displacement. M. VANDENABEELE, however, has frequently found that herniæ which had resisted attempts at reduction by taxis alone, yielded when the patient was directed to cough during the manual effort of compressing the sac. M. Vandenabeele's observations included both inguinal and femoral herniæ, and were not confined to either sex. He believes that during the act of coughing the hernial ring dilates somewhat, and that if well-directed taxis is employed at the right moment most cases will yield.—*Lancet*, October 5, 1889.

Echophotomy.—PROFESSOR QUINCKE, of Kiel, has been recently devoting himself to a careful scrutiny of producing colors by different sounds. When a trumpet is loudly sounded at the ear of a sensitive patient, he will immediately after define the first color he sees as yellow which he formerly recognized in its proper hue. A vocal sound A will give the impression of black, while the vocal sound O conveys the sensation of red. This phenomenon is analogous to the radiating pain of toothache, the shoulder pain in case of hepatic affections, etc., being peripheral excitement transported to another path on its way to the reflecting centre where it is received as a true impression. This observation may be of considerable value in elucidating many cases of color-blindness or perverted vision.—*Medical Press and Circular*, October 2, 1889.

Colored Spectacles.—DR. KÖNIGSTEIN, of Vienna, while giving directions to his class on the uses and prescribing of spectacles, said that green glasses as a protection against strong rays were worse than useless, and did more harm to a sensitive eye than good, as they allowed the yellow rays to be transmitted and unnecessarily irritated the eye. As a protection against strong rays the blue or

smoked glasses were the only real protection. The blue should be light, as a deep blue color produces a clear violet disk in the centre of the lens which apparently corresponds to the fovea centralis, and by a protracted use of dark blue spectacles the patient may become annoyed by the mosaic work of the fundus of the eye appearing before him. The phenomenon seems to be connected with the pigmentary changes in the macula lutea. —*Medical Press and Circular*, October 2, 1889.

Sulphonal in Night-sweats.—Dr. Boettrich, in the *Medical Press and Circular* of October 2, 1889, relates the case of a lady suffering from profuse night-sweats and sleeplessness. He prescribed seven grains of sulphonal, after which the sweating was quickly arrested. On further investigation he found that the drug in this direction is as powerful as atropine, and free from its toxic effects, whilst its influence in suppressing the perspiration lasts longer.

Treatment of Pruritus.—Norman Porritt, in the *British Medical Journal* of July 27, 1889, recommends the employment of a cone of cacao butter, impregnated with two per cent. of cocaine, in the treatment of pruritus and irritable skin. This is rubbed over the part affected. The warmth of the skin melts off a layer of cacao butter, which forms a soothing emollient shield over the irritable patch. The remedy has been put up in the form of cones, inclosed in boxwood cases with screw tops, something after the manner of menthol cones. In irritable affections of the skin, in cases of insect bite, in pruritus, and various forms of hyperæsthesia, the remedy is worthy of a trial, and its use has distinct advantages over the more usual applications.—*Journal of Cutaneous and Genito-urinary Diseases*, October, 1889.

Intestinal Obstruction.—In the *Archives of Surgery* for July, 1889, Mr. Jonathan Hutchinson details the principles which guide him in the treatment of suspected acute intestinal obstruction, from whatever cause. He believes that in all cases in which obstruction is recognized, whether the symptoms are severe or mild, one of the first measures adopted should be the administration of an anæsthetic, under the full influence of which, intestinal spasm will be relaxed, and the passage of scybalæ, gall-stones, or other impediments favored. While anæsthetized, the patient's abdomen should be carefully examined by the surgeon, who should also use enemata, and practise abdominal taxis. An accurate diagnosis of the cause of obstruction is not often possible, and the early use of anæsthesia and taxis is successful in many cases, whatever the causation, and prejudicial to but few. If these measures fail, and the symptoms increase after anæsthesia, exploratory laparotomy should be resorted to.

Intussusception in infants under one year should be treated wholly by taxis and enemata, as the prospect of recovery after abdominal section at this age is exceedingly slight. In older children, laparotomy is probably the best treatment. If the diagnosis is plugging of the gut by a gall-stone, belladonna should be freely administered, and if pain is severe, prolonged anæsthesia; also systematic efforts should be made to force enemata beyond the ileo-cæcal valve. Under no circumstances does this latter condition justify an operation, as with the above measures the probabilities of recovery are great. In cases of long duration, either the "rest, opium, and starvation plan," feeding entirely by the rectum, or repeated recourse to taxis and large enemata, should be adopted.

Mr. Hutchinson describes his method of taxis thus: Under full anæsthesia, the bladder and bowels being empty, the surgeon forcibly and repeatedly kneads the patient's abdomen, pressing its contents in all directions. The patient is then turned on his abdomen, upheld by four strong men, and vigorously shaken. Following this, he is supported by the feet, copious enemata given, and, while still in this position, vigorously shaken upward and downward. The latter, Mr. Hutchinson considers exceedingly important. However rough such treatment may seem, it is in no sense unscientific, but thoroughly rational, and its efficacy is attested by the reports of Mr. Hutchinson's cases.

Potato Poisoning.—The *Journal de Médecine et de Chirurgie Pratiques* for August, 1889, recounts the symptoms noted in one hundred men after eating the young sprouts of potatoes. The symptoms were those of gastro-intestinal irritation, with dilated pupils, sweating, disturbed vision, and vertigo. In most cases the illness lasted five days, but in none was there a fatal result.—*Therapeutic Gazette*, October 15, 1889.

[It seems not improbable that many unexplained cases of diarrhœa, cholera morbus, etc., are due to carelessness in the preservation of potatoes, as the young sprouts almost invariably contain solanine, a poisonous alkaloid.—Ed.]

Intestinal Obstruction from Impacted Feces.—At a recent meeting of the Surgical Section of the Royal Academy of Medicine in Ireland, Mr. W. Thornley Stoker read a paper on "Intestinal Obstruction," in the treatment of which his views closely coincided with those of Mr. Hutchinson, as abstracted above. Mr. Stoker dealt chiefly with the treatment of those cases where the obstruction was owing to the paralyzed condition of the bowel from the accumulation of feces or flatus. In this class of cases a lumbar operation was rarely indicated, and, owing to the extreme meteorism, laparotomy was usually a fatal proceeding. He urged the adoption of other measures previous to any precipitate opening of the abdomen, advocating the employment of pressure and massage, and the judicious use of purgatives. Of these latter remedies he considered undue fear existed. Of belladonna, when pressed to its full effect, he spoke highly, and quoted cases in evidence. Local treatment by rubefacients he disapproved of, as he did also of opium, which he regarded as masking symptoms, and doing little or no good. Tapping the bowel with an aspirator needle or fine trocar he had found of great use where much tympanites existed. The "long tube" he considered a dangerous and useless piece of apparatus.—*British Medical Journal*, October 5, 1889.

The Treatment of Varicose Veins.—For the radical cure of varicose veins Dr. C. H. Y. Godwin recommends the intravenous injection of pure carbolic acid, a method he has used for many years. Previously to the injection the skin is washed, and kept moist for some hours with a 1 in 20 carbolic solution. The patient is then directed to stand, and while in that position an Esmarch tube is tightly fastened around the thigh. On lying down the

veins will remain distended, when a number of injections are made into the most prominent places, each injection not exceeding half a minim. A firm clot forms in a few moments, but the tourniquet should be allowed to remain in place for ten or fifteen minutes longer. The only dressing required is a light, dry, antiseptic pad; the patient should remain in bed for a week. In choosing cases for this treatment a large cluster of varices is more satisfactory than a single dilated vein. In his long experience with the method Dr. Godwin has met with no accident, the results invariably being satisfactory.—*British Medical Journal*, October 5, 1889.

Various Methods of Treating Psoriasis.—The *Medical Chronicle*, October, 1889, in reviewing several of the more usual external and internal measures for the treatment of psoriasis, says:

Most authorities prefer arsenic to any other internal remedy. It may be given in the form of pills or as Fowler's solution, either in the ordinary way or hypodermically, when filtered or combined with an antiseptic. Tar water, carbolic acid, turpentine, copaiba, phosphorus, and even cantharides are spoken of as remedies. BULKLEY (*New York Medical Journal*, July, 1889) says that alkalies are often beneficial. "The best form to give them in is acetate of potassium, lithium, or calcium." Iron and cod-liver oil he finds useful. Oils and fats if digested, pure woollen clothing next the skin, and a warm equable climate he considers important factors in treatment. GUTTELING (*Weekbl. van het Nederl. Tijdsch voor Geenesk*, No. 17, 1889, abstracted in *Wiener med. Blätter*) reports on the results of treating 22 cases of psoriasis vulgaris with large quantities of iodide of potassium. The remedy was given frequently and the doses gradually increased. Five cases were completely cured; in 5 the iodide had to be abandoned. There was a decided improvement in the 12 cases remaining. The largest quantity given in one day was 57 grammes (about 14 drachms), and the largest amount taken during the whole course of treatment by a single patient was 3684 grammes (about 7 pounds). Several patients gained weight whilst taking enormous doses of the iodide, whereas only a few of them had acne or iodic purpura. The drug is said to be especially beneficial in recent cases. Daily doses of from 10 to 20 grammes (about 2½ to 5 drachms) are recommended. If, owing to failure, large doses have to be resorted to, the improvement will be incomplete. In the five cases which were completely cured, the course varied from fourteen days to four and one-half months. BARDUZZI (abst. *Brit. Journ. Dermat.*, from *Gazetta d. Ospitali*, 17, 1889) confirms the good results obtained by Dutchmen: "In three diffuse universal cases of very inveterate character, which had been treated with transient success by all the usual remedies, he obtained results from iodide of potassium which he never hoped for. In none of his cases was the amount of the drug larger than 7 grammes (105 grains) daily."

According to Bulkley, visits to mineral springs reputed to cure psoriasis lead only to disappointment. "He did not know of a single cure effected by sulphur waters, though the reputation of such waters was the highest of any." With regard to external applications, the treatment should vary with the cases. Bulkley has abandoned the use of chrysarobin, antharobin, and pyrogallol, because he has found that white precipitate ointment answers better than these preparations. BESNIER (abst. *Brit. Journ. Dermat.*) has recently recommended β-naphthol. He rubs in this ointment—β naphthol 10, adipis 90—every evening. In the morning the ointment is washed off with warm water and soap, and the skin is powdered with starch. According to Kaposi, who introduced β-naphthol into practice some years ago, the fifteen per cent. ointment, which he prescribes, is a valuable application for the hands, face, and scalp, inasmuch as it does not discolor the skin or the hair. Bulkley believes that local applications used early prevent the development of the eruption. There is no doubt that treatment is most successful when the eruption is fading, and least so when the eruption is coming out, the spots rapidly extending and the exfoliation very great.

The Influence of Olive Oil on Biliary Secretion.—The usefulness of olive oil in hepatic colic seems to be substantiated by the recent experiments of ROSENBERG, who, in dogs with permanent biliary fistulæ, finds that large doses of olive oil greatly increase the flow of bile, and decrease the specific gravity. (*Therapeutische Monatshefte*, September, 1889.) If further experiments prove the accuracy of the statements that olive oil assists the passage of calculi, not, as maintained by the supporters of the treatment, as a lubricant, but by increasing the secretion of bile and washing out the gall-stones it will probably be widely adopted if the patients do not object to the dose.

The Treatment of Erysipelas.—The treatment of erysipelas by the external application of germicides is certainly growing in favor. Carbolic acid, though used to some extent, has the disadvantage of being in itself an irritant if in sufficient strength to modify the disease. Creolin, which is undoubtedly a powerful germicide, is used by DR. KOCH, of Vienna, for this purpose. His formula is: one part of creolin, four of iodoform, and ten of lanolin. This is spread not only upon the erysipelatous area, but for an inch or more beyond its boundaries. To prevent rubbing off and to assist in absorption the whole is covered with thin gutta-percha paper. Dr. Koch believes that the iodine, which is set free in the combination, is, as well as the creolin, an important agent. However this may be, the results are apparently good, and the method is worthy of careful trial.—*Therapeutische Monatshefte*, September, 1889.

Prescription for Psoriasis.—The favorite prescription of MR. JONATHAN HUTCHINSON for psoriasis is:

℞.—Acid. chrysophanic.	gr. x.
Liq. carbonis deterg. (Wright's) .	♏ x.
Hydr. amm. chlorid. . . .	gr. x.
Adip. benzoat.	℥j.

Misce fiat unguent.

At night the patient should wash the diseased surfaces free from all scales, then standing before a fire rub on the ointment, devoting, if possible, half an hour to the operation. This proportion of chrysophanic acid is not irritating, and stains the linen but slightly. With some cases even a weaker chrysophanic ointment is entirely sufficient. Internally, Mr. Hutchinson prescribes arsenic, though he is not convinced that it is an important adjunct.—*Archives of Surgery*, July, 1889.

Use of Pilocarpine Hypodermatically in Tobacco and Alcoholic Amblyopia.—Huel and Leptat, in the *Annales d'oculistique* for March and April, 1889, speak very highly of the employment of pilocarpine subcutaneously in the treatment of the blindness or failure of vision seen in persons who use alcohol to excess. They state that the first injection naturally brings on a profuse sweat and salivation, and the vision becomes better at once and remains improved if no more of the drugs are used. In two cases with retro-bulbar neuritis with central scotomata for red, resulting from the abuse of alcohol and tobacco, pilocarpine produced a cure.

Staderini, who has used pilocarpine in the treatment of the eye, has arrived at the following conclusions:

First. Subcutaneous injections of pilocarpine are of value in most of the inflammations of the eye, particularly those occurring as a consequence of rheumatism, iritis, episcleritis, and inflammation of the optic nerve.

Second. They are valuable in combating those inflammations of the iris and ciliary bodies which are apt to follow the extraction of cataract, and they facilitate the absorption of exudates.

Third. In cases where opacities of a non-organic character occur in the vitreous humor, or in those resulting through infiltration, pilocarpine acts most favorably.

Fourth. In those forms of progressive myopia in which there is involvement of the retina, great amelioration is also brought about by the drug.

Fifth. It can be employed advantageously in certain forms of amblyopia and amaurosis, which are dependent, in all probability, upon disorder of the circulation with a serous transudation into the sensitive nerve centres.

Powder for Papular Erythema.—The following powder is recommended by Besnier, in *L'Union Médicale*, for the treatment of papular erythema:

℞.—Powdered boric acid . . . ʒss to ʒj.
Chalk
Oxide of zinc . . . āā ʒiij.
Powdered starch

This is to be dusted over the part. If the irritation is intense, a mild solution of boric acid is first to be applied and followed by the powder.

The Treatment of Phlebitis.—In *L'Union Médicale* for September 26, 1889, Muselier recommends the following treatment for phlebitis:

In cases of simple phlebitis, leeches should be applied and unctions of mercurial or opium ointment thoroughly rubbed in. Local baths are to be used if the inflammation involves an extremity. If the vein suppurates, free drainage is at once to be established, it being remembered that in spontaneous phlebitis the danger resides in the possibility of embolism. To prevent so grave an accident, the limbs should be placed in cushions and elevated in such a manner as to favor the venous circulation toward the trunk and the disappearance of œdema. Fixation is also a necessary accompaniment of the treatment, and all abrupt movements are to be avoided lest embolism should occur, and even in the application of mercurial ointment violent rubbing should be avoided for fear it may dislodge a clot. If the phlebitis is of long duration and there is much œdema of the limb, it may be well to apply an Esmarch bandage, and if, as a result of this compression, atrophy of the muscles occur, recourse must be had to electrical currents, massage, and baths.

The Antiseptic Treatment of Abscess.—The following method, given in the *Revue Générale de Clinique et de Thérapeutique* for October 10, 1889, as practised by Championnière, while it contains nothing unusual, may be practically useful. Before the operation, the region involved is washed with a solution of carbolic acid, made up as follows:

℞.—Carbolic acid . . . . 750 grains.
Glycerine . . . . 900 grains.
Boiled water . . . . 1 quart.

The bistoury is rendered aseptic by immersion in carbolized water, and, after the abscess is incised, its cavity is washed out with an antiseptic solution until the liquid returns perfectly clear. If the size of the abscess be large, a rubber drainage-tube is inserted, which is rendered antiseptic and contains a little cotton fibre, which is thoroughly soaked previously in the following mixture:

℞.—Glycerine
Crystalline carbolic acid . āā 375 grains.
Boiled water . . . . . 1 quart.

The position where the abscess occurred is now covered by a piece of rubber cloth over which is placed a bandage. Twenty-four hours later the wound is washed out a second time with the same solution as was previously employed, the drainage tube being replaced or left out according to the condition of the wound.

Successful Operation for Ankylosis of Jaw.—In the *Glasgow Medical Journal* for September, 1889, Mr. Campbell describes a successful operation for ankylosis of the jaw—a condition which is frequently so unmanageable. The case in question resulted from an injury many years previously. After unsuccessful efforts at separating the jaws by wedges and screw-gags, an incision was made on the right side extending from a point a little external to the margin of the orbit, downward and backward, parallel to the lower border of the zygomatic arch for a short distance, then directly downward over the ramus of the jaw for about an inch; the temporal artery was thus avoided. On clearing the soft parts from the bone, there was no demarcation between the jaw and the temporal bone; the zygomatic arch, the condyle and the coronoid process were all fixed together. The posterior border of the ramus having been defined, the parts representing the condyle and the coronoid process were chipped away with a chisel until a gap of about one-quarter inch was left between the skull and the ramus of the jaw. The jaws could now be forced apart to the extent of an inch. Passive and active movements were allowed on the third day, and three months after the operation the patient could eat solid food of any kind, the interval between the jaws being then about an inch.—*The Birmingham Medical Review*, October, 1889.

Gymnastics in Diabetes.—Dr. Aye reports three cases of diabetes in the *Berliner klinische Wochenschrift*, in which gymnastics played by no means an inconsiderable part

in the treatment. The first patient was a rather stout woman, æt. forty-three, who had suffered from the disease for a year and a half. The proportion of sugar was 9 per cent., and during a "cure" at Carlsbad it was reduced to 1 per cent. Thirst was only moderate, oppression in the head diminished, tremblings became less frequent, pain in back and debility disappeared completely. The patient could run without great fatigue, but the weakness of thought was not much improved. At the end of March the patient expressed herself improved in every way. The results were much better in two other cases; in one of them, in fact, the cure was complete. The author pleads for a trial of gymnastic treatment, although not equal perhaps to walking, or especially to mountain-climbing, it, in his opinion, deserves a place as a therapeutic measure, especially as in the two former the dosage cannot be so exactly measured as in the exercise he advocates. It has another advantage in being admissible in weak cases, and will no doubt form a useful adjunct to the other recognized methods of treatment.—*The Medical Press*, October 9, 1889.

Treatment of Ingrowing Toenail Without Operation.—DR. HOFMANN, of Erlangen, recommends a simple and painless method of treating this complaint. After the part is thoroughly cleansed and disinfected by sublimate solutions, a few drops of perchloride of iron are dropped on the affected spot. The edge of the nail is then gently raised and dried. This is repeated on the second and third day. If suppuration takes place, the hardened scabs are to be removed with forceps, and the perchloride again applied. The nail soon becomes soft and brittle so that it can be easily removed, and without pain.—*The Medical Press*, October 9, 1889.

Massage as an Aid to Intestinal Absorption.—MR. SYMONS ECCLES, in the *Practitioner*, seems to have conclusively proved the value of both local and general massage in hastening the absorption of the intestinal contents. To determine this he made use of Ewald's test, administering salol to fifty different individuals and noting the time of its first appearance in the urine. Later, to the same series of cases, salol was given and followed for fifteen minutes by abdominal massage, which considerably reduced the time elapsing between the ingestion of salol and its detection in the urine. Again, the patients received both general and abdominal massage for several successive days before the salol tests were repeated, when it was found that absorption was still more active. In two cases of tropical diarrhœa, after a few weeks of general massage, salol appeared in the urine thirty minutes after ingestion, whereas at the beginning of treatment two and a half hours elapsed. Mr. Eccles has also had most excellent results in the treatment of chronic dysentery by massage, muscular atony of the stomach and intestines, and various forms of cachexia, in which the gastro-intestinal tract has suffered. In some of these cases the salol test verified and confirmed the results attributed to massage.

Suggestive Therapeutics.—BINSWANGER in the *Therapeutische Monatschrift, Hefte*, iii., 1, 2, 3, 4, 1889, warns against the inconsiderate and incautious employment of hypnotism. He says that hypnotism under all circumstances has a disturbing effect upon the mental condition, and that subjects of experiment are always transiently hysterical, that the results in different individuals cannot be predicted, and that unfavorable results may follow. He further says that in severe hysteria is the chief ground for suggestive treatment, where the hypnotic suggestion is the most effective and the least dangerous. When other methods are available for cure hypnotism is not needed, and in hysteria minor it should be kept in mind that the possibility of a transition into hysteria major cannot be excluded in the use of hypnotism.—*American Journal of Insanity*, October, 1889.

The Subcutaneous Administration of Mercury.—DR. CHERNOGUBOFF has made a number of observations in the Miasnitski Hospital, in Moscow, in regard to the subcutaneous injections of the yellow oxide of mercury in connection with the treatment of syphilis, and has come to the following conclusions: Two-grain doses cause a quicker disappearance of all symptoms than smaller doses, reducing in ninety-two per cent. of cases the necessity for professional visits to one or two. In fresh cases an interval of ten or eleven days between the injections is sufficient to prevent salivation, but old cases require a longer interval. The injection should be made into the cellular tissue, and not into the muscles, to avoid the great pain in the case of the latter, and the frequent occurrence of abscesses. The treatment is said to cut short all symptoms, both when the disease is progressing and when it is on the decline; new spots, especially on the mucous membrane, are very rare. In tertiary syphilis, according to Dr. Chernoguboff, early gummata, and those which are breaking down, quickly disappear under the treatment; but, in impetigo and rupia, iodide of potassium is often required in addition. Local applications do not usually accelerate a cure, except in sore-throat with papular infiltration of the tonsils, which requires heroic treatment. Relapse occurs as in other methods after two or four months. Men and women equally bear well large doses; children from twelve to fourteen years require one grain only. The treatment is contraindicated in severe anæmia which has not been caused by the specific disease, in general exhaustion, undoubted alcoholism, chronic inflammation of parenchymatous organs, and in extensive dental caries; pregnancy is not a contraindication. Mercury is found in the urine in from four to eight hours after the injection.—*The Lancet*, October 12, 1889.

Bromoform in Whooping-cough.—To the already interminable list of remedies for pertussis has been added another, which, according to a DR. STEPP, is superior to any yet proposed. Bromoform is a clear, colorless liquid resembling chloroform, but having a density double the latter. The odor is agreeable, and the taste slightly sweet. Dr. Stepp tried it in seventy cases, with the greatest success upon children from six months to seven years. At the end of a few days the fits diminished, and in three weeks the patient was well. The following would be a convenient form of administering it:

℞.—Bromoform	. . . . .	♏ x.
Alcohol	. . . . .	ʒ j.
Syrup	. . . . .	℥ ss.
Water	. . . . .	℥ iij.—M.

A teaspoonful every hour.—*The Medical Press and Circular*, October 9, 1889.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 26, 1889.

THE TREATMENT OF RACHITIS WITH PHOSPHORUS.

THE essential morbid change in rickets is softening of the bones and their consequent deformity. Histologically the process cannot be stated so positively, but the researches of Kassowitz seem to prove that increased vascularization of the osteogenetic tissues is the causation of the removal and non-deposit of the mineral salts. It is a long-recognized pathological law that lime salts are more readily deposited in tissues of slight vascularity than in those with an abundant blood-supply. Whatever the histological cause may be, the gross anatomical appearances naturally suggest the search for some drug whose tendency is to produce a deposit of lime, hence the administration of the calcium salts.

In 1872 Wegner, studying the physiological action of phosphorus on animals, noted that after its continuous administration the bones were much more dense, in some instances the cancellous tissue and medullary canal being entirely obliterated. These effects have been confirmed by other observers, and denied only by Kissel, of St. Petersburg, whose observations are open to criticism.

Wegner's observations led to the logical deduction that phosphorus would be found a valuable drug in rickets; a brilliant example of the utility of experimental therapeutics and a knowledge of pathology, for the clinical studies of Kassowitz, Friese, Jacobi, Montmolli, Hartwitz, Hochsinger, and, recently, of Anna Schabanowa, have confirmed the opinion of Wegner.

In the *Therapeutische Monatshefte* (abstracted in detail from *Jahrbuch f. Kinderheilkunde und physische Erziehung*), Anna Schabanowa analyzes the results of the phosphorus treatment of rickets in 105 children, varying in age from one month to five years. The phosphorus was administered after the method of Kassowitz, in almond oil, or in cod-liver oil, in doses of $\frac{1}{120}$ of a grain. The solution in cod-liver oil she found, as a rule, better tolerated. With this internal medication were combined salt-baths, as far as possible nourishing diet, and the usual hygienic measures. In 6 cases the results were brilliant, in 32 good, in 39 fairly good, in 22 poor, and in 6 the rachitic symptoms were aggravated; or, approximately, 75 per cent. of the cases were more or less improved. With most patients the body weight and size increased; in from three to six months the open sutures were decreased in size, the eruption of tardy teeth hastened, the circumference of the chest increased, the costo-cartilaginous swellings subsided, and the fontanelles closed. Particularly marked were the effects upon the nervous manifestations, laryngeal spasm, general convulsions, and hyperæsthesia; the sleeplessness and irritability disappearing in nearly all cases. In one case nocturnal enuresis was relieved. On digestion the effects were very beneficial, dyspepsia, constipation, and meteorism vanishing.

Allowing for the enthusiasm of the author, these results give important testimony as to the value of phosphorus in rachitis. The criticism may be made that the cod-liver oil, in which the phosphorus was usually administered, may have been the potent agent. Doubtless it played an important part; but such effects could never have been obtained with cod-liver oil alone, even under circumstances most favorable to hygiene; and Schabanowa's cases were mostly seen in dispensary practice.

With the steadily accumulating evidence at hand, it can be said that phosphorus has reached a permanent place in the therapeutics of rickets; but it should never be forgotten that there is no specific for this disease, and that all drugs are of secondary importance to the general and dietetic management of each individual case.

Phosphorus should be administered in small doses in an oily solution or emulsion. The possibility of fatty degeneration of the liver, as pointed out by Wegner, should not be forgotten; and Hartwig,

fearing this, advises occasional withholding of the drug to avoid danger. We believe no case has as yet been reported in which ordinary therapeutic doses caused degeneration, but, nevertheless, it may be well to bear such a possibility in mind when administering the drug for any great length of time.

SCROFULOUS GLANDS.

UNTIL comparatively recent years no medical term has been used more loosely, none conveyed less distinct conceptions than *scrofula*. It was alike applied to hereditary syphilis, to new formations, cutaneous diseases, and to most wasting diseases of children and adults, as it is yet in popular usage. Gradually it emerged from the maze of confused ideas surrounding it, and at the present day has come to signify a condition of the organism, rather than a distinct disease; a condition stamping characteristic marks on associated diseases, and with predispositions peculiar to itself, the most marked of which is excessive cell-proliferation. That this condition is a histological deviation seems most probable, and while Formad's assertion that scrofulous tissues contain an excess of lymphoid cells crowding the lymph spaces, has not been indisputably proven, it offers a satisfactory explanation of many otherwise inexplicable phenomena in the strumous. Though the relationship between scrofula and tuberculosis cannot be considered determined, caseated lymphatic glands, frequently the only manifestation of scrofula, are almost invariably tubercular, a menace to their possessor, and in consequence should be done away with.

The basis of treatment since the days of Lugol has been iodine in its various compounds, externally and internally, the syrup of the iodide of iron being the favorite. Mr. Frederick Treves, *Lancet*, September 21, 1889, in discussing the treatment of scrofulous glands enters a strong protest against the indiscriminate use of this preparation, believing it valueless and ranking it with the "royal touch" of history. From the sulphide of calcium he has seen no better effects. This is probably too sweeping a statement, though the syrup is much relied upon as a specific, and with so blind a faith in its potency, that other and more important details of treatment are lost sight of and neglected. Hygienic measures, good diet, and sea air are of vastly more use to the strumous than drugs, particularly drugs so prone to interfere with digestion as the iodide of iron. In local treatment Mr. Treves insists upon the necessity of seeking the peripheral irritant, which always exists, perhaps in a carious tooth, a chronic tonsillitis, ozæna, or eczema. Too much stress cannot be laid upon this much neglected point, for the cure of a lymphadenitis, simple or scrofulous, is hopeless if the area drained by the efferent vessels remains diseased. The time-honored local applications Mr. Treves entirely discards, believing that ointments are productive of good solely by virtue of friction, and that tincture of iodine increases the glandular irritation. Absolute rest of the parts involved he considers of great importance, and to secure this in the neck he advises the wooden collar of Mr. W. Knight Treves.

In 1882 Treves, to destroy these caseous deposits, used the cautery puncture. This he has since abandoned except as the best means of evacuating fluid accumulations, though for what reason it is superior to the knife he does not make clear. Whenever possible he excises the glands in their entirety, avoiding tearing of the tissues and endeavoring to secure primary union. Scraping with Volkmann's spoon is admissible in sinuses and old cavities, but not as a means of removing deposits. Mr. Treves has devoted so much careful work and thought to glandular disease, that his opinions may be considered as reflecting the most advanced opinions upon the subject.

EXPERIMENTAL STUDIES IN THE ETIOLOGY OF TYPHOID FEVER.

THE undoubted success which has attended the administration of intestinal antiseptics in typhoid fever proves the possibility of a favorable modification of the soil in which flourishes the germ of that disease. We are as yet ignorant of the conditions which render this soil arid in one case and fertile in another, but recognize their existence whenever we use the word "predisposition." The soil or culture medium referred to, is composed of the intestinal secretions and the débris of the food—the slag, so to speak, from which the nutritious ore has been extracted. It is evident, therefore, that the soil may be favorably modified in two ways: first, by antiseptics of approved value, such as thymol, naphthalin, carbolic acid, etc.; and, secondly, by a carefully selected diet. In the order of relative importance the latter indication should precede the former, but the humiliating fact must be recognized that our knowledge of diet is less than that of drugs.

A praiseworthy attempt to increase our knowledge of this disease is made by Rachford on another page of this journal. Believing, as do many others, that the symptoms of typhoid fever are largely depend-

ent on the products of the typhoid bacillus, namely, the ptomaines induced by its growth, he is probably the first to submit this belief to the test of experiment. Having cultivated the bacilli in various nutritive media and administered them with due precautions to rabbits, he found that the result varied according with the medium, in each case a food-substance, in which the organism has grown. The most interesting conclusion from these experiments is that the ptomaines produced by the growth of the typhoid bacilli in milk, which is the universal diet in typhoid fever, "do not cause either fever or nervous symptoms."

While the number of Rachford's experiments is too small to render them conclusive, they are suggestive enough to induce others to repeat them, and verify or disprove the deductions which have been drawn from them.

REVIEWS.

Diseases of the Eye. A Practical Treatise for Students of Ophthalmology. By George A. Berry, M.B., F.R.C.S. Edin. With colored illustrations from original drawings. Octavo, pp. 650. Philadelphia: Lea Brothers & Co., 1889.

It is a common custom for the author of a book to offer, in his preface, an apology for adding another volume to the great load which fills the shelves of medical libraries. The request of students, the experience of years, and the desire to record satisfactory methods of personal practice are the excuses usually given. It is hence novel and somewhat refreshing to find that Dr. Berry has, without apologetic explanation, "endeavored to give a description of the principal Diseases which affect the Eye, or lead in any way to impaired vision," and gratifying to state that he has accomplished his task with credit, having written a treatise founded upon the results of personal experience and honest analysis of ophthalmological literature, the whole tinctured strongly with the methods and practice of that master of his art Hansen Grut, to whom the book is gracefully dedicated.

A striking and useful feature is the plentiful supply of colored drawings, the work of Dr. Tatham Thompson, which is scattered through the text. These drawings consist not merely in the usual representations of typical diseased conditions of the fundus oculi, but also of the various disorders of the external coats of the eye; some of them, for example, the cut representing cicatricial ectropion of the upper lid, are wonderfully life-like; others, like the illustration of phlyctenular conjunctivitis, decidedly diagrammatic. The book is divided into three sections. The first is devoted to a consideration of the diseases of the eyeball and its appendages, including affections of the orbit, and concludes with a good discussion of Graves's disease. The descriptions are largely clinical—pathological anatomy being advisedly omitted—eminently practical, and the teachings for the most part sound and satisfactory. We are by no means in accord with all of the methods of practice therein detailed. We do not believe that when a simple or catarrhal conjunctivitis has become chronic, of the various astringent applications "alum in the strength of from two to eight grains to the ounce is perhaps the most useful," nor, in the management of diphtheritic conjunctivitis are we enamored of "the treatment recommended by Tweedie, of frequent bathings with a solution of quinine (three grains to the ounce)." Naturally, however, an author describes and recommends those procedures which have yielded in his hands satisfactory results. It has always seemed to us a mistake, in works on diseases of the eye, that so little attention was paid to the management of the bodily health of patients affected with disorders of the conjunctiva and cornea. Dr. Berry, while he has not neglected this important topic, follows, in too many instances, the common custom of indulging in vague directions, like, "Constitutional treatment should, of course, be adopted from the first."

The chapters devoted to diseases of the choroid, retina and optic nerve, and the section describing intra-ocular tumors are very good. The former have been revised by Mr. Gunn, and the latter is illustrated with several excellent colored drawings. Glaucoma is discussed with clearness and ability.

The second section of the book is concerned with the eye as an optical instrument; and the laws and errors of refraction, accommodation, and the methods of examining an eye, as well as the anomalies of the ocular muscles, receive elaborate consideration. So large a proportion of patients who come to an ophthalmic surgeon suffer from imperfect or painful vision the result of optical errors, that these topics demand careful presentation. The chief fault of the chapter, it seems to us, is the unnecessary introduction of mathematical formulæ—formulæ which would find suitable place in a treatise specially devoted to the refraction and accommodation of the eye, but uncalled for in the present book. On the other hand, certain methods of examination, like the shadow-test, are dismissed in a somewhat cursory manner.

In regard to the treatment of hypermetropia, Dr. Berry concludes that the strength of convex glass required is that which corrects the manifest portion of this error of refraction; that the glass should be worn constantly if asthenopia is present, but that in the absence of asthenopia it is sufficient to make use of the correcting lenses only for near work. In persistent asthenopia he suggests that the whole amount of the hypermetropia should be corrected, although he doubts whether this will prove sufficient to relieve the symptoms. The question of whether or not the patient should wear a full correction, has been so often discussed that it is not necessary to give it place in this review. We would merely suggest that in most instances other conditions beside the mere state of refraction will have to decide the line of practice, and that in the vast majority of instances, as we see refraction error, especially among school children, the mere correction of the manifest hypermetropia is not sufficient to give the relief which has been sought. The question of the diminution of hypermetropia in children, and the gradual conversion, in certain instances, of hypermetropia into myopia is clearly pointed out, and the very proper suggestion made that patients, who in early life have been ordered high convex lenses, must be examined from time to time in order to see whether or

not distention of the eyeball has taken place, rendering a weakening of the glasses necessary. Dr. Berry is disinclined to admit an intimate connection between inflammatory conditions of the conjunctiva, cornea, lids, and hypermetropia, believing that this has been much exaggerated. He prefers to consider these inflammatory affections as entirely independent disorders, although he admits that the presence of this state of refraction may aggravate and perpetuate these diseases. This seems to us to be the correct view in the vast majority of cases—a view which renders it none the less necessary, especially in blepharitis and similar affections, to correct the existing refraction error before a cure can be expected. Astigmatism is briefly discussed; in fact, the chapter is distinctly disappointing. Among the objective tests for astigmatism, that, in the opinion of the author, which gives the best results is retinoscopy. It certainly is most useful in patients who are not gifted in giving accurate answers to questions, or among children whose answers cannot be relied upon. The chapter on the ocular muscles and the treatment of strabismus is entirely satisfactory; so also is the section devoted to the examination of the eye, in which, as we might readily expect, the subjective symptoms of which patients complain are clearly and usefully described. Section III. is devoted to the operations, all of which have been gathered together in this portion, thus avoiding unnecessary repetition in the text. In the description of the operations for advancement of a rectus muscle, preference is given to Prince's method, which the author has found simple and effective. His own plan for performing this operation, although the same in principle, differs slightly in the details which Dr. Prince has described. This entire volume is eminently satisfactory, and we think that it should be in the hands of all students of ophthalmology. It is a credit to the author, and should be a matter of pride to English-speaking ophthalmologists. The publishers have spared no pains to make the book attractive in the printing and binding.

SOCIETY PROCEEDINGS.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, September 30, 1889.

DR. B. K. RACHFORD read a paper entitled

EXPERIMENTAL STUDIES ON THE ETIOLOGY OF TYPHOID FEVER.

(See page 453.)

DR. WHITTAKER said that if his remarks were in the line of criticism, he hoped that he would not seem to deny the value of the paper. At the same time, he could not see what could be gained by experiments in this direction. It was not claimed that any of the rabbits had typhoid fever, except one. Even in this one the spleen was not enlarged. It is still a question whether any other animal than man ever suffers from the disease.

The experiments made with a view to determine the proper diet for typhoid fever patients arrive substantially at the results reached by clinical medicine. Furthermore, he could not conceive what bearing such experiments could have upon man, because in man fever and stupor are present, even if the patient be confined to a milk diet. He had under observation at the hospital three cases, in each of which the fever had mounted to 100°–104°, with coma vigil and stupor, who were under a milk diet, exclusively. We must remember that typhoid bacilli are received into the body two weeks before the disease shows itself, be the diet what it may. The diet may aggravate but cannot change the character of the disease.

DR. LEONARD FREEMAN thought the essayist had not claimed that his rabbits died of typhoid fever, except in the case of rabbit No. 10. The experiments were carried out with the object of showing that the bacillus of typhoid fever when grown in different culture-mediums produced different ptomaines with various physiological effects. It was the action of the ptomaines and not the action of the bacilli which the author attempted to demonstrate; and it was rather a surprise when rabbit No. 10 died, apparently of true typhoid fever. It is claimed by most authorities that animals, including rabbits, do not have typhoid; but Dr. Rachford's interesting experiments furnish weighty evidence against this idea. The rabbit's intestines contained follicular ulcerations, and its spleen furnished a pure culture of the Koch-Eberth bacillus, identified by all the means known to bacteriology.

To illustrate the effects of slight external influences on ptomaine-formation, the results of temperature changes upon the bacillus of anthrax may be mentioned. When grown at a somewhat higher temperature than that to which it is accustomed, it loses its frightful virulency altogether or in part, and does not regain it, in some cases, until it is grown again upon a culture-soil suitable to its requirements—that is, until it has passed through the body of a mouse. This is a case in which an exceedingly virulent germ loses all its pathogenic properties by means of an insignificant change in its surroundings. Why may not the character of the ptomaine produced by the bacillus of typhoid be changed by similar slight alterations in its conditions of growth?

It was, in the opinion of the speaker, not the main object of Dr. Rachford's investigations to prove that milk was the best food in typhoid fever. This was merely a side issue. His investigations dealt with the ptomaines and their effects under different conditions of development.

DR. RACHFORD, in closing the discussion, said that in the presentation of this paper he had been careful to draw only such conclusions as were warranted by his experiments, and the accuracy of the experiments or the value of the conclusions drawn is to be judged by others. At the same time it seemed to him that, unless some flaw in the technique or the arguments can be shown, the resulting conclusions are not without value. If rabbit No. 10 died from typhoid fever, it requires no argument to show that this is testimony to a most important proposition, which, although almost universally believed, has never been absolutely demonstrated, viz., that the Koch-Eberth bacillus is the cause of typhoid fever.

He wished also to state that his sole object in undertaking these experiments was to demonstrate that the typhoid bacillus under different conditions produced ptomaines differing in physiological and poisonous properties. His experiments, he thought, warranted this conclusion.

The third conclusion, that milk is the best diet in

typhoid fever, is an opinion long since established by clinical experience. Yet this does not detract from the value of experimental studies which not only corroborate this opinion, but also show us why it is so. The fact, that "some cases of typhoid fever fed upon an exclusive diet of milk have most profound nervous symptoms," when considered in the light of these experiments, gives us an important insight into the etiology of the nervous symptoms of typhoid fever. If the nervous manifestations were produced only by ptomaines formed in the intestinal canal we could, by an exclusive diet of milk, prevent these symptoms. It seems, therefore, probable that the nervous symptoms are produced not only by ptomaines formed in the intestinal canal, but also by ptomaines formed in the various organs of the body, wherever the bacilli find a lodgement and multiply. While a milk diet could in no way affect the symptoms arising from this latter source, it can, by preventing those caused by the absorption of intestinal ptomaines, very much modify their severity.

Since the question of typhoid fever being a "mixed infection" had been introduced into the discussion, Dr. Rachford wished to say that he knew of no evidence either experimental or clinical that would warrant such an opinion. That other than typhoid bacilli are capable of producing poisonous ptomaines in the intestinal tract is quite true, and that these bacilli may in this manner act as a complication of typhoid fever, scarlet fever, puerperal fever, and other diseases, is also probable, but they exist simply as a complication, and are no more the cause of typhoid fever than they are of scarlet fever or any of the other acute infective diseases.

AMERICAN RHINOLOGICAL ASSOCIATION.

Seventh Annual Meeting, held at the Palmer House, Chicago, Illinois, October 9, 10, and 11, 1889.

WEDNESDAY, OCTOBER 9TH.—MORNING SESSION.

The Association was called to order at 10 A.M by the PRESIDENT, DR. JOHN NORTH, of Toledo, Ohio.

The following gentlemen were elected Fellows of the Association: Dr. E. L. Siver, of Fort Wayne, Indiana; Dr. C. L. Dreese, of Goshen, Indiana; Dr. O. F. McGahan, of Chattanooga, Tenn.; Dr. Ely McClellan, of Chicago, Ill.; and Dr. L. B. Gillette, of Omaha, Neb.

After the election DR. JOHN NORTH delivered the

PRESIDENT'S ADDRESS,

which dealt (1) with the relations which the physician bears to the public; (2) the relation of the specialist to the general practitioner and other specialists, and (3) what the American Rhinological Association has done for the public and for the profession.

A paper was read by DR. L. B. GILLETTE, of Omaha, entitled,

REPORT OF A CASE OF BRAIN ABSCESS EMPTYING INTO THE NASO-PHARYNX.

The patient, aged twenty years, farmer by occupation, strong and healthy, while working on an embankment in September last, was driving a loaded wheel-scraper when in some way it became unlatched, and the handle flying up struck him forcibly under the chin, knocking him down a sixteen-foot embankment where he lay unconscious for some thirty minutes. A week afterwards he noticed that something was wrong with his eyes. About the 15th of October he began work in a brick-yard, and after three days complained of nervousness and slight headache. On the evening of the third day he got wet in a rain, which was followed by a chill and fever. A physician who was called pronounced it malarial fever. When Dr. Gillette was summoned he found the patient suffering with intense headache, the pain extending down between the shoulder-blades, and particularly into the right arm. Both pupils were widely dilated. Temperature was 101°; pulse 105°. A day or two after this there developed marked evidence of compression of the brain. The temperature fell to 96°; pulse was as low as 42; and the respirations nine or ten per minute. Complete paralysis of right side, and partial paralysis of left side came on, with complete loss of sensibility as well as of consciousness. The patient also lost the sense of sight, and remained in this condition four days without any perceptible change. Both food and medicine were always taken regularly. Dr. Gillette was surprised one morning by finding him much improved. The mother stated that during the night the patient had a violent attack of coughing, and showed the sputum, which consisted of about an ounce of green, stinking pus mixed with mucus. From this time the patient improved. There was an immediate return of consciousness, an increase of the heart's action and the respirations. Examination of the throat showed that the pus came from above. None came from the Eustachian orifices, but when the patient leaned forward it would run from the anterior nares. The discharge lasted two weeks. Where it came from, or how it got through, Dr. Gillette could not tell, but his opinion favored the ethmoidal and sphenoidal sinuses. As a result of this terrible ordeal the patient, when seen three months since, was totally blind, with the sense of hearing lost in right ear, his right arm useless, and his mind not as clear as formerly.

In the treatment of the case Dr. Gillette used opium, quinine, mercury, cold applications to the head, and cupping at the back of the neck, also the three bromides as they were indicated. When marked compression of the brain developed, he used eighty grains of iodide of potash daily, continuing for thirty days.

DR. THOMAS F. RUMBOLD, of St. Louis, read a paper entitled

REASONS WHY SO MANY PHYSICIANS FAIL IN TREATING CHRONIC RHINITIS.

The first reason is defective instrumentation. Not one of the physicians whose offices he visited had a tongue depressor that would not cause a patient to retch when introduced into the mouth, and the blades of all the instruments were too wide to go between the teeth, and too long. These depressors were seldom used in examinations, but instead, the exceedingly defective method of drawing the tongue out with a napkin.

The second cause of failure is that the spray-producers used were made for watery solutions only. None of these physicians possessed an instrument that would throw warm vaseline, which he considers superior to fluid cosmoline.

Third, the compressed air used was taken from a reservoir of a capacity of from three to five gallons, at

a pressure of from thirty to seventy pounds. The reservoir was filled by an air-pump whose barrel was made of brass; the piston was packed with leather, which readily decomposes, and the pump was lubricated with rancid oil. Ten pounds is the greatest pressure that the mucous membrane will tolerate, while the majority of patients require only from six to eight pounds pressure.

The fourth reason for failure is an *anatomical* one. By this Dr. Rumbold referred to errors in locating the disease. Innumerable clinical observations and post-mortem examinations prove conclusively that rhinal inflammation invariably commences on the superior and middle turbinated processes and extends in all directions from the nasal passages into the passages connected with them.

Keeping in mind that every irritant produces inflammation, the indications for treatment of chronic rhinitis may be summarized as follows:

(*a*) The diseased secretion, which is always irritating, should be removed. Morbid growths, also being irritating, should invariably be removed.

(*b*) The new secretion, which is formed upon the cleansed surfaces, should not be allowed to become acrid.

(*c*) Hygienic and sanitary measures should be insisted upon.

DR. A. DE VILBISS, of Toledo, in opening the discussion, differed from Dr. Rumbold in that he did not believe properly tanned leather readily decomposes. Rancid oil for lubricating the air-pump is hardly ever used. Personally, he used vaseline and naphthol. With regard to vaseline, it was used as a protector to the mucous membrane on account of its density.

DR. O. F. MCGAHAN, of Chattanooga, heartily concurred in what Dr. Rumbold had said regarding vaseline. Where a protection of the surface is desired, nothing will take the place of vaseline. He sometimes uses iodine in weak solutions, and has so far observed no ill effects following its use.

DR. A. G. HOBBS, of Atlanta, uses the liquid vaseline. First, for cleansing purposes; and, second, for its convenience. He can warm it much more rapidly than the solid vaseline. The danger and greatest objection to the douche in cleansing the nasal passages, is its liability to set up a catarrh of the middle ear.

DR. JOHN NORTH, of Toledo, did not favor the use of tongue depressors, and believed that patients should be trained to manage their tongues without them. He uses the oil of vaseline for cleansing the nasal passages, with an alkali, eucalyptus, or some other antiseptic dissolved in it.

DR. C. L. DREESE, of Goshen, Indiana, read a paper on

REFLEX SYMPTOMS OF RHINAL DISEASES, WITH REPORTS OF CASES.

The first case was one of heart, stomach, and lung troubles, caused by sympathy from rhinal disease. The removal of the latter affection was followed by recovery from the former. The second was one where incontinence of urine, as a reflex symptom of chronic catarrh, was cured by treating the catarrhal trouble alone. In the third, epilepsy was a complication of rhinal disease.

AFTERNOON SESSION.

DR. C. H. MOORE, of Indianapolis, contributed a paper on

OCULAR REFLEX SYMPTOMS OF NASAL DISEASES.

He had relieved a case of neurotic affection of the Eustachian tube of the left ear, by spraying the nasal passages with vaseline. Hack mentions a number of cases of hemicrania and asthma cured by the galvano-caustic destruction of hypertrophied nasal mucous membrane. Voltolini demonstrated that asthma could be relieved in some cases by the removal of nasal polypi. A certain group of eye symptoms, as lachrymation, photophobia, conjunctival hyperæmia, are observed in a number of patients under the care of the rhinologist, when the examination of their eyes reveals no anomaly. The vision may be normal, no eye-strain present, the conjunctivæ healthy, the puncta lachrymalia normally situated, and the tear ducts open. For such cases a simple eye-wash may have been ordered, cold or warm applications recommended, and a general hygenic treatment pursued without any relief to patients, while treatment of the rhinal affection was generally followed by a cure.

In the cases reported the following symptoms were noted:

1. Burning and smarting sensation of the eyelids, especially in the morning.
2. Difficulty of distinguishing objects in daylight.
3. Increased vascularity of the conjunctiva and lachrymation on exposure to the air.

DR. N. R. GORDON, of Springfield, Illinois, said his rule of proceeding with such cases is to examine the eyes for the condition of refraction, which, if normal, and no other source of irritation can be found in the eye, he examines the mucous membrane of the nasal passages, where very often the cause is found.

DR. E. R. LEWIS, of Indianapolis, said there was no doubt that a number of such cases are being constantly referred to the rhinologist. About one-third of his cases were sent to him by oculists, but not until the eye-trouble had been corrected. This he believed to be the logical course to pursue in such cases.

DR. E. FLETCHER INGALS, of Chicago, related the case of a lady which illustrates the possibilities of eye-trouble being caused by nasal disease. She came to him with hypertrophic rhinitis. He proceeded to cauterize the turbinated bodies, and before she left the office she asked him if he could not do something for her eyes, stating that she was unable to use them more than five minutes at a time. He referred her to an oculist; on her return, two weeks later, she said she had not been to an oculist, but that the day after the nose had been cauterized she was able to read at night without difficulty.

DR. N. R. GORDON read a paper on

THERAPEUTIC MEASURES IN RHINOLOGY.

He said that after the surgical removal of hypertrophied tissue, a local treatment, continued at short intervals for one or two years, or even longer, is necessary. This should consist in the application of the oil of vaseline with a small amount of eucalyptol, or something of that character. Astringents do but little, if any good. Where the oil of vaseline fails, salt and water in proper propor-

tions with a small amount of Listerine or Dobell's solution are suitable remedies. To prevent mouth-breathing during sleep he recommends his patients to wear a little instrument made of celluloid that fits between the teeth and lips.

In atrophic catarrh, after the removal of all secretion on the surfaces, where the mucous membrane is very thin, or even ulcerated, he finds the application of a solution of resorcin, one drachm to the ounce, to be exceedingly beneficial. In the most unyielding and obstinate forms of nasal catarrh he uses a glycerine suppository composed of 95 per cent. glycerine, and 5 per cent. stearin. The solidified glycerine is placed so as to come in contact with the atrophied or ulcerated portion of membrane. The glycerine soon asserts its well-known affinity for water, and the result is an abundant flow of thin mucus.

Thursday, October 10th.—Morning Session.

Dr. C. H. Von Klein, of Dayton, Ohio, read a paper entitled

atrophy, hypertrophy, and deviations of the septum,

in which he said he had examined the nasal cavities in over 600 patients, and found not more than 2 per cent. with absolutely straight division of the nares. In almost every case he observed deformities of some sort, either atrophy, hypertrophy, or deviation.

The causes which most commonly cause deviation of the septum arise during babyhood. When children commence to creep and walk they frequently fall, and, nine times out of ten, on their nose. Personal observation leads Dr. Von Klein to believe that atrophy of the septum is confined to the cartilaginous portion. Hypertrophy, on the other hand, is confined to the osseous portion and these conditions are generally caused by such injuries as may occur to any other part of the bony system.

This paper was followed by one on

the treatment of chronic nasal catarrh,

by Dr. C. F. McGahan, of Chattanooga, in which the author said: Formerly this disease was treated principally with strong astringents. Where we have polypi the first thing to do is to remove them, either by the snare or the galvanic cautery. Where they are located in the anterior chamber, he prefers the cautery; but when they are in the posterior chamber of the nose, the snare. Acids he does not like in the treatment of hypertrophies, as it is impossible to control the amount of tissue which they destroy, and the pain is greater than that of the cautery. The excessive hypertrophy being reduced, we have simply a case of chronic catarrh to combat.

Having cleansed the nasal cavities thoroughly with Dobell's solution, or the combination with Listerine which is recommended by Lefferts, we are now ready to apply our medicaments. In moderate hypertrophy he generally uses a spray of vaseline with a combination of the iodides, or with iodine and carbolic acid, which should be used about three times a week. On account of the hydragogue effect of glycerine upon the tissues, it occurred to him some time ago that in hypertrophic conditions of the nasal cavity it might be useful by drawing water from the tissues and thereby reducing them in size. He had often seen it advised in combination with other drugs in the different sprays, but his way of using it was similar to that of the gynecologist. The cavity having been thoroughly cleansed, he applies to the hypertrophic membrane a tampon soaked in a solution of glycerine one part, water four parts, which he allows to remain from one to four hours. As the membrane becomes accustomed to the glycerine, he rapidly increases the strength until equal parts of it and water are used.

Afternoon Session.

Dr. A. De Vilbiss, of Toledo, contributed an interesting paper entitled

surgical treatment in diseases of the nose,

in which he said that he did not wish to be understood as holding that every case of nasal catarrh demands surgical interference, but that in every case that does demand operation a catarrhal condition of the nasal passages is usually found. He has relieved frontal headaches, mental depression, etc., by the removal of hypertrophic tissue from the middle turbinate. He believed the time was not far distant when the sphenoidal and frontal sinuses, posterior and anterior ethmoidal cells (after death) would be examined at autopsies. Schwable, Axel Key, and Retzius have demonstrated the fact that not only can the lymphatics of the nasal mucous membrane be injected from the subdural and subarachnoidal spaces, but if force be used the fluid will pass through the lymphatics to the surface of the nasal mucous membrane. Permanent nasal stenosis should be relieved by an operation, as it is due either to traumatism, hypertrophic tissue over turbinate bones, thickening of tissue or deflections of the nasal septum, gelatinous polypi, adenoma of vault of pharynx, fibromata, or sarcomatous tumors. Preparatory to operating he cleanses the nasal cavities, and after operation protects the cut surfaces by keeping them covered with iodized or carbolized albolene or vaseline. Hemorrhage he controls by cotton plugs. If the source of the hemorrhage is well back in the nasal cavities, he uses small cotton plugs tied with a string in the form of a kite-tail, which are easy to introduce and easy to remove.

A paper by Dr. E. L. Sessions, of Hillsboro, Texas, entitled

the administration of quinine where there is defective hearing,

was read by title in the absence of the author.

Friday, October 11th.—Morning Session.

At the solicitation of Dr. Seth S. Bishop, of Chicago, a committee to report annually was appointed by the President to coöperate with the United States Hay Fever Association, with reference to the investigation and treatment of hay fever.

Dr. R. S. Knode, of Omaha, contributed a paper on the

importance of constitutional treatment in rhino-pharyngeal inflammations,

in which he said the rhinologist often becomes discouraged with the means at his command when he finds

that patients do not improve, but if their history was carefully investigated there would be found some diathetical condition causing the nasal trouble, which, if relieved, would be followed by a subsidence of the local inflammation. This catarrhal condition frequently extends into the stomach and intestines, and from the duodenum to the ductus choledochus, when we have the combined symptoms of gastro-intestinal catarrh and jaundice.

The principal sympathetic phenomena caused by this condition are sick headache, depression, melancholy, sleeplessness, hypochondria, disturbed heart's action, lassitude, and irritable temper.

The treatment of such cases is the usual treatment for gastro-intestinal catarrh.

DR. E. L. SIVER, of Fort Wayne, Indiana, read a paper on

REFLEX INFLAMMATION OF THE NOSE AND THROAT.

The author reported a case of laryngitis with aphonia, which lasted two weeks, and, he thinks, arose from a deflected septum and posterior hypertrophy of the inferior turbinated bone.

DR. A. G. HOBBS, of Atlanta, read a paper on

CATARRHAL NEURALGIA,

by which he meant to include not only the headache and browaches that are caused by pressure of nasal hypertrophies or foreign bodies, but all reflex pains that have for their origin pressure in the nasal cavities, wherever located. He had no statistics bearing upon the comparative frequency of catarrhal and ocular neuralgias other than his own note-book of the last three years. In it he found fifty-four cases under the combined headings: *Catarrhal neuralgia, ocular headache, and catarrhal and ocular neuralgia combined;* thirty-six cases occur under the first caption, fourteen cases under the second, and four cases under the third.

After recognizing the etiology of a case exhibiting these reflex pains, temporary relief should be given the patient by the application of cocaine sprays, or in the case of complete stenosis, the cotton probe saturated with cocaine, followed by the spray. The effort then should be to reduce the pressure permanently by the most rapid means. If the pressure be due to a polypus, extract it; if to a deflected septum, remove the deflection; and if it be (as is most likely the case) due to an hypertrophy, reduce it with the galvano-cautery, the snare, glacial acetic acid, or chromic acid. He most frequently resorts to the latter. After the removal of the pressure, pain decreases to a great extent; if it does not entirely cease, when the more soothing treatment of vaseline sprays, in combination with cocaine, pinus canadensis, oil of terebene or oil of eucalyptus, daily or triweekly, will complete the resolution.

He knew of no class of cases that applied to the rhinologist for relief in which treatment gives more prompt and satisfactory results. Indeed, if the diagnosis is correct, the result is absolutely sure under proper treatment

DR. ELY MCCLELLAN, of Chicago, read a paper on the *Physiological and Therapeutic Action of Certain Drugs in the Treatment of Affections of the Upper Air-passages.*

OFFICERS FOR 1890.

President.—A. G. Hobbs, M.D., of Atlanta, Ga.

First Vice-President.—A. B. Thrasher, M.D., of Cincinnati, Ohio.

Second Vice-President.—E. R. Lewis, M.D., of Indianapolis, Ind.

Secretary and Treasurer.—R. S. Knode, M.D., of Omaha, Neb.

Librarian.—John North, M.D., of Toledo, Ohio.

Member of Council.—C. H. Von Klein, M.D., of Dayton, Ohio.

Place of next meeting, Louisville, Ky., in 1890, in conjunction with the Mississippi Valley Medical Association.

CORRESPONDENCE.

BALTIMORE.

(*From our Special Correspondent.*)

To the Editor of THE MEDICAL NEWS,

SIR: The period of summer stagnation is now past, and the currents of medical life are beginning to quicken once more. Many of our prominent physicians have taken the opportunity to run across to Europe, whence they send home enthusiastic accounts of the great clinics to which the ready courtesy of foreign professors has given them access. The opening of the training-school for nurses of the Johns Hopkins Hospital, on the 9th inst., was largely attended by the physicians and prominent citizens who were invited, and the ceremony, the neatness and intelligence of the nurses, the careful arrangements for the comfort and the training of the pupils, as well as the "afternoon tea," to which all were asked, formed the topic of much conversation after the return of the favored guests to their homes. It is to be hoped that the Baltimore public will prepare for the advent of these graduates by enlarging their ideas of nurses' wages, for, if not, the cities of the North will reap all the benefits of our training-school.

As to what a nurse is to do when she is chosen to serve under a doctor who is ignorant of modern advances in medical and surgical treatment, and who "doesn't see any use in disinfecting typhoid-fever stools," or who "never split a perineum in forty years' practice of obstetrics," is a hard matter to decide.

The Medical School of the Johns Hopkins University, the University itself, and the Hospital have all won such high esteem from our citizens that there is not the faintest doubt that, should the Baltimore and Ohio stock be entirely lost, Baltimoreans would in due time provide fully, either by donation or by legacy, for their establishment on a firm basis. Fortunately, the stock of this road is rapidly increasing in value, and before long all receipts may be expected to equal their original amount.

It is reported that the Medical School of the University of Maryland has terminated its contract with the Sisters of Mercy, and will engage trained nurses (not belonging to a religious order) in their stead.

The College of Physicians and Surgeons has appointed Dr. George Preston, a gentleman well known for his work in diseases of the nervous system, to lecture upon physiology during the coming winter. Dr. George Rohé, whose writings upon diseases of the skin and hygiene, and medical electricity are well known, has been chosen

to fill the Chair of Obstetrics in the same institution. Although he has written little upon this subject, it is expected that, with his experience based upon private obstetrical practice, he will make a name for himself in this as in other branches of medicine. Prof. Sewall is at present in ill-health, and has been compelled to delay his entrance upon his duties at the College.

DETROIT.

(*From our Special Correspondent.*)

To the Editor of THE MEDICAL NEWS, .

SIR: On the 7th inst. the Detroit Medical and Library Association held its thirteenth annual meeting, and the reports of the secretary and treasurer showed the Association to be in a most flourishing condition. It numbers one hundred and twenty-two active members on its roll, and is the leading medical society of the city, and I may say, from the amount of work accomplished, in the State.

An item of interest to the State of Michigan, more particularly to Ann Arbor and Detroit, was the election, by acclamation, of Dr. Donald Maclean, late Professor of Surgery in the University of Michigan, to the presidential chair of the Detroit Medical and Library Association for the coming year. It will be remembered that Dr. Maclean, who has been connected for the past nineteen years with the Medical Department of the University of Michigan, has done a very large amount of successful work, and brought the department to the high position it now holds, was compelled to resign from the Chair of Surgery on account of his persistent efforts to move the Clinical Department to Detroit, where it might enjoy a larger field, and more thoroughly fit the students for active practice; the Board of Regents deemed it best for the welfare of the University and the education of students to keep the clinic in the small town of Ann Arbor, and thought that Dr. Maclean's presence in the Faculty was a disturbing element.

In addition to the above, and as an evidence of the entire approbation of the movement to establish the Clinical Department of the University in Detroit, Dr. J. E Frothingham, Dr. Maclean's colleague in the movement, was elected by unanimous vote to the presidency of the State Medical Society, at its meeting held in Kalamazoo last May.

The Association of Baggagemen, which recently met in this city, passed resolutions insisting that all bodies of persons dead from contagious diseases, held for transportation, must be properly prepared for shipment by being wrapped in sheets saturated with mercuric chloride and placed in metallic caskets, to prevent the spread of disease.

The Michigan State Board of Health, at Lansing, has recommended that typhoid fever be classed with diphtheria, scarlet fever, and similar affections, and that it be reported in a similar manner to the health officer of the city or town in which it occurs; furthermore, it recommended the adoption of a system of placarding houses where such cases exist. The suggestion is at present under the consideration of the Detroit Board of Health, and Dr. William Brodie, its president, has issued invitations to the physicians of the city to meet and consider the advisability of adopting the measure.

An epidemic of dysentery has been prevailing at Stockbridge, Michigan, for some time past, which presents the disease in a typical form.

NEWS ITEMS.

The Southern Surgical and Gynecological Association.—The annual meeting of the Southern Surgical and Gynecological Association will be held at Nashville, Tennessee, on the 12th, 13th, and 14th of November, under the presidency of Dr. Hunter McGuire, of Richmond, Virginia. The programme promises to be a most interesting one. In all, thirty-eight papers will be presented, among which are the following: Direct Herniotomy; Abortive Treatment of Acute Pelvic Inflammation; Relation of the Nervous System to Reparative Surgery; Cranial Surgery; Treatment of Ectopic Pregnancy; Laparotomy in Extra-uterine Pregnancy; Experimental Study of Intestinal Anastomosis; Operative Interference in Ascites; Puerperal Convulsions; Coccygodynia; Improved Cæsarean Section *versus* Craniotomy; Tropho-neurosis as a Factor in the Phenomena of Syphilis; Gynecology in its Relation to Obstetrics; Triple Amputations; Treatment of Contracted Bladder by Hot-water Dilatation; The Achievements of Modern Surgery; Pus in the Pelvis, and how to deal with it, etc.

Among the members of the profession intending to read papers are the following: Drs. R. B. Maury, of Richmond, Va.; Wm. C. Dabney, of the University of Virginia; D. W. Yandell, of Louisville, Ky.; C. Kollock, of Cheraw, S. C.; G. Frank Lydston, of Chicago, Ill.; Joseph Taber Johnson, of Washington, D. C.; A. Lapthorn Smith, of Montreal, Canada; J. Ewing Mears, of Philadelphia; Joseph Price, of Philadelphia, and others.

Trouble over the Presidency of a Medical Staff.—The Bushwick Dispensary in Brooklyn is just at present involved in a litigation because of a quarrel between two rival factions in the medical board. As these two parties have both elected presidents, each of whom claims that he has been legally appointed, one of them, Dr. Sizer, has applied to the Supreme Court for a mandamus obliging the board of trustees to recognize him as the legally elected officer.

Smallpox in Kings County, New York.—During the last twenty-five years it is estimated that there have been 4800 cases of variola in Kings County, New York, with 1200 deaths; while of varioloid there have been 1500 cases with only 2 deaths.

Cincinnati Hospital.—The successful candidates in the competitive examination for the position of residents to the Cincinnati Hospital were Messrs. Minor Morris, John H. Sandis, M. B. Brady, Lincoln Mussey, A. H. Freiburg, and H. W. Bettmann, students of the Medical College of Ohio, and Mr. Arch. I. Carson, of the Miami Medical College.

Medical College of Ohio.—This institution opened with a much larger attendance than for several years. No preliminary course of lectures is now given; but for three weeks preceding the opening of the regular session, more than eighty students were engaged in practical work in the chemical, histological, pathological, and bacteriological laboratories.

Leprosy in the Sandwich Islands.—The leper colony of the Sandwich Islands now contains less than 100 inmates, the majority being males. The number is on the decrease. The Hawaiian Government devotes $100,000 annually toward the maintenance of the colony. According to Dr. Hoffman, the resident physician, the duration of the disease is about eleven years. Dr. Hoffman is himself a victim of leprosy.

A New Illinois Medical Register.—Dr. Rauch, Secretary of the Illinois State Board of Health, announces that a new medical directory for his State will soon be published. There has been no revised edition of this useful publication since 1886, the Secretary's hands having been tied by unfriendly legislators and a want of the necessary funds.

Warner's "Safe Cure".—The *New York Medical Journal* of October 19, 1889, states that the police of Vienna have seized the entire stock of "Warner's Safe Cure," held by the pharmacists of that city. This was done not so much because of the character of the compound as because of the charlatanic advertisements which accompanied the nostrum. The agents for its sale had complied with the Austrian law, which directs that the formula of its composition shall be made known in regard to every proprietary medicine before it can be put on sale in the pharmacies. The *Pharmaceutische Post* is quoted as saying that the fault really lay in the quackish pretensions that were published in relation to the compound. Very severe rulings and examples have recently been made against certain preparations on that account.

Dr. James Downie, a young Scotchman who has been imprisoned on the charge of homicide, in Brooklyn, N. Y., has been set at liberty, the Grand Jury having found the testimony against him entirely inadequate to justify his detention. He will probably return to Glasgow, where he formerly practised.

A Biological Endowment.—Dr. Daniel Ayres, of Brooklyn, last week, made known his intention to give to the Wesleyan College eighty-six acres in New Jersey, worth over $20,000; this is an additional endowment of the Department of Biology, to which he gave $25,000 last April. Dr. Ayres feels called upon to befriend the cause of biology for the reason that in our colleges this important branch is about the last to be remembered when endowments are being dispensed.

Dr. W. Remsen Taylor, the Heath Officer of Long Island City, has been charged with receiving extortion money, for permitting certain acts on the part of contractors engaged in filling sunken lots. The persons who paid the money are not indicted, but the alleged receiver of it is. Dr. Taylor, in his own defence, avers that the funds paid him were used for the disinfection of the materials brought to the town, and for other proper sanitary purposes.

Typhoid Fever at Yale College.—Two deaths from fever alleged to be typhoid occurred last week among the collegians at Yale, and six cases of sickness of like nature have been reported among the students. Dr. Seaver, the medical consultant to the University, has expressed doubt as to whether it is enteric fever in all the cases, and no common cause for them can be made out.

Philadelphia Polyclinic.—At a meeting of the Board of Trustees of the Philadelphia Polyclinic held October 21, 1889, Dr. R. J. Levis was elected Emeritus Professor of Surgery; Dr. Charles B. Nancrede, Emeritus Professor of Orthopædic Surgery; Dr. Charles H. Burnett, Emeritus Professor of Otology; and Dr. J. Solis-Cohen, Emeritus Professor of Laryngology. Dr. T. G. Morton was elected to the Chair of Orthopædic Surgery, Dr. T. J. Mays to that of Experimental Therapeutics and Physiology.

The Chair of Clinical Surgery was filled by the election of Thomas S. K. Morton, M.D. Professor C. L. Bower, M.D., was elected Adjunct Professor of Clinical and Operative Surgery.

A plan for the progressive endowment of free beds, supplementing the present arrangement, was adopted whereby a person can, by the payment of $500, endow a free bed for one month in every year in perpetuity. By this arrangement one month may be added at a time until a bed becomes free all the time in perpetuity. The report of the Building Committee was read, in which it was stated that contracts had been signed for preliminary work to the amount of $25,150. About $30,000 will be required to finish the building, and it was decided to push the building to completion as fast as donations for the purpose could be obtained.

The laying of the corner-stone of the new Polyclinic building, on Lombard Street, west of Eighteenth, will take place on the afternoon of November 2d, at 3.30 o'clock. Mr. Clifford P. McCalla, Grand Master of the Masons of the State of Pennsylvania, will officiate at the Masonic ceremonies, and Dr. R. J. Levis's testimonial free bed fund will be presented by Mr. C. B. Baeder, Chairman of the Committee having in charge the raising of this $5000 fund. Judge William N. Ashman, of the Orphans' Court, will accept the custody of this fund on behalf of the trustees. Hon. Henry K. Boyer will deliver the address of welcome, and Professor John B. Roberts, the originator of the Institution, will read a retrospect. The ceremonies will last about an hour.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING OCTOBER 17, 1889.

BERTOLETTE, D. W., *Surgeon.*—Detached from the "Franklin," and ordered to duty at the Naval Hospital, Philadelphia.

RUSH, N. H., *Passed Assistant Surgeon.*—Detached from the Naval Hospital, Philadelphia, and ordered to the "Saratoga."

HIBBETT, C. T., *Passed Assistant Surgeon.*—Ordered to the "Franklin."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM OCTOBER 5 TO OCTOBER 19, 1889.

VANSANT, JOHN, *Surgeon.*—Granted leave of absence for fifteen days, October 16, 1889.

GOLDSBOROUGH, C. B., *Surgeon.*—Leave of absence extended thirty days, on surgeon's certificate of disability, October 18, 1889.

PERRY, T. B., *Assistant Surgeon.*—Ordered to temporary duty at San Francisco, California, October 15, 1889.

VAUGHAN, G. F., *Assistant Surgeon.*—When relieved, to proceed to Evansville, Indiana, for temporary duty, October 9, 1889.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LV. SATURDAY, NOVEMBER 2, 1889. No. 18.

ORIGINAL ARTICLES.

THE USE OF ASCENDING DOSES OF NUX VOMICA, AS AN AID IN THE TREATMENT OF INSUFFICIENCIES OF THE OCULAR MUSCLES.

BY G. E. DE SCHWEINITZ, M.D.,

OPHTHALMIC SURGEON TO THE PHILADELPHIA AND TO THE CHILDREN'S HOSPITALS; OPHTHALMOLOGIST TO THE INFIRMARY FOR NERVOUS DISEASES.

IN recent years unusual care has been bestowed upon the study of the ocular muscles, and their relation to the production of headache, asthenopia, and reflex nervous disturbances has afforded the subject of many researches. The older tests for the detection of muscular troubles have been believed to be imperfect, and we have for use the ophthalmodynamometer of Landolt, the useful modification of this instrument by Alleman, the phorometer of Stevens, the method of Holden, the obtuse-angled prism of Maddox advocated by Randall, and the ingenious adaptation of Crêtes's revolving prism by Risley for measurement of the degree of discovered deviation. After lack of equilibrium in the ocular muscles has been demonstrated by any or all of these means, the important problem for solution consists in the proper method for the restoration of the disturbed balance.

Here, again, we have a variety of measures at hand, depending upon the degree and character of the defect—decentration of the correcting lenses, the use of prisms, tenotomy, combined or uncombined with advancement, and the method of "graduated" or "partial tenotomies" revived and advocated by Stevens, Ranney, Webster, Standish, and other surgeons. Perfectly aware of the fact that where high degrees of insufficiencies, especially of insufficiency of convergence, exist, surgical treatment is the only one which is efficacious, and also fully alive to the fact that, especially owing to the work of American colleagues, the correction of minor degrees of heterophoria by means of partial tenotomies has become more and more a satisfactory operative procedure, there are none the less a class of cases in which operation is either impossible, from lack of consent, or inadmissible owing to complicating circumstances. It is, perhaps, only necessary to refer to the instances of so-called neurasthenic asthenopia associated with great reduction in the amplitude of convergence, cases in which Landolt has so well shown that surgical treatment, without perhaps being entirely excluded, must be associated with general invigorating methods. It is in those cases, then, of muscular troubles in which an operation cannot be performed, or, having been performed, has proved insufficient, and in which the use of correcting lenses combined with prisms has failed to relieve the symptoms, that I wish to call attention to the relief that is afforded by the use of ascending doses of nux vomica.

Ophthalmic surgeons have long been accustomed to employ nux vomica or strychnia in the treatment of various forms of ocular disturbance. Since Nagel, in 1871, called attention to the value of strychnia in the treatment of nerve atrophy, it has been largely employed with varying degrees of success in the treatment of atrophy of the optic nerve. Nux vomica has been much used in forms of functional disturbance of the retina, associated with a lack of general bodily tone, in which at once a bitter tonic and stimulant to the trophic centres and a vaso-motor excitant were indicated. Naturally, weakness of the external eye muscles has called for its use, exactly as lack of tone in the general muscular system has always been one of its most important indications. It is not the purpose, therefore, of the cases which follow to show any new use for the drug, but only to describe a method of administration which has proved successful in my hands.

CASE I.—Private patient, female, æt. twenty-one. Painful eyes; supra-orbital neuralgia; violent frontal and occipital headache; general health good; no lesion of the fundus; refraction error a compound hypermetropic astigmatism; insufficiency of the internal recti of seventeen degrees in the act of accommodation, and five degrees at five metres. Correction of the refraction error afforded partial relief, but the headaches returned when any close application with the eyes was practised. Ascending doses of the tincture of nux vomica were begun as follows: Ten drops three times a day, to be increased on succeeding days by one drop at each dose until some physiological action of the drug was manifest.

When the dose had reached twenty-five drops three times a day, eye-tire had greatly lessened. At thirty-five drops three times a day the headaches had ceased, although the occupation of the patient was that of a school-teacher. The remedy was pushed until forty drops were taken three times a day, then gradually decreased to twenty-five drops, and finally discontinued, with the direction to renew the remedy should headaches reappear under the stress of work. The amount of insufficiency varied; the lowest that it reached was ten degrees. Prisms were never used.

CASE II.—Private patient, male, æt. twenty-two. Exceedingly nervous, and the subject of occasional attacks of hepatic congestion; marked asthenopia; pain in the eyeball; frontal and occipital headache; in the fundus of each eye slight retinal haze, otherwise no changes; myopia of one dioptry; insufficiency of the internal recti of eighteen degrees in accommodation and eleven degrees at twenty feet. Adduction three degrees; abduction eleven degrees. Nux vomica, in the method already described, was employed, and under its influence a severe winter of work was successfully undertaken, during which the patient was practically free from headaches, using at the same time three-degree prisms with their bases toward the nose. The prisms alone failed to give relief, but the prisms with the nux vomica were successful.

CASE III.—Private patient, female, æt. nineteen. In good general health, but somewhat mentally depressed owing to domestic troubles; blurred vision during reading; eyes easily tired; severe frontal headache aggravated by all near work. The refraction a simple hypermetropia; insufficiency of the external recti of eight degrees. Correction of the refraction error produced almost entire relief for a number of months, then the headaches returned and were stubbornly present for a long time. Under the use of nux vomica they speedily improved. The maximum dose was thirty-five drops three times a day. The insufficiency through the correcting lenses became as low as three degrees.

CASE IV.—Private patient, female, æt. thirty-four. In poor general health; of gouty ancestry; had recently recovered or partially recovered from pelvic peritonitis; was the subject of the most atrocious occipital headaches occasioned by any use of the eyes. The refraction a compound hypermetropic astigmatism. Insufficiency of the internal recti of twelve degrees. The use of the correcting lenses, together with prisms, afforded some relief, but eye-work instantly brought on the headache. During a period when it became absolutely necessary for the patient to use her eyes at sewing and similar work, ascending doses of nux vomica, while they failed to give the relief recorded in the previous cases, lent sufficient aid to enable the work to be performed. During a similar necessary period of eye-work on another occasion, without the use of nux vomica, the patient had a complete eye-breakdown.

CASE V.—Private patient, male, æt. thirty. In good general health; occasional attacks of blurred vision; some asthenopia, and now and then severe orbital neuralgia. Refraction error a simple astigmatism. Insufficiency of the internal recti from eight to ten degrees. During certain seasons of the year this patient is obliged to perform much night-work, during which time the supra-orbital neuralgia has usually been much aggravated in spite of the use of prisms. Ascending doses of nux vomica have never failed to give marked relief, so much so that it is with difficulty that he is persuaded during the administration of the drug to make use of any optical therapeutics. The maximum dose has on a number of occasions been fifty drops. The usual dose is thirty-five drops.

CASE VI.—Private patient, female, æt. twenty-three. A slender woman in delicate health, a school-teacher by profession; aggravated asthenopia; occipital headache; occasional attacks of migraine. Refraction error a compound hypermetropic astigmatism; no disease of the fundus; slight haze of the retinas. Insufficiency of the internal recti of ten degrees. The usual treatment with nux vomica has been productive of much relief, enabling the patient to perform long periods of eye-work with comparative comfort. The maximum dose was twenty-five drops; beyond this point there was production of disturbance of the alimentary canal and wakefulness at night. Although the comfort of the patient was increased by the use of the drug, no lessening in the amount of the insufficiency was observed, nor was the relief from headache perfect.

CASE VII.—Private patient, female, æt. forty. A florid woman, but with flabby muscles; easily tired; much headache; eye-pain and inability to perform any lengthy work requiring tension on the accommodation. The refraction a simple hypermetropia of one dioptry. No disease of the fundus except a slight patch of old choroiditis in the nasal half of the left retina. Insufficiency of the internal recti of eight degrees. Ascending doses of nux vomica, the maximum dose being twenty-five drops, beyond which amount the drug produced great restlessness and some nausea, greatly increased the eye-comfort and improved a very troublesome symptom, namely, an appearance as if the lines on a printed page were broken.

CASE VIII.—Private patient, female, æt. nineteen. Of large frame and fine proportions, but intensely nervous, at times hysterical, and subject to intervals of great mental depression; much headache, chiefly in the morning and usually in the occiput, sometimes above the brow. Inability to read for more than a few minutes at a time without great aggravation of the symptoms just detailed. Refraction error a slight compound hypermetropic astigmatism. Insufficiency of the external recti of six degrees; the fundus of each eye reasonably healthy. Her symptoms were practically unrelieved by the use of correcting lenses and prisms. All manner of general treatment was tried with but indifferent success. Finally the use of nux vomica, in ascending doses, was followed by surprising improvement. No lessening in the degree of the insufficiency was detected, but the relief to the eyes was evident and gratifying. The maximum dose was forty drops, without the development of any unpleasant symptoms.

These eight examples will suffice to show the class of cases in which this remedy thus applied has proved useful. I could quote many others with similar results. I could also quote instances which, under apparently exactly similar circumstances, have not been benefited by the drug. The method of using nux vomica in this manner was suggested to me by the paper of Dr. John H. Musser.[1] In his experiments,

[1] Therapeutic Gazette, vol. ii., 1886, p. 9.

in which he desired to demonstrate the influence of age on the dosage of nux vomica, he came to the conclusion that the effect of the drug was in inverse proportion to the age of the patient; the susceptibility increased with the age. The manner in which Musser administered the drug was to give ten drops three times a day, and increase three to five drops every second day until some physiological effect was produced. That very full amounts of the remedy can be safely employed in this way is attested by the fact that one of his patients took 200 drops three times a day, and between the ages of fifteen and forty forty-five drops were well borne. It may with perfect reason be asked, What is the use of giving large doses of an exceedingly bitter tincture, when the equivalent amount of its active principle could be gained by the administration of a small granule of strychnia, five minims of a good tincture being equal to $\frac{1}{200}$ grain of strychnia? I have often employed strychnia in precisely similar cases, and it has not seemed to me that the same satisfactory results were obtained. The nux vomica in this class of cases, in the form of the tincture, seems to act somewhat analogously to the use of Fowler's solution in ascending doses in chorea and anæmia. At all events, the clinical fact remains that under this method of administration, distinct improvement in asthenopia and headache occasioned by ocular insufficiency, especially in neurasthenic cases, is distinctly manifest, precisely as it improves the general tone of the muscular system, aids digestion, and corrects the action of the alimentary canal. One very curious fact which I have observed, is that it never seems to do good if the insufficiency exists in the vertical muscles. As an example of this I may quote the following case:

Private patient, female, æt. twenty-nine. A highly nervous woman, a school-teacher by profession; the subject of menstrual disorders and atonic dyspepsia. The two latter difficulties were greatly improved after a course of regulated diet, tonics, and dilatation of the cervix of an anteverted uterus. She was the subject of the most aggravated asthenopia. All manner of glasses had been prescribed without avail. Occipital headache was constant; reading, sewing, and similar occupations had become impossible. The refraction was a low compound hypermetropic astigmatism. There was an insufficiency of the superior recti of three degrees—right hyperphoria of Stevens's classification. Decentration of the lenses, and prisms were productive of no benefit (operation was declined). The persistent use of nux vomica signally failed to give relief.

This is not a single example on which I base my opinion that the use of this drug will not be found to be of value in the treatment of the various forms of hyperphoria. I have tried it in a number of cases, and it never had one particle of effect, unless, perhaps, the good of a bitter tonic upon the stomach.

Another point of interest in the administration of nux vomica and of strychnia, for this and for similar purposes in disturbances of the eyes, is the condition of the retina. It is a well-known fact that irritations of the nerves contraindicate the use of full doses of nux vomica or its alkaloid. It is a therapeutic law which must not be broken, that this drug should not be administered in paralyses from cerebral hemorrhage until all irritation produced by the clot has passed away. On precisely the same principle, nux vomica and strychnia are contraindicated in ocular insufficiencies associated with headaches, if at the same time there is much retinal irritability, characterized by dread of light, manifest haze and thickening of the fibre layer, and the presence of numerous lymph reflexes throughout the eye-ground. I have more than once not only not seen the drug relieve the patient, but distinctly aggravate the headache. This was beautifully illustrated by the following case:

Private patient, female, æt. ten; very anæmic; of rapid growth; much headache, worse during school hours. The refraction was a simple hypermetropia. There was a slight insufficiency of the internal recti, and marked retinal irritation sufficient to produce decided photophobia. This somewhat subsided under the prolonged use of atropine and afterward of the correcting lenses, but still remained, and the headaches failed to disappear. The child had long been taking a tonic from her family physician. Upon investigation this was found to contain very full doses of strychnia, the exact amount of which I am unable to state. When this was discontinued and simply iron substituted, the headaches rapidly disappeared, and, so far as I am aware, they have never returned.

This is not a mere coincidence, for I have over and over again tried the experiment in patients who had markedly irritable retinas, and have always succeeded, when I pushed nux vomica, in aggravating their pain.[1]

In conclusion, I would say that in those cases of ocular insufficiencies affecting the lateral muscles, where surgical interference is either impossible or contraindicated, where the use of correcting lenses and prisms has not been sufficient, and where the retina is quiet and dread of light is absent, ascending doses of a good tincture of nux vomica

[1] I have heard my colleague, Dr. B. Alexander Randall, bring out this point with much force in a discussion in the Neurological Society some years ago, during the presentation of the subject of Tobacco Amblyopia, contrasting the remarkable facts that on the one hand irritations of the optic nerve and retina were usually aggravated by the use of strychnia, while on the other, when tobacco was the poison which had produced an axial neuritis, this was speedily and often remarkably relieved by the administration of the drug.

will afford, in most cases, marked relief. If the method be tried, the drug must, however, be pushed up to its full physiological effect, and, according to the experiments of Musser, between the ages of fifteen and forty, a dose of forty-five drops will readily be borne. In fact, very much larger doses, if watched, may be administered without hesitation.

A PORRO-CÆSAREAN SECTION,

Rendered Necessary by a Deformed Pelvis, and a Uterus Enormously Enlarged by Fibroid Growths; Together with a Cyst of the Right Broad Ligament.

BY JOHN J. BLACK, M.D.,
OF NEW CASTLE, DELAWARE.

IN April, 1889, Dr. Benjamin B. Peters, of Christiana, New Castle Co., Delaware, sent Sarah T——, colored, aged twenty-seven years, to me, requesting that I should examine her, and give my opinion as to the condition present, at the same time informing me that he was sure she had had for some time an abnormal growth in the abdomen, and in addition that he thought at the present time she was very likely pregnant. Sarah was mentally a bright woman of her class, and full of vim and pluck, unmarried, and apparently much distressed over her fears of becoming a mother, although she said, "She knew she had had a lump in her stomach for several years." She was a markedly deformed woman, very short in stature, with the peculiarly developed head of a dwarf, very long arms, a fairly developed body down to the pelvis, but from thence down much distorted and out of shape. Her thighs and legs were very much bowed, very short naturally, and there was very little motion in the right hip-joint; not from its being defective, but from distortion about the upper part and neck of the femur. The case was one in every respect typical of rickets. She had a brother even more deformed than herself, and two sisters more or less deformed, one of whom, Dr. F. L. Springer, of Christiana, informed me he had delivered, several years previously, after craniotomy.

The father and mother were both large, and, physically, fine specimens of their race, and no suspicion of deformities could be traced in their ancestors. An examination of Sarah showed a considerable abdominal enlargement, somewhat larger to the right of the median line and having a somewhat nodulated feeling lower down to the left. Palpation over the prominence showed the presence of fluid. Vaginal examination told me little, as I could not reach the os uteri, and it at once became evident that I had a seriously deformed pelvis to deal with. I could not hear the fœtal heart, and she had felt no motion, but acknowledged it was possible she might be pregnant, as she had not menstruated since the preceding November.

From rational and clinical signs I believed there was abnormal growth or growths in the abdomen, and agreed with Dr. Peters in his suspicions of pregnancy. Shortly after her visit to me I made an appointment with Dr. Peters, and examined her critically as to the condition of her pelvis, at her home, with a view to the treatment of her condition. I soon found out the extreme nature of the deformity, and the utter impossibility of delivering her of a living child by inducing premature labor, at the viable period, or even by craniotomy—the space was so contracted. Dr. Peters and I could only introduce two fingers through the inferior strait, and could make no satisfactory examination of the os. My hand is small, but I could by no means force it into the vagina.

The right limb could not be sufficiently moved to give good working space to the outlet of the pelvis. The arch of the pubes was very narrow, scarcely admitting two fingers, the symphysis was depressed, and the promontory of the sacrum was encountered when the fingers were introduced, giving at first the sensation of the presence of a child's head. I doubt if there was more than one inch in the antero-posterior diameter.

From the condition of the uterus, enlarged as it was by the fibroid masses, it was impossible for a fœtal head to engage in the superior strait.

The condition of affairs was stated to the patient and to her mother, and they agreed to let us do all we could to save her and her child. We could propose nothing short of a gastro-hysterotomy.

Monday, August 19, 1889, I was summoned to the case by Dr. Peters. I found the woman in labor, and, unfortunately, before I could get to her residence, the waters had come away, thus probably rendering the extraction of the child from the uterus a little more difficult. The woman was in fair condition and good health, as far as her kidneys and other organs were concerned. After consultation with Dr. Peters, Dr. Francis L. Springer, of Christiana, and Dr. R. R. Tybout, of New Castle, we decided to perform the Cæsarean operation and treat, as we went on, any complications that might arise. The fœtal heart could be heard and a left vertex presentation made out, externally.

Dr. Peters kindly took charge of the anæsthetic—chloroform—while Drs. Tybout and Springer gave me direct assistance. Antiseptic precautions were used in every detail, from the beginning to the end of the case. After putting the abdominal surface in proper condition, I at once made an incision from the navel to near the pubes, incising the parts as they appeared, and on opening the abdomen a cyst at once came into view. With a towel (antiseptic) around the wound, the cyst was evacuated of a straw-colored fluid. The uterus now came into view—a large, interstitial fibroid mass extending from above the centre down the left wall to the neck. Over the surface were also numerous fibroid nodules. A large fibroid mass was felt behind, along with several smaller nodes. The very serious nature of the case now became apparent. I prolonged the abdominal incision above the navel to the left, and then at once opened the uterus through the fibroid masses. The hemorrhage was terrific, but we kept the blood from entering the abdominal cavity as much as possible by towels held by Drs. Springer and Tybout. After the incision into the uterus was sufficiently large, I introduced my hand, and felt first the child's

head, but the waters having been evacuated the walls of the uterus tightly clasped it. I seized first one foot and handed it to Dr. Springer, then I seized the other foot and gave it to Dr. Tybout, and they at once dexterously delivered a large, male child. The cord was wound tightly around the neck three times, and the child was in a condition of asphyxia. It was given in charge of Dr. Tybout, who, by skilful manipulation, soon had it restored and crying lustily. In the meantime Dr. Springer had grasped the uterus around the neck and checked the hemorrhage. I at once delivered the placenta and turned the uterus completely out of the abdomen, and constricted it at the neck by a piece of rubber tubing, thus controlling all bleeding. The woman was in good condition, and had the uterus been normal, by Sänger's method I believe we could have saved both mother and child without trouble. The mass could not, however, be sewed up and returned into the abdomen; the patient would never have rallied, and the hemorrhage could not have been controlled; the only thing was to separate the mass and extirpate it.

The remains of the cyst were found about the right broad ligament, and there was a small cyst of the same kind, the size of a hen's egg, about the parovarium on the left side. We ligated with silk, and separated the round and broad ligament and attachments on either side, and cut the ligatures short, carefully lifting the bladder from the uterus (the first having been emptied by a catheter before the operation) and applied the serre-nœud, expecting at least to constrict the neck sufficiently to check hemorrhage and allow us to take away the rubber tube, and then treat the pedicle in the lower angle of the wound. I soon found to my sorrow that the screw-threads slipped, and the wire would not hold sufficiently even as a constrictor, and as I was utterly without resource as to other instruments, there was nothing left to do but to ligate the part, which we did—fortunately finding a strong hemp cord in the house. After ligation I removed the whole organ, tumors and all.

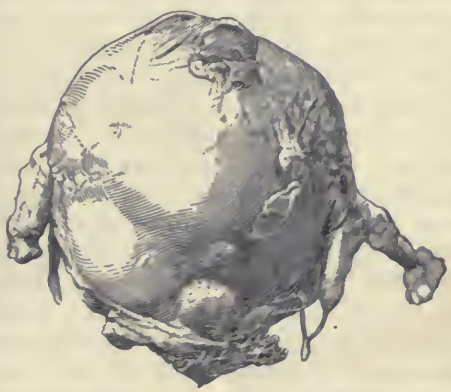
There was no hemorrhage or further trouble. The child and the ablated mass weighed eight pounds. The abdomen was closed by catgut in the usual manner, after having been cleansed and sponged thoroughly dry. The ligature was brought out the dependent angle of the wound, and antiseptic dressings and bandages were applied. The woman was now quite weak. A syringeful of fluid extract of ergot and a number of syringefuls of whiskey were injected into the outer parts of the thighs, and she was put to bed, with warm blankets, etc., around her. The child was now in a very satisfactory condition, just as much so as though he had been born by an easy birth *per vias naturales*. We then and there named him Cæsar Trippet.

We found, on examining the pelvis, that the deformity was fully as much as had been expected, and its condition and that of the uterus would have probably demanded delivery by other than the natural way at any period of the pregnancy. If the uterus could have contracted sufficiently to expel the child, I doubt if it could have so contracted as to prevent the mother dying from post-partum hemorrhage.

As to the time of election for the operation, the old mother was superstitious and very peculiar, and the only election we had was to await the coming on of the symptoms of labor. Up to this point we had done all we could for this unfortunate patient, and now we were compelled to leave her without the care of any one skilled in nursing or attention to the sick. The only intelligent care she did receive was what her physicians were able to give her in a house destitute not only of the luxuries but even of the necessaries of life.

The bladder was relieved regularly by Dr. Tybout, and the contents, when evacuated, showed this viscus to be intact. Her diet was chiefly milk, with stimulants as required, and opium to control the bowels and any irritation that might arise. The next morning she was lively and joking, and remarked to me that it was the "fust time" she had seen her feet over her belly for a very long time.

Her pulse was 95, and her temperature 100°. She had not vomited or complained of nausea; had some appetite, and no abnormal thirst, and her countenance was not serious. In the afternoon of this day her pulse and temperature began to go up, and Dr. Tybout removed the dressings and examined the wound and the adjacent parts. All were in good condition. There was no very marked tympanites. Soon after this, irritability of the stomach came on, which increased until the time of her death, at 9 P.M. of the third day after the operation, from exhaustion.



Posterior view of uterus showing fibroids.

I have found no such case as this on record; here is not only a Cæsarean section, but a Porro-Cæsarean section, complicated by the existence of an ovarian cyst, or rather a cyst of the broad ligament, from either one of which a fatal result might follow. The only case I can find on record approaching it is that in which Dr. Horatio R. Storer, in 1869, performed the Cæsarean section to remove a dead fœtus—a fibro-cystic tumor filling the pelvis. After incising the uterus, the hemorrhage was so alarming that he ligated the cervix, and removed the uterus with the écraseur. The patient died.

Dr. Emmet says, in his *Principles and Practice of Gynecology*, edition of 1884, p. 579 *et seq.*: "To remove the uterus when enormously enlarged from a

fibroid growth is unquestionably one of the most formidable operations a surgeon can be called upon to undertake. The degree of success which has so far attended the operation offers but little encouragement for the future. Seeing the results of the operation in this country, no surgeon is justified in attempting to remove the uterus for the growth of a fibrous tumor, except as a forlorn hope." Such being the opinion of one whose authority is so unquestioned, how much more of a forlorn hope was the case I have reported!

NEW CASTLE, DEL., September, 1889.

Dr. Robert P. Harris, of Philadelphia, has kindly added the following remarks: "This operation of Dr. Black deserves a special notice, from the fact that it was the first Cæsarean section ever performed in the State of Delaware. That death should have followed it is not to be wondered at, when we consider that the subject was a rachitic dwarf, with a collapsed pelvis; and that her case was rendered far more serious by reason of the abnormal state of her uterine tissues. Women with uterine fibroids have been saved under the old Cæsarean, Porro-Cæsarean, and new Cæsarean sections, it is true; but the proportion has been very small, compared with that of the cases in which the uterine tissues have been free from disease. The Porro method can rarely be employed with advantage in cases of obstruction by uterine fibroids, because of the fact that the cervix is generally involved in the disease itself; and in the new Cæsarean the degeneration of tissue to be sutured is a serious obstacle to a satisfactory closure and an early union. Two Sänger and two Porro cases in Philadelphia, all fatal, attest the risk to life in operating on parturient women with obstruction by fibroids. There have now been performed, in all countries, 269 Porro-Cæsarean operations, with 122 deaths; the record of our own country is 11 cases, with 8 deaths—a higher mortality than any European country, except Scotland, which has lost 4 out 5; Austria has saved 43 out of 61. Germany has lost only 13 out of her first 98 Sänger cases."

A CASE OF CHRONIC PURULENT DISCHARGE FROM THE EAR, WITH DEAFNESS, CURED BY EXCISION OF THE MEMBRANA TYMPANI AND MALLEUS.

BY CHARLES H. BURNETT, M.D.,
AURAL SURGEON TO THE PRESBYTERIAN HOSPITAL, CONSULTING AURIST TO THE PENNSYLVANIA INSTITUTE FOR THE DEAF AND DUMB, LECTURER ON OTOLOGY IN THE WOMAN'S MEDICAL COLLEGE, PHILADELPHIA.

IN a paper on "Purulent Inflammation of the Tympanic Attic," read at a special meeting of the American Otological Society, held in Washington, September 18, 1888,[1] in speaking of the treatment of this disease of the ear, I said, in referring to the comparative uselessness of all means of treatment heretofore used in this disease, and of the encouraging results promised by excision of the membrana, "although I have not yet performed such an operation for the *relief of this disease*, I feel sure that hereafter I can obtain a radical cure most surely by this means—and perhaps not at all by any other—and I am prepared thus to inform my patients, as this form of purulency of the middle ear, from its proximity to the brain, is the most threatening to life, and demands a careful consideration of every means for its radical cure."

Case XX., alluded to in the aforesaid paper as then under treatment, remained under treatment a year without being cured, and forms the subject of the present paper. The notes of the case are as follows:

July 14, 1888. Miss M., aged twenty-three years, states that in her childhood her tonsils were enlarged: excision of these was soon followed by some earache and dulness of hearing in both ears; but these symptoms soon passed off and were forgotten, excepting that, she thinks, the right ear, the now suppurating one, has never heard sharply. Six years previous to the time of her first consulting me, suddenly, without any pain or warning of any kind, the right ear felt stopped. Examination by her physician at that time revealed the presence of a polyp, the precise location of which cannot now be stated. The polyp was removed. Since then, off and on, there has been a constant, slight, but offensive purulent discharge from this ear—hardly enough to flow from the meatus, however. In the meantime numerous polypi have been removed, probably from the region of the perforation in the *membrana flaccida*, by surgeons in this country and in Europe, but no permanent relief has followed these operations.

The hearing was found, at the above date, to be practically nothing in the affected ear. Examination revealed the *membrana vibrans* to be intact, retracted, white, dry, and shining and a *large perforation in the membrana flaccida*, or Shrapnell's membrane, through which the white neck of the malleus could be seen, and from which a slight, scanty, offensive discharge came.

Treatment.—The attic was syringed with peroxide of hydrogen and then with a 2 per cent. solution of carbolic acid, by means of Blake's tympanic syringe. At the second syringing a small polyp was brought to view, attached to the inner edge of the perforation, and which had been concealed in the attic at the time of the first examination. This was removed with slender forceps, after which the discharge seemed less. During the subsequent two months the patient wiped out her ear every second day with absorbent cotton, this being sufficient to keep it clean, and sometimes mopped it out with a 2 per cent. carbolic acid solution.

By September 1st there was found to be a minimum discharge—some days none at all. At this time peroxide of hydrogen failed to make the char-

[1] New York Medical Journal, November 24, 1888.

acteristic foaming, and it was concluded that no pus was in the attic. A small granulation was removed from the edge of the perforation, and the attic washed out with a 2 per cent. solution of carbolic acid, by means of the tympanic syringe inserted through the perforation in the flaccid membrane.

This form of treatment, by means of injections of peroxide of hydrogen, carbolic acid solution, and alcohol into the attic once, twice, or three times a week, was kept up for a year. Between the treatments in my office, the patient instilled into her ear, once daily, peroxide of hydrogen, and followed it by instilling alcohol or carbolic acid solutions. While the discharge became extremely small in quantity, and no more granulations or polypi formed at the perforation in the membrana flaccida, the discharge did not cease, and there were several attacks of acute otitis externa, with some pain, usually quickly relieved by applying a few drops of a 20 per cent. solution of ichthyol to the affected ear. *But the ear did not get well*, as the discharge still continued, though small in quantity. The hearing in the affected ear was *nothing*.

Being convinced that the disease in the ear was due either to defective drainage or the continued presence of diseased tissue in the attic, which injected solutions could not reach, or if they did reach, could not cure, I resolved to excise the membrana tympani and the malleus, in order to secure access to the diseased parts; to remove them, if possible, and, in any event, to secure ample means of direct medication to and drainage from the walls of the attic. Accordingly, on July 29, 1889, the patient was etherized, and under illumination of the auditory canal, by means of the electric head-lamp, the membrana tympani and the malleus were excised. The head of the malleus was found half destroyed by necrosis on its free surface, its articular surface with the incus being normal. The other auditory ossicles and the walls of the attic and atrium were entirely normal. Here, then, was the cause of the incurable purulent discharge from the attic. The ligaments at the neck of the malleus were very tough and broad, and had acted as a diaphragm between the attic and the atrium below, and also as the floor of a sinus running from the diseased malleus head and the perforation in the membrana flaccida.

The steps of the operation of excision consisted in :

1. An incision behind the short process, with a slender curved blade.

2. Through this initial incision a round-pointed blade, curved in the plane of its broad surface, was introduced, and being kept close to the manubrium, below the insertion of the tendon of the tensor tympani, was pressed upward against the latter, and the tendon thus severed.

3. Then a straight blade, with rounded blunt point was used to cut around the membrana tympani in the annulus tympanicus, thus entirely detaching it, and severing the hammer ligaments at the neck of the bone.

4. Instead of forceps, the polypus snare was now used to seize the malleus, being passed around the manubrium, and the malleus with the membrana tympani were removed from the ear.

The slight hemorrhage was controlled by mopping the fundus of the ear with a four per cent. solution of cocaine muriate. During the operation the fundus of the ear was mopped frequently with a two and a half per cent. solution of carbolic acid. After the operation the meatus of the canal was lightly tamponed with cotton sprinkled with iodoform, and left in place for twenty-four hours.

The next day the patient went about the house. The cotton tampon was slightly discolored on its inner end with a pinkish serum. There was no purulent discharge, and there has not been any since the operation, nearly three months ago.

The iodoform tampon in the auditory canal was discontinued in four or five days, and one containing powdered boric acid sprinkled over it was substituted, and worn for a week longer. Then simply a little cotton pellet was worn in the meatus, in the open air, to protect the exposed tympanic cavity. On some days the tampon was a little moistened with a serous fluid, but this soon ceased to appear. The absence of any reaction, and the tendency to rapid healing in this case, I am disposed to attribute largely to the antiseptic measures during and after the operation.

August 12. There was now no discharge of any kind from the ear. The hearing was found to be a little improved; about a foot for loud words.

19th. Still no discharge. The mucous membrane of the promontory is pale and rough, but entirely dry. The region of the membrana flaccida is narrowing. Hearing equals a whisper at six inches.

The patient now went on a tour to the Adirondacks, *free, for the first time in seven years, from the annoyance of a running from the ear, and the care it demanded.*

The patient was not seen again until September 25th, when it was found that a new membrane had formed from the segment of Rivinus, the region of the membrana flaccida, down to the promontory. There was no discharge. The hearing was, for whispered words, two to three feet.

October 11. The delicate membrane, bluish and transparent, rises and falls under gentle suction with the pneumatic speculum. The hearing was *nine fee* for isolated words in ordinary conversational tone.

Here, therefore, is offered an account of a case of chronic purulency and deafness, caused by necrosis of the head of the malleus, and altered tension and conductivity in the ossicles, cured of the discharge and the deafness by excision of the useless membrane and a necrotic malleus. The cure of the purulency is easily explained, but the improved hearing is not as easily explicable. I venture to suggest that the conducting power of the ossicles was interfered with by the presence of pus about the ossicles in the attic, and by the pathological bands about the malleus already mentioned, which prevented ready vibration. Also the diseased condition of the head of the malleus loosened its articulation with the incus, and impaired its leverage on the latter. Hence, a wave of sound falling on the membrana and malleus could not

transmit its inward oscillations to the incus, and thence to the stapes and the labyrinth.

When the membrana tympani and the necrotic malleus-head were removed from the attic, waves of sound fell directly upon the incus and the stapes, and were conveyed to the labyrinth. As the new membrane formed, its expansion offered a broader surface to the waves of sound, and possibly helped to increase their leverage on the remaining ossicles, thus transmitting more sound and increasing the hearing. The continuance of this normal stimulus to the movements of the stapes in the oval window gradually overcame the partial ankylosis which had ensued at that point from disease, and the hearing, in consequence, has *steadily improved*, since the operation, from nothing to *nine feet*.

Let us suppose that the chronic purulency of the attic had been, or could have been, cured by injections through the perforation in the membrana flaccida into the attic cavity. The hearing would not have been improved, because the impaired malleus-head, the stiffened ossicles, and the pathological bands around the neck of the malleus would not have been removed, and hence the impaired mobility of the incus and stapes would have still remained as a hindrance to hearing.

We see, therefore, that the operation of excision of the membrana tympani and the malleus offers not only a great hope of curing chronic purulency, especially of the attic, but also of relieving deafness due to a stiffened membrana and ossicles, by the removal of pathological bands prohibiting free oscillations in the ossicles, and by thus permitting sound-waves to fall directly upon the stapes in the oval window, and perhaps also upon the membrana tympani secundaria.

The gradual improvement in the hearing in this case, as has been observed by Sexton in other cases, is worthy of note, and would seem to indicate, as suggested above, that the deafness, in many instances, is due to a quasi-ankylosis in the ossicles, especially in the stapes, and that when this bonelet is exposed by the operation to the direct action of sound-waves, the passive motion thus brought to bear on the ankylosed structures renews their ready vibratility, and the hearing is improved to a greater or less degree.

OSTEOTOMY FOR OVERLAPPING UNION OF A FRACTURE OF THE FEMUR.

BY ERNEST LAPLACE, A.M., M.D. (PARIS),
PROFESSOR OF PATHOLOGY IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA; LATE VISITING SURGEON TO THE CHARITY HOSPITAL OF NEW ORLEANS.

AMONG the great advances of surgery made possible by the strict application of antiseptic measures are the operations on bones. Deformities such as would, no doubt, have been abandoned some years ago, are to-day remedied with the greatest ease, restoring, as in the following case, the perfect use of a limb which, owing to its deformity, the patient wished to have amputated.

W. K., aged forty years, entered the Charity Hospital, in New Orleans, presenting the following history: He had had an attack of acute articular rheumatism about one year previously, as a result of which his right knee had become ankylosed in a semiflexed position, necessitating his using crutches. Three months afterward he fell and broke his right thigh, and the treatment having been somewhat neglected, solid union took place in the following abnormal position. The ankylosed and flexed knee was everted, and there was an overlapping of the fractured ends of the femur to the extent of fully six inches. There was also a large tumor, consisting of callus, around the overlapping fragments, so that the limb was a great encumbrance to the patient, who came to have it amputated.

Instead of this we had recourse to osteotomy. The patient being anæsthetized, and the parts having been rendered thoroughly aseptic, an incision eight inches long was made on the external surface of the thigh, extending to the bone, directly over the overlapping fragments. The Esmarch elastic bandage having been previously applied, we were not troubled with hemorrhage. After having exposed the overlapping portions of the bone, they were entirely separated with hammer and chisel. The ends of the fragments were likewise denuded. This being done, the wound was thoroughly washed with the acid sublimate solution,[1] and then packed with iodoform gauze, and a stout bandage applied around the thigh. Forcible extension was made about the knee-joint, destroying the fibrinous ankylosis, and straightening the joint. The patient being still anæsthetized, forcible extension was continued, and in about fifteen minutes the limb had been brought to measure the same length as its fellow. When this point was reached, the limb was put up in a Liston's splint, with a weight and pulley extension apparatus.

During the first twenty-four hours after the operation, considerable oozing took place from the wound. The dressing was removed, and the hemorrhage found to come directly from the chiselled bone; the wound was again packed as before. But the patient had lost so much blood that it was thought wise to resort to transfusion. For this purpose sixteen ounces of the following solution were injected into the median basilic vein of the left arm:

Sodii chloridi	℥ j.
Potass. chloridi	gr. x.
Sodii sulphat.	gr. jss.
Sodii phosphat.	gr. iij.
Sodii carbonat.	gr. vj.
Aquæ destill.	℥ xxiv.

Prior to its use, this solution was boiled, and allowed to cool to 98½° F.

Half an hour after the injection the patient was very much better; his pulse became firm and regular. Stimulants were also administered. From this on, improvement was rapid. Appetite increased; no

[1] Saure Sublimat-Lösung als disinficirendes Mittel, etc., by Dr. Ernest Laplace. Deutsche med. Wochenschrift, 1887, No. 40.

fever was present, and no suppuration from the wound. The dressing was changed twice, so as to make room for granulation from below. Forty days after the operation the patient left his bed, there being no perceptible difference in the length or appearance of the two thighs, except the line of incision for the operation. Massage and passive motion restored considerable motion to the once ankylosed knee. To-day the patient goes about with almost as sound a limb as he possesses in the unaffected one.

From this case we learn that:

1. With antiseptic precautions, the operation for deformities even as extensive as this was, should be attempted.

2. That a proper management of the case will restore the limb to as great a degree of usefulness as it ever had.

3. That should an unavoidable and profuse hemorrhage endanger the patient, transfusion as it was used in this case will materially improve the condition of the patient, putting him in better condition to rally from the injury.

HOSPITAL NOTES.

CARCINOMA OF CERVIX; CARCINOMA OF LIVER.

Abstract of a Clinical Lecture
Delivered by Matthew D. Mann, M.D., at Buffalo, New York.

Case I.—This patient entered for operation, the diagnosis of cancer of the uterus having previously been made. There was a history of much pain in the case, which is not, according to Dr. Mann's experience, a frequent symptom of cancer of the cervix. Vaginal examination revealed the entire cervix and part of the vaginal walls to be an irregular mass of soft bleeding tissue, which is characteristic of cancer. Adenoma of the cervix grows from a more or less distinct pedicle, does not break down under the fingers or bleed so readily.

The patient was etherized in the dorsal position, the legs being retained in position by the apparatus of Dr. H. A. Kelly. Further examination discovered cancerous infiltration of the broad ligament, which, of course, precluded the possibility of a radical operation. With a sharp spoon as much of the growth as seemed safe was removed. Following this, the vagina was irrigated with an antiseptic solution, and packed with non-absorbent cotton, which previously had been soaked in a solution of hydronaphthol and alum, and sprinkled with iodoform. The following day this tampon was to be removed, and the raw surfaces covered with small pledgets of cotton soaked in a fifty per cent. solution of chloride of zinc. These should be covered with gutta-percha tissue, and to neutralize the excess of the caustic, the vagina be tamponed with cotton wrung from a solution of bicarbonate of soda. After forty-eight hours the tampon should be removed and followed by frequent antiseptic irrigation until the sloughs separate. If necessary the cauterization will be repeated.

Case II.—This case sought relief from an enlargement of the abdomen which had taken place during the last three years, and had been diagnosticated as an ovarian tumor. From her facies alone, Dr. Mann believed that she was not suffering from an ovarian tumor, in which opinion he was confirmed by further examination. The abdomen was greatly distended, and as the patient lay upon her back there was anterior flattening with bulging in the flanks. The entire enlargement was soft and uniformly yielding. On percussion there was tympany in front, and flatness at the sides, which is an important point in the diagnosis between free fluid and fluid confined in a cyst. Dr. Mann's diagnosis in this case then, was ascites from disease of the liver, kidneys, or heart, but which of the three could be determined with certainty only after drawing off the fluid. Subsequently the abdomen was tapped and about ten quarts of yellowish, but clear, serum drawn off. After this a tumor on the under surface of, and attached to, the liver was detected, which was considered cancerous.

MEDICAL PROGRESS.

The Treatment of Pertussis with Resorcin.—Dr. Justus Andeer reports quite remarkable results in the treatment of whooping-cough with resorcin. In a child of seven years, on the second day after resorcin was prescribed, there was great improvement in the symptoms, and sleep at night was much less disturbed. In ten days, the cough had disappeared. With five other children the effects were even more pronounced, all being cured within a week. An infant of six months with vomiting after each paroxysm of coughing, was relieved by the second dose, and in five days the cough ceased. In the latter case, Dr. Andeer used a one-half per cent. solution in sweetened water given from the nursing bottle. In the former cases, he gave a two per cent. solution in water, of which half a wineglassful was administered four times daily, with directions that part should be used as a gargle, the remainder swallowed. He does not think that inhalations, or painting of the pharynx, with this solution, possess any advantages over this simple method. —*Centralblatt für die medicinischen Wissenschaften*, October 5, 1889.

Methods of Rendering Sponges Aseptic.—Perren, in the *Revue Générale de Clinique et de Thérapeutique* for October 10, 1889, gives the following method for the preparation of aseptic sponges: They are to be pounded with a wooden mallet and afterward carefully soaked in plenty of pure water. Following this, the sponges are placed in a bath of hydrochloric acid of the strength of one per cent., in order to dissolve thoroughly calcareous particles, and when this is accomplished, they are inserted into a jar containing a solution of potassium permanganate, in which they remain six hours. For blanching they are submitted to the action of a solution containing bisulphite of soda in the proportion 150 grains to a quart of water. Finally, all these processes being completed, they are placed in one of the following solutions for preservation:

℞.—Carbolic acid	15 grains.
Alcohol	1½ drachms.
Water	1 quart.

or:

℞.—Thymol	15 grains.
Alcohol	1½ drachms.
Water	1 quart.

The Effects of Ergot after Confinement.—In order to determine the precise value of ergot in childbed, Dr. Pinzoni administered it to ninety-one lying-in patients, generally in the form of about two grammes of the powder daily. Seventy-nine similar cases were treated without ergot. After comparing the two series, he came to the following conclusions: Ergot has little or no influence on the temperature; at the most a slight rise is occasionally observed. It hastens the pulse a little, yet has no marked influence on the physiological retardation of the pulse observed during the first days after delivery. The physiological increase in the secretion of urine during the earlier days is favored by ergot. The involution of the uterus, according to Dr. Pinzoni's researches, is either totally uninfluenced or slightly retarded. The escape of the lochia remains normal when the drug is given; but clots, as universal experience has proved, are more readily expelled. The lochia seldom smell fetid when the ergot is taken. It delays the after-pains in primiparæ, and lessens them when they have already commenced. The secretion of milk is retarded and lessened, and sometimes completely suppressed. Ergot seems, in the belief of Dr. Pinzoni, to be a prophylactic against puerperal fever, and an indirect antiseptic agent. When infection has already taken place, it appears, on the other hand, to hasten the entrance of the virus into the circulation. Dr. Pinzoni's researches appeared in the *Bolletino delle Scienze med. Bologna*, series vi., vol. xx. —*Archives of Gynæcology, Obstetrics, and Pædiatrics*, October, 1889.

Pseudo-orchitis.—In *L'Union Méd. et Scient. du Nord-Est* for July, 1889, GUELLIOT, of Reims, gives an interesting account of this condition, which he asserts is produced by effort of such a kind as to cause a strain involving the cremaster muscle. The result of the effort may produce rupture of the spermatic vein, the effused blood being limited to the cord, and, perhaps, in addition, the epididymis. The symptoms of this state are characteristic in that they are generally on the left side, the pain is circumscribed in its intensity, while the presence of dilated veins, completely engorged, also acts as a diagnostic sign.

Cornutin in Uterine Hemorrhage.—DR H. THOMPSON has used cornutin extensively in various forms of uterine hemorrhage. According to Dr. Kobert's method, the remedy was administered either subcutaneously, in the following formula:

℞.—Cornutin . . . . . gr. ¾.
Water . . . . . ʒ ijss.
Mix, make solution, and add:
Hydrochloric acid . . . gtt. iv.

or in the form of pills:

℞.—Cornutin . . . . . gr. 1⅛.
Hydrate of aluminium . . grs. 46.
Add water and glycerine āā q. s. for twenty pills.
Dose, two or three pills.

The cornutin in solution generally is not to be recommended, as it becomes cloudy and unfit for use in a very short time. In weak or inefficient pains the use of this drug is not to be recommended, while in atonic hemorrhage or after abortion it is of great value. Especially rapid is its action in metrorrhagia and menorrhagia following endometritis, metritis, and inflammatory conditions of the uterine appendages. In two cases of menorrhagia the result of endometritis, from one-third to one-half grain of the drug, subcutaneously administered, produced intense lumbar pains followed by complete cessation of the hemorrhage within ten minutes. The influence of the drug lasted for two hours, after which another dose was necessary. In a case of very severe metrorrhagia caused by double ovarian tumors, two three-quarter-grain doses gave entire relief.

The average dose of this drug is from one-thirty-second to one-eighth grain subcutaneously, and from one-eighth to one-fifth grain by the mouth.—*Archives of Gynæcology, Obstetrics, and Pædiatrics*, October, 1889.

Treatment of Gastric Ulcer.—In a recent clinical lecture on gastric ulcer, Dr. Byrom Bramwell, in speaking of the treatment of gastric ulcer, insisted upon the importance of giving the patient as much food as is necessary for the purpose of nutrition, and the avoidance of all foods which irritate the inflamed and ulcerated stomach, and which produce pain or vomiting. Liquid food, and especially milk, fill these requirements, though the latter is sometimes not well borne, unless boiled or partially predigested with pancreatin. Half a teaspoonful, or a teaspoonful, of the liquor pepticus given immediately after a meal, is often useful in those cases in which it is not considered necessary to peptonize the food before introducing it into the stomach. In the severe cases in which peptonized foods disagree, the stomach should, for a time, be placed at absolute rest, and the patient fed *per rectum*. It is now well known that it is possible to support patients for long periods of time by means of nutrient enemata (milk, beef-tea, defibrinized ox blood) and nutrient suppositories. Nutrient enemata should be given in small quantities at a time, to insure their retention, and when the rectum becomes irritable, a few drops of laudanum should be added to every third or fourth enema. Potatoes, raw apples, meat, and pastry, are especially injurious. Tea also is bad.

The second indication is to administer remedies which will promote the healing of the ulcer. In ulcer of the stomach, as in every other disease, one of the great principles which should regulate our treatment is to remove the cause of the condition. Ulceration of the stomach is very frequently seen in chlorosis, and in such cases he has found arsenic in the form of Fowler's solution, with a teaspoonful of liquor pepticus (Benger's), a most valuable remedy. Bismuth and nitrate of silver are also very useful in the treatment of many cases of ulcer of the stomach. In others, where the pain after taking food is severe, a small dose of opium or morphia, given in the form of a pill, is of advantage. In cases where there is distinct tenderness on pressure, the application of a blister is often beneficial.

In treating ulcer of the stomach, it is necessary to attend to the condition of the bowels. Cascara, or castor oil, may be given when medicine is required; strong purgatives should be avoided.—*Studies in Clinical Medicine*.

Subcutaneous Saline Injections.—In the *Archiv f. Gynäkologie*, DR. MUNCHMEYER, of Berlin, reports his results in the treatment of anæmia by subcutaneous injections of saline solution. The solution was 0.6 per cent. of

common salt, and the results were satisfactory. The anæmia was in nearly all the cases the result of post-partum hemorrhage.

In ten further cases of extreme debility after laparotomy and other serious operations, a similar injection was without effect, owing, as was believed, to paralysis of the cardiac muscle from brown atrophy. It is just possible that death was hastened in some of these cases by œdema of the lungs. All cases of anæmic debility are not suitable for treatment, as the pulmonary circulation is readily overladen with fluid. In those cases of post-partum hemorrhage in which the injection was without result, it was probably because it was done too late. As the point for puncture, the infra-clavicular region was considered very suitable, being near the heart and offering the best chance for rapid diffusion of the fluid. Strong stimulants should be given previously, and the injection supported by hot packings and wrapping of the extremities in hot cloths. As used, the solution was always sterilized. Not more than a litre (thirty-five ounces) was ever injected; the range being between half a litre and a litre. The apparatus used consisted of a funnel, an India-rubber tube one metre long, and several needles, which are readily kept disinfected. The needles can be sterilized in a flame, and the tube by passing a five per cent. solution of carbolic acid through it. The physiological fluid should, of course, be passed through before puncturing. The fluid injected is to be dispersed through the adjacent parts by massage, and, if the lumps produced by the collections of fluid are too large, another spot may be chosen. The injection must be continued until a result is obtained. In the eight cases reported, success was achieved in, at the longest, three hours.

Dr. Pregaldioli recommends the subcutaneous injection of a solution of sea-salt in acute anæmia. He claims that this increases blood-pressure, and thereby stimulates the nerves. Acute anæmia causes death, not by want of oxygen, but by rapid sinking of the blood-pressure, which causes sudden anæmia of the nerve-centres. His experiments showed that the fluid injected into the cellular tissues (a six per cent. solution of sea-salt) was rapidly absorbed, and that it had no deleterious influence on the regeneration of the blood corpuscles. The quantity of fluid required was from half to two-thirds of the quantity of blood withdrawn.—*The Medical Press and Circular*, October 9, 1889.

Treatment of Seborrhœic Eczema.—According to the *Monatschrift für Dermatologie*, Dr. Unna's favorite formula for the treatment of seborrhœic and other varieties of eczema, is a solution of three drachms of finely powdered resorcin with an equal quantity of glycerine, in six ounces of alcohol, diluted with four times the quantity of water or chamomile tea. A thin layer of cotton-wool well moistened with the solution is applied, covered with some waterproof material, and fastened by a bandage. These applications are particularly useful when the treatment is prolonged, or when it is carried out by night. They are, of course, impossible in general eczema of adults, but not in that of infants. Dr. Unna describes an especially important effect following the application of resorcin, viz., a swelling of the epidermis, by which all painful fissures are healed in a single night. In order to insure healing, he advises that the skin should be anointed after the removal of the bandage, and that washing with soap should be avoided. A few people suffer from a resorcin idiosyncrasy, which necessitates the immediate cessation of this treatment, and the application of powder to the affected parts. This idiosyncrasy is, however, very rare, as he has only met with it ten times among two thousand cases.—*Therapeutic Gazette*, October 15, 1889.

Menthol in Pruritus.—Dr. Saalfeld uses the following formulæ in itching of the skin from various causes:

℞.—Menthol . . . . . gr. xx.
Alcoholis . . . . . f ℥ij.—M.

Or an ointment:

℞.—Menthol . . . . . gr. xl.
Olium olivæ . . . . ℥iij.
Lanolin . . . . . ad ℥ij.—M.

—*Provincial Medical Journal*, September 2, 1889.

Formula for Uterine Hemorrhage.—The *Revue de Thérapeutique* publishes the following formula for menorrhagia:

℞.—Extract. cannabis Ind. . . gr. vijss.
Extract. ergot. fluid. . . f ℥j.
Extract. hamamel. fluid. } . āā f ℥ss.—M.
Tinct. cinnamomi }

Signa.—One teaspooful three times daily.—*The Canadian Practitioner.*

Operative Treatment of Bunion.—Dr. George R. Fowler recently operated after Peterson's method for severe bilateral bunions. As this disease is so painful to the patient, and troublesome to the surgeon, we append a description of the operation, which, in Dr. Fowler's case, was eminently successful: An incision was made from a point on the dorsum of the foot, somewhat below the level of the head of the first metatarsal bone, and just outside of that portion of the tendon of the extensor brevis digitorum which goes to the great toe; this was continued to the bottom of the web between the first and great toes. A similar incision was made on the plantar surface of the foot, slightly to the outer side of the line of the tendon of the flexor longus pollicis. The intervening parts were divided through the whole thickness of the sole of the foot, so as to join the two incisions. The great toe was then strongly adducted, and the external lateral ligament divided, opening the joint. After freeing the soft parts from the neck of the first metatarsal bone with the handle of a scalpel, the phalanx was completely displaced, The great toe was adducted still further, until its inner border lay along the inner border of the foot, its point looking directly backward; the head and neck of the first metatarsal bone, together with a large exostosis constituting the "bunion," were thus freely exposed. The latter, together with the inner half of the articular surface of the former, were sawn off by an oblique cut. The toe was then replaced in its normal position, and drainage provided by a tube in the bottom of the gap. The soft parts were sutured; dressings of sublimate gauze and paper wool, and a splint, were applied to retain the toe in a straight position. The other foot was operated upon in the same manner. In three weeks the patient could walk comfortably, but was kept under observation until the end of the sixth week,

when she was discharged from the hospital cured. After cicatrization it was found that a shoe and stocking, with separate compartments for the great toe, furnished all the support that was necessary—*Medical Record*, September 7, 1889.

Treatment of Chronic Prostatitis.—MATTHEW BERKELEY HILL, in his lectures at the Royal College of Surgeons of England, "On Some Affections of the Genito-urinary Organs," says that the treatment of chronic prostatitis is very tedious. Few remedies are trustworthy. In the first place, dyspepsia must be cured. The most beneficial tonics are the non-astringent forms of iron, to which nux vomica or strychnine may be added, and belladonna, if micturition during sleep, be a symptom. Ergotine is especially useful when the organ is large, and aching is caused by walking, standing, or railway journeys.

Local Treatment.—Cold sitz-baths are useful when the organ is enlarged, soft, and not tender. The bath should at first be taken at 50° F., once or twice daily, and for one or two minutes only, and the duration gradually increased to ten minutes while the temperature is gradually decreased to 35°. The cold douche on the anus and perineum is also useful. Two to four ounces of cold water as an enema, to be retained in the rectum, is more generally beneficial than the bath. No faith is put in blistering. When the prostatitis is the result of masturbation or excessive venery, the urine is often more or less bloody. To the touch, the organ is little changed. The liquid extract of salix nigra, in dose of one drachm, three times daily, has often a marked effect in checking involuntary emissions and preventing the irritation, exhaustion, and neuralgia which occur after them. Topical treatment must be omitted after the mucous catarrh and chronic inflammation are quelled. Coitus may be rendered imperfect or impossible by reason of too speedy ejaculation, in those who have suffered from congested prostate. In these cases the fluid extract of damiana has a powerful effect, but cure is almost impossible if continence is neglected. A condition of helplessness, intense neuralgia of the lower extremities following the shortest walks, pains extending from the sacrum to the occiput while at rest, deteriorated digestion, etc., are complained of. The best remedy in such instances is a quiet life, absence of exertion of any kind, and a long sea-voyage. In rare cases chronic parenchymatous prostatitis excites temporary mania which disappears if the physical affection is cured.—*Journal of Cutaneous and Genito-Urinary Diseases*, September, 1889.

Peruvian Balsam in Laryngeal Phthisis.—SCHNITZLER, of Vienna, at a recent meeting of the International Congress for Otology and Laryngology, spoke highly of the local and general treatment of laryngeal phthisis with Peruvian balsam. Internally he prescribes it in the form of pills, or emulsified with cod-liver oil or lipanin. Locally, he uses it mixed with bismuth. subnit. and milk sugar as an insufflation, and equal parts of the balsam and alcohol as an inhalation. If much ulceration exists, he curettes the ulcers and applies to the freshened surfaces equal parts of the balsam and alcohol with a small percentage of cocaine. Combined with collodion it serves to protect the diseased surfaces from the pulmonary secretions. With this treatment, according to Schnitzler, the swelling of mucous membrane diminishes and ulcers cicatrize.—*Münch. med. Wochen.*, No. 40.

Nitrate of Silver in Purpura Hæmorrhagica.—DR. POULET, in the *Bullet. gén. de Thérap.*, reports two cases of purpura successfully treated by the internal administration of nitrate of silver. The first, a child of twelve years, had previously been treated with iron, and by other methods, without result. After one-sixth grain doses of the silver salt, twice daily, had been ordered, he rapidly recovered. The second case, a woman of twenty years, was also quickly relieved with doses of one-eighth of a grain three times daily. Poulet believes that the silver acts in this disease by virtue of its well-known effects upon the central nervous system.—*Therap. Monatshefte*, September, 1889.

Alopecia Simplex.—DR. E. BESNER recommends the following somewhat heroic but efficient method of treating baldness: The hair is cut short, and the scalp reddened with a mild sinapism. Then, for the following five days, a daily application of equal parts of chloroform and acetic acid is carefully made; and, in addition, an ointment composed of salicylic acid one part, precipitated sulphur four parts, vaseline twenty parts.—*Monatshefte f. Praktische Dermatologie*, October 1, 1889.

The Use of Strophanthus in Children.—DEMME, in the *Rev. Mens. des Mal. de l'Enf.*, reaches the following conclusions upon the use of strophanthus in children:

1. Strophanthus, especially in the form of the tincture, may be given to children after their fifth year; but as in large doses it may suddenly and unexpectedly paralyze the heart, three drops four or five times daily should be the maximum amount administered. Exceptionally, its use is followed by dyspeptic symptoms.

2. The predominant action of strophanthus is to increase diuresis, and consecutively to diminish the phenomena of venous stasis. This effect is produced by an increase of blood-pressure, and is especially evident in connection with lesions of the left auriculo-ventricular valves. Unlike digitalis, it does not produce a compensation of the valvular lesion. In affections accompanied by exaggerated, or even normal, arterial pressure, the diuretic effect of the drug is wanting.

3. Strophanthus also exercises a remarkable influence upon dyspnœal phenomena, which is due to its action on the respiratory centres. This effect is seen in cases of chronic nephritis, and in other diseases, as bronchial asthma and whooping-cough.

4. While there are close analogies in more respects than one between the effects of strophanthus and digitalis, each drug possesses its own peculiar therapeutic action. Digitalis is indicated in those cases in which it is desirable to obtain with rapidity, a compensation of valvular lesions, augmented blood-pressure, slowing of the pulse, and increased secretion of urine. If digitalis does not produce these effects, they cannot be obtained with strophanthus. On the contrary, when a valvular lesion has been compensated by digitalis, and it becomes necessary to act anew upon the heart, in order to obtain a new increase in blood-pressure and diuresis; when, in addition, dyspnœa becomes an urgent symptom, strophanthus will give excellent results. In such cases the combined action of strophanthus and digitalis is useful.

5. In no case did Demme observe cumulative effects or weakening of the action of strophanthus, even though used for a long time.—*Archives of Pediatrics*, October, 1889.

Treatment of Vomiting of Pregnancy.—In the *Berliner klin. Wochenschrift* for October 7, 1889, DR. SIGMUND GOTTSCHALK reports a severe case of vomiting of pregnancy in which cocaine and other measures entirely failed, but which quickly yielded to small and frequently repeated doses of menthol. He suggests that further observations be made in this direction, and as menthol is not only a local anæsthetic, but also an antiseptic, it will, probably, be found a valuable addition to the long list of drugs used in combating this troublesome condition. Dr. Gottschalk prescribes about one-third of a grain, in alcohol and water, repeated hourly until the patient is relieved.

Treatment of Herpes Zoster.—DR. BRAMWELL, in speaking of the treatment of herpes zoster, says: In most cases the administration of a brisk purge at the commencement of the attack is probably advantageous. Arsenic—which, as Mr. Jonathan Hutchinson has pointed out, is a specific in many cases of recurrent herpes—has no influence in arresting herpes zoster. Indeed, it is remarkable that, in some cases, the long administration of arsenic seems to produce the disease.

When the pain is very severe, the administration of opium or morphia, either by the mouth or subcutaneously, is necessitated. The application of a fly blister, or of the actual cautery at a red heat, with the object of producing blistering, but not sloughing, over the point where the affected nerve-trunk becomes superficial, is said, in many cases, to be highly advantageous. Cocaine, in the form of ointment (ten grains to the ounce of vaseline), or a spirituous solution of menthol may also be applied locally. Both are useful for the purpose of allaying the painful sensations which persist after the acute stage of the disease is passed, rather than for the relief of the acute pain which is so often met with in the earlier stages of the affection. Hydrobromic acid is, when combined with syrup of oranges, or infusion of gentian, a pleasant remedy, and useful for allaying the uneasy painful sensations which attend convalescence. During the latter stage, arsenic and strychnine are the most reliable remedies for promoting repair in the affected nerves. The constant electric current seems in some cases to be the most effective means of relieving the very distressing after-pains. If this, with internal remedies, fails, stretching, or, better still, dividing, the affected nerve may be employed.

In order to prevent pitting, great care should be taken to prevent suppuration or rupture of the vesicles. The vesicles may be painted over with flexible collodion, or dusted with a drying powder, such as powdered talc 87 parts, powdered starch 10 parts, and salicylic acid 3 parts. Carbolic oil is also a useful application.—*Studies in Clinical Medicine.*

Chloralamid, the New Hypnotic.—The new hypnotic, chloralamid, is being extensively investigated in Germany, and if the studies of LETTOW, KNY, and others are confirmed, it is certainly a valuable discovery. Lettow, after prescribing the drug in thirteen cases of sleeplessness from various causes, concludes that—

(1) Chloralamid is a very efficacious and useful hypnotic, though no panacea for all cases of insomnia.

(2) The greatest advantage over other hypnotics is that it has no influence on pulse, respiration, or temperature.

(3) After-effects are few; if occurring at all, they consist of slight headache, or a trace of giddiness.

(4) The safe dose for an adult is forty-five grains.

(5) The drug is best given one, to one and a half hours before the desired sleep should commence.

(6) Chloralamid when given as an enema is very reliable.

(7) The hypnotic effect is occasionally prolonged over a part of the following day.

Dr. Eugen Kny, assistant physician to the clinic for mental diseases of the University of Strassburg, published, in the *Therapeutische Monatshefte* for August, 1889, the results of his extensive physiological and clinical experiments with chloralamid. He first gave the drug to a large number of animals, and observed a marked hypnotic effect in nearly all. After the artificially produced sleep was over, the animals felt the better for it, and showed no unpleasant symptoms whatever. In one series of experiments the effect of the drug on blood-pressure was studied, the latter being recorded before, during, and after administration. The result of these experiments was, that chloralamid, in contradistinction to chloral, with which it is in close relation chemically as well as physiologically, does not materially alter the arterial blood-pressure. Chloral frequently causes a decrease of the blood-pressure to the amount of fifty to eighty mm., chloralamid caused only seventeen mm. reduction—*i.e.*, not more than is observed during natural sound sleep. This shows that the drug not only has no toxic influence on the heart, but does not even affect its action to any marked degree. Dr. Kny, after having proved the harmlessness of the new substance on animals, went a step further and tried the drug on patients. He gave it more than one hundred times in thirty-one different cases of insomnia, in some of which he had previously given chloral, so that he had an opportunity of comparing the therapeutic value of the two drugs. Chloralamid had a favorable effect in all cases of insomnia caused by nervous excitation, if not accompanied with intense physical pain; furthermore, in all cases where organic lesions, such as phthisis, heart disease, pleurisy, etc., caused the sleeplessness. As a rule, the sleep was deep, refreshing, and sound; and its duration varied between six and ten hours. In the morning the patients woke with perfectly clear heads, and without any derangement of the digestive organs. Sensation of weight in the head, general malaise, and unpleasant taste in the mouth, complaints quite common after chloral sleep, were, Kny states, never noticed after chloralamid. He considers that another important advantage of the latter consists in its not irritating the mucous membranes. A 10 per cent. solution applied to the conjunctiva did not cause any burning sensation, whilst intense pain is felt by similar application of chloral solutions. Regarding the methods of administration, he recommends to dissolve the drug in wine or other alcoholic beverage. Given in this method, even in patients of very weak constitutions and deranged states of digestion it was followed by no ill effects—*The Provincial Medical Journal*, October 1, 1886.

Detection of Sugar in the Urine by the Cupro-potassic Solution.— DRS. YVON and BERLIOZ communicated to the Paris Academy of Medicine, during a discussion on diabetes, the results of experiments undertaken some time previously for the detection of sugar in the urine, and on the choice to be made of the various processes described to detect this abnormal element.

The processes and reagents they divided into the following groups:

1st. By *fermentation*. This process, notwithstanding the different contrivances that have been suggested to shorten the time, is very tedious, not practical, and often gives unsatisfactory results.

2d. By the *polariscope*, *saccharimeter*, or *diabetometer*. In using these instruments it is necessary that at least half a gramme of sugar per litre should be present. When this quantity is not exceeded, the presence of sugar can be detected only by a skilful operator possessing a good apparatus.

3d. By *reagents*, of which there are many. Their names and composition are as follows:

1. Fehling's solution.	Sulphate of copper, neutral tartrate of potassa, soda lye.
2. Bareswill's solution.	Sulphate of copper, acid tartrate of potassa, soda lye.
3. Violette's solution.	Sulphate of copper, Rochelle salts, soda lye.
4. Trommer's reagent.	Sulphate of copper and potassa.
5. Capezzuoli's reagent.	Hydrated blue oxide of copper and caustic potassa.
6. Moore's reagent.	Caustic potassa.
7. Böttger's reagent.	Nitrate of bismuth and carbonate of soda.
8. Mulder's reagent.	Carmine of indigo and an alkaline solution.
9. Neubauer and Vogel's reagent.	Ammoniacal solution of nitrate of silver.
10. Pratesi's reagent.	Bichromate of potassa and an alkaline silicate.
11. Hager's reagent.	Ferrocyanide and caustic potassa.
12. Knapp's reagent.	Cyanide of mercury and an alkali.
13. Penzoldt's reagent.	Diazobenzosulphuric acid and caustic potassa.
14. Loewe's reagent.	Subnitrate of bismuth, glycerine, and soda lye.
15. Almen and Nylander's reagent.	Subnitrate of bismuth, Rochelle salts, solution of caustic potassa.
16. Fischer's reagent.	Phenylhydrazine and acetate of soda.

Amongst these reagents, and others that have not been mentioned, Fehling's solution, or one of its substitutes, is the easiest and quickest, and one that permits the detection of the minimum traces of sugar. To obtain with it the utmost accuracy precautions are necessary.

Among the various formulæ for a cupro-potassic solution, one described by Mehu has been adopted, rendering it only more alkaline than he advised. It is better to prepare it in small quantities, so as to renew it often, preserving it in bottles closed with a rubber cork, and kept in the dark. This solution can be so prepared that a cubic centimetre will be entirely reduced by five milligrammes of glucose. Under these conditions any given volume of this solution is entirely reduced by an equal quantity of urine containing five grammes of sugar to the litre. But five grammes to the litre is far from indicating the limit of the sensitiveness of the solution. It simply signifies that to have a complete decolorization of a sample of urine one must use:

1. One volume of solution.
   One volume of urine containing five grammes of sugar per litre.
2. One volume of solution.
   Two volumes of urine containing 2.5 grammes of sugar per litre.
3. One volume of solution.
   Three volumes of urine containing 1.66 grammes of sugar per litre.
4. One volume of solution.
   Four volumes of urine containing 1.25 grammes of sugar per litre.

In qualitative examinations it is not necessary to obtain the total reduction of the solution; it suffices if it is pronounced enough, and if there is an appreciable quantity of oxide of copper precipitated. It is no exaggeration to say that the reduction is very apparent when only a third of the oxide of copper contained in the solution is precipitated. Under these conditions, in varying the quantities of urine from even one to four times that of the solution, a quantity of glucose corresponding to one-half a gramme per litre can be detected. This limit can be still further reduced by evaporating the urine to a third, fifth, or even less, of its original volume.

With certain urines of high densities, rich extractive matter, and strong color, the reduction is often indistinct.

If the proportion of glucose is very low, it is necessary to treat the solution with a volume of urine three or four times greater; and the disturbing influence will increase in proportion. Of all the substances that react upon the cupro-potassic solution, glucose is the one that can be reduced most easily at a temperature much below 100° C., and it will even react in the cold. This property is made use of by heating on a water bath to 85° or 90° C.

For this test it is necessary to clarify the urine, which may be done with subacetate of lead.

If after having treated the urine with Fehling's solution in the ordinary manner, the mixture remains limpid and transparent before and after cooling, the absence of sugar can be confidently assumed. If, on the contrary, the reduction is not sufficiently distinct, and there is doubt as to the presence of glucose, then proceed in the following manner: Mix in a test tube, of about half an inch diameter, two parts of urine and one part of the copper solution, heat the upper part to boiling; if there is sugar in notable quantity there is formed a yellowish coating or deposit, which adheres firmly to the sides of the tube; the mixture assuming at the same time a greenish-yellow color, or the test may be repeated using three or four parts of urine to one of the solution. It is important to have it well mixed. In either case, but particularly in the second, a control test should be made thus:

1. Heat only on a water bath for the reasons we have given.

2. Treat the urine with subacetate of lead and carbonate of soda: the latter in powder so as not to dilute the urine. Under these conditions sugar can be detected in urine containing half a gramme per litre. If there is still doubt as to the presence of sugar, concentrate the urine in a water bath, reducing it to a volume small enough for the glucose which it contains to react sharply. It must be clarified with subacetate of lead, then evaporated to a syrupy consistence and the residue taken up with alcohol. The red or yellow decolorization of the copper solution will not alone determine the presence of sugar. It is necessary to observe a characteristic reduction by the loss of transparency in the mixture, and the appearance of a precipitate of oxide of copper, which may be either red, yellow, or black. A good way to verify a true reduction is to hold the tube before a bright flame. If the solution becomes opaque and obscures the light, it contains a precipitate.

The presence of sugar in normal urine has been sought in vain by the authors.

Sugar in urine is not met with as often as one would think. Among 10,650 suspected urines that they examined, but 2777, or 26 per cent., contained sugar.

The phenylhydrazine test they considered to be one of the least reliable. When urine contains only a small quantity of sugar, it must stand from twelve to twenty-four hours before the crystals of phenyglycosanone are formed; and, what is more serious, the speakers had obtained so-called characteristic crystals in urines which in their judgment contained no sugar.

The conclusion of these experimenters is that the cupro-potassic solution, used with the precautions pointed out, appears to-day to be the quickest and the most exact reagent for detecting the presence of sugar in urine. —*Archives de Médecine Experimentale d'Anatomie et Pathologique*, No. 5, September 1, 1889.

Oxygen in Leukæmia and Chlorosis.—In *The American Journal of the Medical Sciences* for October, 1889, Drs. Da Costa and Hershey report their results in the treatment of two cases of splenic leukæmia, and two of chlorosis, with inhalations of oxygen, and though it is manifestly unwise to draw positive conclusions from so few cases, the improvement in all was so rapid that the method should certainly be given a fair trial in every case of grave anæmia.

Their first patient was a boy of thirteen years, with general weakness, an enlarged spleen, and blood corpuscles numbering 2,350,000 red, to 320,000 white per c.mm. Iron, arsenic, trinitrine, and other measures had been used without effect, the patient was steadily growing weaker. Improvement began immediately upon the inhalation of from twenty to thirty litres of oxygen daily, and in two months the patient was able to resume work. One month later, his red corpuscles numbered 4,850,000, and the white were so nearly normal that a count was not made.

The second case, a man of thirty-five years, had probably been leukæmic for several years, and had also suffered from polyuria. Customary treatment was followed by no benefit. When inhalations of oxygen were commenced the patient was exceedingly weak, with œdematous feet and legs, dyspnœa on slight exertion, profuse watery diarrhœa, and a temperature of 102.3°. His spleen was enormous, extending two inches beyond the umbilicus. The red corpuscles numbered 1,440,000, were pale in color, and did not form rouleaux. The leucocytes were 1,120,000 in number, and of various sizes and shapes. Two days after ten litres of oxygen three times daily was begun, the distorted and large leucocytes had entirely disappeared, and the red corpuscles formed rouleaux rapidly. At the end of a week œdema had almost disappeared, the temperature had fallen to normal, the white corpuscles had decreased nearly one-half, while the red had increased nearly-two-thirds. With the exception of a short period, during which, from indiscretions of the patient, the white corpuscles increased and the red diminished, he has steadily improved in every respect, the spleen being markedly reduced in size. From the time that oxygen was begun no drugs were given other than a mild hypnotic at night and, for a few days, Basham's mixture.

In the two cases of chlorosis, oxygen was used as an adjunct to iron, and the effects, though not as striking as in the leukæmics, were excellent.

At present the authors have a case of pernicious anæmia under the oxygen treatment, a report of which will be awaited with interest.

Corrosive Sublimate Hypodermatically.—In controlling late syphilitic manifestations, such as gummata, nocturnal headache, and periostitis, Dr. Langdon, of Cincinnati, has found the hypodermatic administration of corrosive sublimate satisfactory. He plunges the needle deeply into the muscular tissue, usually of the upper gluteal region. Some smarting follows the injection, but he has never seen an abscess produced. His solution is prepared by dissolving one part of the sublimate in three or more of glycerine, and diluting with water to the desired strength. To avoid precipitation, the solution should not be kept long.—*The Cincinnati Lancet-Clinic*, October 12, 1889.

Creasote for Diseases of the Air-passages.—Additional testimony as to the value of creasote in diseases of the throat, bronchi, and lungs is furnished by Dr. William Perry Watson, who, in the *Virginia Medical Monthly* for October, 1889, reports his results in fifty cases. His conclusions are that, while creasote will not cure all cases of consumption, yet it will benefit nearly all; that in cases with simply consolidation before the "breaking-down" process begins, it seems to arrest the diseased process, and further investigations will be required to ascertain its permanent utility, although similar cases observed for a long time by Robinson and Flint would convince us that the improvement was lasting.

In acute and chronic diseases of the bronchi, it was very beneficial, cases of the former being quickly cured, while those of the latter were improved sufficiently for them to leave the hospital in a short time. Another very important fact noticed in these experiments was, that the more constant the inhaler was worn, and the internal mixture taken, the more marked was the improvement; so that Dr. Waln was satisfied that, to obtain the full benefits of this treatment, the system should be saturated with the creasote as rapidly as possible; and while he would not expect miraculous cures, yet he believed it is, combined with good hygienic and dietetic

surroundings, the most promising treatment of consumption in the laboring classes we yet possess.

Dr. Watson in most cases used creasote both as an inhalation and internally. For inhaling he prescribes:

℞.—Creasoti
Sp. chloroformi
Alcoholis } . . āā equal parts.—M.

Sig.—Five to twenty drops to be used in the inhaler every three hours.

Or,

℞.—Iodoformi . . . . gr. xxiv.
Creasoti . . . . ♏ iv.
Ol. eucalypti . . . . ♏ viij.
Chloroformi . . . . ♏ xlviij.
Alcoholis
Ætheris } . āā q. s. ad. f℥ss. —M.

Sig.—Five to twenty drops to be used in inhaler every three hours.

For internal use:

℞.—Creasoti . . . . . ♏ xxiv.
Glycerinæ . . . . f℥j.
Spts. frumenti . . . ad. f℥ij.—M.

Sig.—Half a teaspoonful every three hours.

Creasote.—DR. J. E. NEWCOMB prescribes creasote for pulmonary phthisis in adults in the following mixture:

℞.—Creasoti
Tincturæ capsici } . . . āā f℥iij.
Mucilago acaciæ . . . f℥ss.
Aquæ . . . . . ad. f℥iv.—M.

Sig.—Dose, one teaspoonful well diluted.

The proportion of creasote may be reduced or increased, according to the age or toleration of the patient. —*College and Clinical Record.*

Formula for Migraine.—DR. HAMMERSCHLAG publishes, in the *Allgemein medicinische Centralzeitung*, the following prescription which he has found valuable in migraine:

℞.—Caffein citrat. . . . . gr. jss.
Phenacetin . . . . gr. iij.
Sacchar. lacti . . . . gr. v.—M.
Ft. Pulv.

Such a powder may be taken every two hours until the patient is relieved.—*The Provincial Medical Journal*, October 1, 1889.

Chronic Gonorrhœa.—DR. WILLIAM FLEINER recommends the following injection for chronic gonorrhœa:

℞.—Argent. nitrat. . . . . gr. j.
Lanolin . . . . . gr. l.
Ol. olivæ . . . . . gr. xx.—M.

The nitrate of silver should be dissolved in a minimum amount of water before incorporating with the other ingredients.—*Münchener medicinische Wochenschrift*, No. 40.

Tuberculosis in Children.—According to the *Medical Press and Circular*, DR. JACOBI believes that arsenic is a remedy of much usefulness in the treatment of tuberculosis in children, but it is necessary only to administer the drug in small doses. A young patient, for example, could take every day, and that for weeks or months, two drops of Fowler's solution. This dose should be diluted in a sufficient quantity of water, and given three times a day after meals. If any signs of saturation supervene, the dose should be withheld for a time. A second remedy of almost equal value in these cases, is digitalis. Under the influence of this drug the contractility of the heart muscle is strengthened, and, consecutively, the arterial pressure is increased, and the rapidity of the pulse diminished. The general effect of the increased arterial pressure is to favor the nutrition of the tissues. The choice of the particular preparation of the drug is a point of some moment. Oftentimes the infusion and the tincture are badly borne by the stomach; digitaline, on the other hand, is an inconstant preparation; thus the fluid extract is most to be recommended, either in pills or in capsules, and this can be dispensed with other drugs, such as iron.—*Cincinnati Lancet-Clinic*, October 26, 1889.

Poisoning from the External Application of Chromic Acid.—DR. J. WILLIAM WHITE reports the following case in the *University Medical Magazine* for November, 1889:

A young woman was suffering from non-specific vegetations covering the labia majora and the nymphæ, extending up toward the pubes and down toward the anus, and several inches in thickness. The vegetations had been treated for two weeks with cold poultices, after the method of Peters, of Prague. No improvement following, Dr. White ordered the usual application of chromic acid solution, of the strength of one hundred grains to the ounce of water, directing the neighboring parts to be protected and an excess of the acid to be avoided. The application was made on the afternoon of the same day. The acid solution was applied by means of a tuft of absorbent cotton, about a half ounce of the liquid being used. The vagina and anus were carefully protected by tampons of cotton soaked in carbolized oil. After coming from under the anæsthetic she complained of a burning pain referred to her vulva; this continued through the night, during which time she was restless, and frequently called for water. About 4 A. M. she rose to urinate, and fell; she was assisted to bed and slept until 7 A. M. She continued thirsty but not feverish, all the morning, complained of nausea, and refused her food. When next seen, at 3 P. M., she was pale, with cold extremities, rapid pulse, complained of pain in the left hypochondriac region, and expressed fear of approaching death. Temperature in axilla 99°. Although active treatment was instituted her condition did not improve, and she died at 6.30 P. M., twenty-seven hours after the application of the acid. Intellection was preserved to the last.

At the autopsy the cause of death was not evident, but portions of the viscera submitted to Dr. John Marshall for chemical examination showed that the kidney tissue and the liver tissue both contained chromium, most likely as sodium chromate—a substance poisonous in doses of from one to three grains. The chromic acid was absorbed, and entered into combination with the sodium of the sodium carbonate of the blood to form sodium chromate. This is the most probable explanation of what occurred.

[It seems not impossible that the prolonged poulticing may have had some influence in the unusual absorption of the chromic acid.—ED.]

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, NOVEMBER 2, 1889.

HYPNOTISM IN THERAPEUTICS.

THAT hypnotism is assuming a certain position in rational therapeutics, can no longer be denied by the unprejudiced, though its value is difficult to determine, and, being in a transitional stage, its future is impossible to prophesy. For more than a century, empirics have claimed that through it marvellous cures resulted, but, until the time of Braid, its literature was a mass of such mystical theories and absurd statements, that to the rational mind intentional imposture seemed the only explanation. Braid, of Manchester, was the first to study the subject in a spirit approaching the scientific, and to him is due much of the modern revival of interest. His conclusions, that this curious psychological condition could be explained without the aid of subtle magnetic fluid or mysterious force, were announced shortly after the Paris Academy of Sciences had autocratically declared the subject unworthy of further discussion, and at first excited little comment. Contemporaneous with Braid was Esdail, of Calcutta, who, utilizing the hypnotic state as an anæsthetic, performed more than six hundred surgical operations on patients under its influence. For a time, little credence was placed in his statements, but a committee appointed by the Indian Government finally substantiated them in every particular.

Systematic use of suggestions during hypnosis began with the so-called Nancy school of physicians, who, represented by Bernheim and Liébault, claim not only to cure all manner of ailments, but, with the assurance of the charlatan Mesmer himself, to elevate depraved characters and exorcise vicious propensities. The possession of such powers, however devoutly to be wished, is so entirely at variance with human experience, that the statements of this school are generally ridiculed and discredited. Charcot, who has added much to our knowledge of hypnotic phenomena, has studied it as a curative agent less than Voisin and other physicians of the Salpêtrière. Voisin has obtained indubitable cures of hysteria, hystero-epilepsy, and probably of dipsomania by means of hypnotic suggestions.

Among the insane he also claims excellent results: quieting mania, removing hallucinations, producing natural sleep, and controlling obstreperous patients. His assertion, that 90 per cent. of the mentally diseased are susceptible to hypnosis, opens his results to criticism, for it is incredible that so large a proportion can be induced to submit to the necessary procedures, and force would here be entirely useless. It is at least suggestive, that his most brilliant results have been in the treatment of French women, who are notoriously hysterical and imaginative. Furthermore, Voisin and other enthusiasts invariably lose sight of the dominating influence of a strong intellect over a weaker, and forget how much can be accomplished by excitation and skilful guidance of the imagination. Forel, another apostle of suggestive therapeusis, disagrees with Voisin as to its wide applicability in the treatment of insanity.

The most recent contribution to the literature of hypnotism in therapeutics, is from the pen of von Corval (*Therapeutische Monatshefte*, September, 1889), who publishes a long list of diseases in which he has seen suggestive therapeutics productive of remarkable results. If his statements could be unreservedly accepted, we have in the method almost a specific for acute alcoholism, neuralgia of all varieties, lightning pains of tabes, epilepsy, deafness, tinnitus aurium, asthma, and muscular rheumatism. Acute alcoholism he finds invariably benefited after a single sitting, the appetite and sleep returning, nervousness disappearing. He does not seem convinced that relapses can be prevented, but believes them less frequent than with the ordinary methods of treatment. For the relief of neuralgia he considers it superior to morphine, with more or less permanent effect. The convulsions of epilepsy, according to this writer, are reduced in frequency or altogether prevented. Deafness and tinnitus are

improved, if anatomical changes are not too great. The paroxysms of bronchial asthma are quickly relieved, the dyspnœa disappearing, and the patient falling into a comfortable sleep. Corval's results read like the advertisement of a patent medicine, and it is utterly impossible to accept them in their entirety. It is just such enthusiastic and sweeping assertions that prejudice the profession against the method as a whole, and keep it in disgrace.

Notwithstanding his apparent overstatement of facts, Corval's deductions are quite dispassionate. He believes that in suggestive therapeutics we possess a method of treatment which is in some cases curative, in others simply palliative; that with judicious selection of cases, and avoidance of unnecessary experiments, it is no more dangerous than many other curative means; that the indications and contra-indications being as yet imperfectly defined, its use should be confined to those cases in which the usual treatment is unsatisfactory or dangerous—replacing morphine in neuralgia and chloroform as an anæsthetic; that the method should be studied earnestly and scientifically; and, finally, to prevent abuse, its use should be confined, by law, to physicians.

As an anæsthetic it is extremely doubtful if hypnotism will ever replace chloroform or ether, as it is impossible to determine what individuals are susceptible, and every case must be an experiment. In hysteria and functional diseases of hysterics will its true field probably be found, though even here it is doubtful if its use becomes general. It is not to be forgotten that hypnotism has been followed by injurious effects: epilepsy has grown more severe, hysteria has been produced in the previously well, and permanent hysterical contractures have developed. In several instances it has been impossible to arouse patients from the hypnotic sleep for several weeks.

A few words on the methods by which the hypnotic state is induced may not be out of place. Braid's process, which is the one usually adopted, consists in requiring the patient to stare at any small, bright object held just above the bridge of the nose. This causes strong upward convergence of the eyes and a strain upon the ocular muscles, which assists in fixing the subject's attention. It is also essential that the surroundings be quiet, and that, as far as possible, the patient be convinced of certain success. After a variable length of time, in a susceptible person, the eyes close, when the operator tells him in a positive voice that they cannot be opened. If they remain motionless he is hypnotized, and the suggestions or commands deemed advisable are now given. With many individuals frequent attempts on succeeding days will be required, before success is attained, but with perseverance, probably more than one-third of all persons can be so influenced. The so-called "passes," or strokings, are apparently attended with no greater success than Braid's method, and while savoring more of charlatanism, possess, nevertheless, certain advantages over the employment of the fixed stare at a bright button, in that they are made by the operator, and do not require obedience on the part of the patient. This is particularly true in persons who are insane or unruly.

THE TREATMENT OF URETHRAL STRICTURE.

IN the London *Lancet* for September 14, 1889, is an admirable clinical lecture upon "Stricture of the Urethra and its Treatment," delivered by Mr. Walter Rivington, Surgeon to the London Hospital. One or two points upon which the lecturer dwelt, although neither of them might at first sight attract attention, are, nevertheless, of grave practical importance. The first of these points is that, in treating a stricture, the utmost care should be taken to avoid making a false passage. This injunction may appear trite, but unfortunately it is a necessary one. There is, probably, no surgeon of wide hospital experience who has not been called upon to deal with cases in which this unfortunate accident has occurred. In most instances it has occurred during efforts at catheterization for the relief of retention of urine resulting from alcoholic or sexual debauch, in a case of long-standing and neglected stricture. The stricture which, prior to the debauch, may have permitted the urine to pass, if only by drops, is occluded by congestion of the mucous membrane and muscular spasm. It is, in fact, for the time being at least, practically impermeable. In spite of this fact, however, attempts are made to get a catheter to go through it, and, one after another, successively smaller instruments are called into service until, finally, the smallest metallic catheter is passed down to the anterior face of the stricture. After prolonged efforts, something yields, the instrument advances, but not within the urethral walls—a false passage has been made; the congested, softened, unhealthy mucous membrane has been penetrated, and that without the employment of any consider-

able force. From this moment a new source of danger is added to the patient's already serious condition, and a vexatious obstacle is put in the surgeon's way.

Bearing in mind the fact that retention of urine may exist for twenty-four hours before danger of rupture of the bladder becomes imminent, it will be seen that very often there is really no immediate necessity for resorting to the use of a catheter. Even should there be imperative demand for speedy relief, we have the resource of suprapubic aspiration of the bladder. Mr. Rivington's advice that in dealing with cases of retention, the physician should, wherever practicable, abstain from catheterism, "especially from the employment of the finer instruments," we consider sound. To use his own language, when speaking of a case applying at a hospital: "If a No. 5 or 6 (English) silver or flexible olivary catheter can be gently passed, well and good; if not, the patient should be taken in, ordered a warm bath, a drop or two of croton oil, or a dose of house medicine, and afterward some tincture of opium or a similar sedative, whilst warm fomentations are applied to the abdomen. Retention of urine generally yields to these measures within twenty-four hours." This latter statement will be supported by practical surgeons. It will be seen, therefore, that one way to avoid making false passages is to be tardy in the employment of instruments capable of doing mischief.

Another point dwelt upon by Mr. Rivington is the value of rest in the treatment of stricture. Practical experience has established so clearly the beneficial action of rest in the recumbent posture in cases of tight stricture, that it is scarcely necessary to allude to it; but it is well to bear in mind the value of preceding a period of active treatment with one of wholesome inactivity.

Such observations as these are of the greatest use to those to whom they were originally made—students of medicine—and are not without value to the general practitioner, and while the surgeon who is skilled in the treatment of genito-urinary diseases may, for the moment, think such points so obvious as not to need comment, he will, upon reflection, realize their import to others less familiar with the subject than himself.

The opening meeting of the D. Hayes Agnew Surgical Society of the University of Pennsylvania will be held in the University Chapel, Saturday, November 2, 1889, at 8 P.M. Addresses will be made by Dr. William Pepper and Dr. D. Hayes Agnew, President Ex-officio.

REVIEWS.

Hand-book of Materia Medica, Pharmacy, and Therapeutics. Compiled for the use of students preparing for examination. By Cuthbert Bowen, M.D., B.A. Duodecimo, pp. 366. F. A. Davis, publisher; Philadelphia and London, 1889.

The author's object, as stated in his preface, has been to furnish to the student a book containing, in a compact form, the questions and answers generally encountered in coming up for examination. That the volume is not intended as a text-book, the author himself appreciates.

The general plan is similar to that of like manuals already at the student's command. The book opens with some good practical remarks upon and rules for proper prescription-writing, dosage, and administration of remedies. Following this, the author gives a very full list of drugs chemically and pharmaceutically incompatible. The remainder of the volume is occupied by questions and answers relating to the source, nature, preparations, doses, physiological actions and uses of the various drugs. A good feature of the book is the presentation o a number of typical prescriptions containing each drug as it is mentioned.

The author supports the use of the term hypodermatic as opposed to hypodermic, but throughout the volume uses the latter word. It is unfortunate that none of the more recent hypnotics and antipyretics have been mentioned. This, of course, deprives the book of much of its value as an aid to students.

Although, with the above mentioned exceptions, most of the drugs are fully dealt with, there are many important remedies, notably hyoscin, that have received but scant mention.

The form in which the book is prepared is attractive, but its range of usefulness is strictly limited to the particular class for whose benefit it was written.

Wood's Medical and Surgical Monographs. Volume I. Number 2. Octavo, pp. 267. New York: William Wood & Co., February, 1889.

Considerably more than one-half of this, the second number of the series, is devoted to an exhaustive treatise by Dr. William Japp Sinclair on Gonorrhœal Infection in Women. The first two chapters are mainly historical, showing how this important subject has been neglected, yet how frequent the disease is in females, and by what serious sequelæ it is followed. Dr. Sinclair does not seem to think Noeggerath's statement exaggerated, that in New York eighty per cent. of all men have had gonorrhœa, ninety per cent. of whom remain uncured, and that ninety per cent. of women marrying these men are infected. Have more than *one-half* of the women in New York some disease the result of gonorrhœa? We hope not, and believe not.

Neisser's gonococcus is unreservedly regarded as the causation, and its presence a pathognomonic sign. "If gonococci are present in the discharge from an inflamed mucous membrane the discharge is of gonorrhœal origin." "Without the gonococcos there is no gonorrhœa." Dr. Sinclair virtually denies that urethritis in the male is ever caused by non-specific discharges in the female. The remaining chapters are devoted to the

complications, uterine, tubal, ovarian, and urethral, of gonorrhœa in the female, to prophylaxis and to treatment.

The whole article represents an immense amount of research and reflects the most advanced medical thought. Following this essay are three lectures of Dr. Thomas Grainger Stewart on Giddiness, a subject which is carefully reviewed in detail as a symptom of cerebral, aural, and gastric disturbances. Dr. Stewart's profound knowledge and happy style make these lectures valuable alike to the student of nervous diseases and to the general practitioner.

The remaining monograph—A Critical Study of the Clinical Value of Albuminuria in Bright's Disease, by Dr. Pierre Jaenton—is a fair representation of the latest views on this much-discussed subject. An extensive and valuable bibliography is appended to several of the chapters.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS. Vol. II., No. 2. ON THE PREVENTIVE TREATMENT OF CALCULOUS DISEASE AND THE USE OF SOLVENT REMEDIES. By SIR HENRY THOMPSON, F.R.C.S., M.B.

SPRAINS: THEIR CONSEQUENCES AND TREATMENT. By C. W. MANSELL MOULLIN, M.A., M.D.

IN the article by Sir Henry Thompson, given us in this number of the so-called *Monographs*, the advanced and logical idea of the day in respect to the treatment of stone in the bladder is clearly stated. Careful reading of this paper impresses one with the fact that the old proverb, "an ounce of prevention is worth a pound of cure," obtains more largely in relation to such troubles than is generally supposed, and we learn that the greatest of living genito-urinary surgeons relies not upon the solution of stones already formed, but upon the measures directed to the systemic states which predispose to their formation. His idea in this respect is, briefly, to prevent their development, and this failing, to resort to surgical relief. Not one case in a thousand has been cured in the past by the methods resorted to for the solution of the stone.

By far the largest part of the volume is, however, taken up with the article on "Sprains," written by Moullin. This is the most exhaustive paper concerning these rather common accidents that we have ever seen, and is also one of the clearest and most intelligent in its dealing with the subject at hand. The anatomy of the parts involved, the conditions of the muscles predisposing to such states, the symptoms present after the reception of the injury, and, finally, the sequelæ so commonly seen after ruptures of ligaments, are all taken up and considered with great thoroughness and exactitude. The chapters on treatment are extremely well written and practical, and are worthy of the series which they so well represent.

THE RADICAL CURE OF HERNIA BY MEANS OF THE BURIED ANTISEPTIC ANIMAL LIGATURE. By HENRY O. MARCY, A.M., M.D., LL.D. 12mo., pp. 251. Detroit: George S. Davis, 1889.

THIS number of the "Physician's Leisure Library," which has just been received, is presented in the same attractive shape as its predecessors. It is a very complete monograph upon the various forms of hernia, and the different methods employed for their radical cure, from the earliest times to the present day. The author claims no originality in the performance of his operations, but simply details the results attained and the conclusions arrived at during a careful study of hernia, and in an extensive operative practice of eighteen years.

The classification of herniæ in the introductory chapter would, from its multiplicity of terms, tend rather to confuse than aid the average reader, for, among other things, we cannot conceive that the terms "supra-pubian" or "infra-pubian" convey any more distinct idea than do inguinal and femoral. The anatomical relations of the structures involved, in the various forms of hernia, are exhaustively considered, and the illustrative plates are well selected.

After an elaborate series of tables, showing the relative frequency of the occurrence of hernia, the author proceeds to give a careful *résumé* of the radical operation, discussing with great minuteness the indications for it, the manner of preparing both patient and operator, the actual surgical procedure, and the necessary after-treatment. The methods of ligation of the sac and closure of the ring are clearly and concisely described.

Dr. Marcy has evidently spared no pains in collecting and carefully arranging the views of the best surgeons, both in this and other countries. His style is easy yet forcible, and the reader cannot fail to be interested by his masterly treatment and clear exposition of the subject.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 1, 1889.

THE PRESIDENT, G. W. JACOBY, M.D., IN THE CHAIR.

DR. A. A. BOYER presented a case of

LESION OF THE PONS,

with a history, of which the following is a brief synopsis:

C. W. B., aged forty-five, syphilitic, in June, 1888, while at work, felt a sudden sensation at the occiput, as though he had been shot. It was immediately followed by intense headache and nausea. Later, vomiting and insomnia became prominent symptoms, lasting for six weeks. There was then an interval of two weeks without these symptoms, after which they returned in greater severity. On August 14th, his left thigh became cold and numb; which sensations, in a few hours, extended up the trunk, left arm, and left face. In the morning there was anæsthesia with paralysis of the entire left side of the body. When first seen, eight months later, he had a hemiplegic gait, inco-ordination and paralysis of the left arm, good equilibration, paresis of the left leg, drooping of left side of mouth, and left-sided hemianæsthesia and hemianalgesia. The lesion would, therefore, seem to be located in the pons, to the right of the median line, above the line of Gubler, and involving the fillet, the reticular formation, and pyramidal tract. The speaker thought a lesion here would be high enough to produce paralysis of the facial muscles of the opposite side, and

low enough to leave unaffected the ocular nerves. He believed the most reasonable theory as to the nature of the lesion was thrombosis resulting from obliterating endarteritis or hemorrhage.

Dr. Birdsall saw no necessity for assuming a lesion of the pons to explain the symptoms, which seemed to be wholly unilateral. He usually expected something particularly characteristic in pontic lesions, such as alternating paralysis. He thought a capsular lesion would account for all the symptoms in this case, the absence of other pontic features strengthening such a view.

Dr. Starr agreed with Dr. Birdsall as to the localization of the lesion. He believed the case to be one of ordinary hemiplegia, with a lesion in the internal capsule. Unless there were alternating paralysis, or some other characteristic symptoms, it was unnecessary to locate the disease in the pons.

Dr. Boyer in closing the discussion said he located the lesion in the pons because there was no loss of consciousness at the onset of the attack, although decided and varied paralyses immediately followed. In his opinion this pointed strongly to a minute lesion, which only in the pons could produce such marked symptoms. The inco-ordination now remaining after the disappearance of most of the motor symptoms indicated a lesion of the fillet or of the commissural fibres in that vicinity.

Dr. L. C. Gray then read a paper entitled,

THE CURABILITY OF LOCOMOTOR ATAXIA.

Speaking first of the modern knowledge of the pathology, he then went into the question of histology. He regarded the original focus of disease as a cellular or inflammatory alteration of the cord, sometimes possibly a meningitis, from either of which the ascending secondary degeneration started. Erb and Schultze had reported a case of indubitable locomotor ataxia, in which the cord was examined microscopically, and in which the symptoms had disappeared almost entirely for some twelve years. He did not believe there was a cure on record, although it is unquestionable that many cases of great improvement had been reported, more especially among those with a history of syphilitic infection.

Dr. Gray narrated a case of his own, illustrating the association of locomotor ataxia with general paresis, the mental hebetude of the latter disease causing an apparent improvement in the former.

Dr. Dana said that we had changed our conceptions as to the variations in clinical types and as to the pathological lesions of locomotor ataxia. Probably ninety per cent. of our cases are typical and answer to the classic descriptions of the disease, but there is a minority of cases which have non-typical manifestations, types with optic atrophy, latent, spinal and spastic symptoms, with peripheral lesions, etc., and the prognosis varies in these forms. For instance, in the spastic variety, the prognosis is not bad, but exceedingly so where there is rapid emaciation of the lower extremities. He had recently examined his notes, and the results of treatment in 56 cases, which were as follows:

10 very much improved (3 syphilitic);
6 improved (4 syphilitic);
14 stationary (3 syphilitic);
13 progressive (6 syphilitic); 2 fatal;
10 doubtful, or unknown.

He believed locomotor ataxia to be a degenerative disorder, affecting nerve fibres primarily, not beginning at a single focus, but at different places at various times, and to cure the disease we should have to discover a drug which would stop this degenerative process. As to suspension, he had tried it in twenty-two cases, with six hundred suspensions, since last April. Of these, four were much improved, six improved, six unimproved, and six discontinued the treatment.

Dr. Birdsall coincided with the speaker in the opinion expressed as to the incurability of the disease. In one of his own cases, a syphilitic, ataxia had disappeared for nine years, although the patient now suffered again from various crises, gastric and laryngeal, and some cerebral symptoms. For five years the active symptoms had been referred to the trunk and upper extremities. He had seen other very similar cases and could speak of none as cured.

He had tried suspension in a few cases, with no favorable results, though he did not deem it wise to cast it altogether aside.

He had seen injurious effects from large doses of potassic iodide, and, in his opinion, tabetic cases could not tolerate this drug as well as others.

Dr. Starr said, with regard to the differential diagnosis between peripheral and cerebral cases, we first judge from the order in which the symptoms occur, as well as from the symptoms themselves, which in the former class developed more rapidly than in the latter.

Some seven years ago, Dr. Austin Flint read a paper in this Academy upon the self-limitation of phthisis, and a description similar to his might apply to locomotor ataxia. It is possible that the sclerosis of the cord may be a protective process, an effort of nature to arrest or provide against the effects of disease; indeed, a pathologist of this city has taught for two years that connective tissue is always thrown out by nature as a defence. Thus, locomotor ataxia might be a self-limited disease like phthisis in a few instances.

His own records showed 25 cases seen in the last four years, 17 of which are carefully detailed. In 9 of the 17 there had been various periods of non-progression, while in 8, with similar treatment, there had been steady advance. He thought specific treatment worthy of trial in patients with a syphilitic history, but he had little faith in its efficacy, as in his experience it afforded less benefit in locomotor ataxia than in other specific nervous affections. He usually employed the English treatment—small doses of arsenic and biniodide of mercury.

Among 13 patients treated by suspension at the Vanderbilt Clinic, tabulated by Dr. Peterson, there were 7 cases of locomotor ataxia. In 2 cases only had there been distinct improvement, and none at all in 4, while in 2 the results were injurious, the suspension producing syncope, nausea and vomiting, severe pain, and enuresis at different times.

Dr. Sachs had observed in two cases the disappearance of the cardinal symptoms of locomotor ataxia, without treatment. The first was as follows:

B. L., merchant, aged forty-eight, seen August 18, 1886. His symptoms were retching, dizziness, numbness of arm, unsteadiness in walking, absence of knee-jerk, slight swaying with closed eyes, and a feeling as though his drawers were too tight around the waist. Dr. Sachs

had made the diagnosis of tabes incipiens, though with some hesitation, for the general condition of the patient was very good. After two months a slight knee-jerk had returned on the right side, and later the left was recovered. Three years had now elapsed since the observation of these symptoms, and the man was in perfect health at the present day. He believed it to have been a functional derangement of the cord, due to overwork.

In syphilis a simple specific spinal meningitis might simulate a posterior sclerosis, and should be borne in mind when cases improve under treatment.

Suspension he had found unsatisfactory in ataxia, but in spastic cases, such as myelitis, it seemed to him of more use.

DR. WAITZFELDER had used suspension in a case of spastic paraplegia, which became worse, but he had noted considerable improvement in gait in several ataxics who were subjected to this method of treatment.

DR. GRAY then closed the discussion. He said that Fournier's and Rumpf's specific cases showed great improvement under treatment, but such had not been his own experience. He believed that in certain cases there would be great difficulty in distinguishing peripheral from central symptoms. As to self-limitation, mentioned by Dr. Starr, he saw no analogy between tabes and phthisis. In treatment he preferred to follow French authors and employ inunction in specific cases, rather than potassic iodide, for the results were better in his experience.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

R. C. M. PAGE, M.D., CHAIRMAN.

Stated Meeting, October 15, 1889.

DR. A. JACOBI read a paper on

CHRONIC PERITONITIS, WITH SPECIAL REFERENCE TO THE DIFFERENTIAL DIAGNOSIS OF SOME OF ITS VARIETIES.

Having enumerated a number of the causes of peritonitis, Dr. Jacobi said that perhaps the most frequent was a preceding attack. In autopsies upon cases of perityphlitis, he did not remember one without adhesions and other evidences of previous inflammation, and foreign bodies in the vermiform process were, in his opinion, seldom, if ever, a cause of the disease. Both enteritis and ulceration, acute or chronic, were also the causation in some cases, the inflammation extending by continuity; thus it was that a simple diarrhœa might become an enteritis and terminate in peritonitis.

Old local peritoneal adhesions over a cicatrized ulcer of the stomach or intestine, were soft and prone to rupture, and this was probably a frequent cause of acute peritonitis in persons apparently perfectly well. In diagnosis, chronic peritonitis was frequently overlooked, the intestines becoming glued together, or floating kidneys being fixed by adhesions without recognizable symptoms or signs. In chronic peritonitis, respiration was not necessarily accelerated, particularly if the inflammation was in the pelvis.

Vomiting was occasionally present, but perhaps not as frequently as in other conditions, and was often entirely absent even in acute peritonitis. Either constipation or diarrhœa might be present. A horizontal position might be painful, but this was also not infrequently the case in ordinary colic from accumulated gas, though in the former condition the patient was more likely to remain quiet than in the latter. Tumidity might be observed, but was often difficult to distinguish from the fat, which is so common in this situation, or from hysterical tympany, or distention from habitual constipation. The superficial abdominal veins were more frequently dilated in chronic peritonitis than in any other condition excepting certain hepatic diseases. Inspection might also show swellings, corresponding to intestinal convolutions, and palpation might reveal hard or soft exudations in the form of nodules or cakes, which consisted of organized lymph, thickened omentum, or a mass of intestines glued together. Fluctuation would indicate the presence of fluid more certainly than percussion dulness, which might be rendered uncertain by the presence of adhesions, retaining the distended gut between the abdominal walls and an accumulation of fluid. A chronic peritonitis may be sometimes discovered by placing the patient on his back, and having him alternately flex and extend his thighs; while doing this, pressure of varying depths is made by the physician, who may in like manner discover a painful area. In many cases, however, a better method is to make deep pressure with the fingers or palm, and on suddenly removing them a painful spot may be detected; the pain being caused by a sudden change in the position of the bowels. Every changed position of the intestines or other abdominal organs, may cause pain: hence, in adhesions to the stomach, pain may be felt after a full meal; pain several hours later, may indicat adhesions to the colon; pain on coughing, or quickened inspiration, a perihepatitis; pain at the end of micturition, a peri-cystitis. Pain, of varying degree and duration, was, in Dr. Jacobi's opinion, a very frequent symptom in chronic peritonitis. The seat of the pain would vary with the location and extent of the lesions. Extensive pelvic peritonitis might give rise to pain only during defecation, sexual intercourse, or micturition. The pain of peri-cystitis resembled that of vesical catarrh in coming on when the bladder was about one-half emptied, but differed in being more localized above the pubes, and more readily detected by pressure. In some cases the pain of chronic peritonitis could not be distinguished from that of flatulent colic; indeed, peritonitis by interfering with peristalsis, may cause not only flatulence but twisting of the gut and stenosis.

The remainder of Dr. Jacobi's paper was devoted to the subject of tabes mesenterica. That there were several distinct varieties of this disease he thought was proven by the histories and symptoms of different cases. Besides the simple infiltrations of the mesenteric glands causing tabes mesenterica, chronic tubercular peritonitis would produce the same symptoms. Recognition of the latter condition was usually difficult, but in some cases it could be determined with certainty. Of course, in such the prognosis would be fatal; in others uncertain.

DR. FRANCIS DELAFIELD spoke of the frequency with which chronic peritonitis arose for diagnosis, how many mistakes were made concerning it, and of its great importance. He divided the cases into three classes; those in which there were simple adhesions of connective tissue, those in which there were both adhesions and serous or purulent fluid, and the cases in which there was diffused thickening with fluid, but without adhesions. The first

condition was often not detected until the autopsy. When in addition an enlarged liver existed, it was frequently confounded with tubercular peritonitis. Other conditions, from which it was difficult to distinguish this class, were irritable colon and dilated pylorus. The second closely simulated carcinoma and tubercular disease of the peritoneum. The third class was difficult to diagnosticate, not only from the latter conditions but also from cirrhosis of the liver.

DR. WILLIAM H. THOMPSON spoke of the remarkably low percentage of urea in the urine of patients with cancerous disease, as a point that might sometimes be of diagnostic value.

DR. L. WEBER said that he had never seen a case of chronic peritonitis that was not infectious in character. He did not look upon the cases mentioned by Dr. Jacobi as really cases of chronic, but of acute peritonitis and its results. Tabes mesenterica, he believed, was always a tubercular disease.

Stated Meeting, October 17, 1889.

THE PRESIDENT, ALFRED M. LOOMIS, M.D., IN THE CHAIR.

DR. LEWIS A. STIMSON read a paper on

GUNSHOT WOUNDS OF THE ABDOMEN, WITH SPECIAL REFERENCE TO WOUNDS OF THE INTESTINES.

Dr. Stimson said that in upholding laparotomy for gunshot wounds of the abdomen it was not sufficient to show that some patients had survived the operation, nor that in cases operated upon such a procedure alone would have saved life, but it should also be shown that a larger proportion of patients recovered with operation than without. Even this being so, it might still be a question whether the cases to which laparotomy was adapted could be selected from among others in which operative interference was uncalled for, and consequently injurious. The speaker, after mentioning the few cases in which laparotomy had been performed for gunshot wounds of the intestines prior to the introduction of antiseptics, reported three recent cases in his service at the hospital, two of the operations being performed by himself, and one by his house surgeon; the latter patient, in whom there were six perforation of the intestines by a 38-calibre pistol bullet, died forty-eight hours after the operation. In one of his own cases a 32-calibre bullet had made several perforations; the operation, twelve hours later, was promptly followed by death. In his other case the calibre of the bullet was 22, and operation nine hours after the injury was followed by recovery. Four perforations of the intestines were found.

In the Chambers Street Hospital, between 1876 and 1889, there had been treated, without laparotomy, 13 gunshot wounds of the abdomen, with 11 deaths; with laparotomy, 12 cases and 9 deaths. In the New York Hospital had been treated, without operation, 4 cases, with 2 deaths; with operation, one case, which was fatal. At the Roosevelt Hospital, treated, without operation, 6 cases, with 2 deaths; with laparotomy, 3 cases, all of which were fatal. Thus the mortality without operation had been 65 per cent., while with operation it had been 81.2 per cent.

When a bullet penetrated the abdominal cavity, the possibility of its not wounding the viscera was so slight that it should have no influence on treatment. The symptoms were divided into three classes, namely, those common to all serious injuries, those peculiar to visceral injuries, and those excited by the pathology. Shock, though often extreme, he believed as likely to be emotional as physical.

The speaker opposed rectal injections of hydrogen gas for diagnostic purposes, as it was liable to cause extravasation of feces; and in case of doubt he believed it better to make an exploratory incision. If operative interference was to show superior results, it must be undertaken early, before the bad symptoms following shock had set in. If not done then, it should not be attempted. The argument might be advanced that the patient would die without laparotomy; but since, if delayed, he would be more likely to die with it, its performance could only bring surgery into disrepute.

Dr. Stimson closed with the statement that no rules for interference or non-interference could be drawn, and that the surgeon should be guided by his convictions in each particular case.

DR. J. A. WYETH thought that the question of operation was involved in about as much doubt to-day as it was nine years ago, when Dr. Sims read a paper on the subject before the Academy. He thought one had to be guided by the condition of the patient, situation of the wound, direction and size of the missile. The smaller the bullet the less demand there was for an operation. If the patient when first seen was weak, and there was extravasation of fecal matter, he would simply enlarge the abdominal wound for better drainage.

DR. ROBERT ABBE said that though the view was commonly held that a small bullet entering the abdomen was of less importance than a large one, experience had shown that a calibre of 22 not infrequently made a very large intestinal perforation. He agreed with Dr. Stimson and Dr. Wyeth, that where a number of hours had elapsed after the injury, lymph having formed around the wounds, drainage was all that should be attempted. Earlier, laparotomy should be done. If penetration was doubtful, cocaine or nitrous oxide were safer anæsthetics than ether, which caused vomiting. He spoke against immediate anastomosis in resection, and in favor of establishing primarily a fecal fistula. Too little, rather than too much, should be done.

DR. WILLY MEYER mentioned a case in which the bullet, entering the abdominal walls, and passing through the lung, penetrated near to the spinal column, where it could be externally felt. Though there was vomiting of blood, at the laparotomy, some hours after the wound had been inflicted, only the outer coat of the stomach was found injured, the bullet not having penetrated the mu cous coat. The patient died, but a post-mortem was not obtained.

DR. B. F. CURTIS thought statistics by one experienced operator might show a higher percentage of recovery than where laparotomy was not done. He preferred chloroform to ether.

DR. THOMAS MANLEY referred to a case which he had already reported, of four perforations of the intestine by a bullet, the operation being followed by recovery. He also mentioned two others without operation, one recovering, the other dying from internal hemorrhage. It had been argued that operation should not be attempted during shock; but he thought that if the operation was

not done then, it should not be done all, for adhesive material was very soon thrown out, and an attempt made by Nature to close the wounds; to disturb the case then would add to the inflammation.

DR. STIMSON said, in answer to Dr. Curtis, that collective experience might be of value in the selection of cases, but that proficiency in operating would have to come from general surgical experience.

CORRESPONDENCE.

LONDON.

(From our Special Correspondent.)

On Medical Education in the United Kingdom.—The methods resorted to by persons desiring to obtain the right to practise medicine in Great Britain, differ so radically from those carried out in other parts of the world, and are so little understood by many Englishmen themselves, that a few words on the subject may not be out of place at a time when Americans seem to be coming more frequently to London for medical training.

Here, when a man chooses the career of a medical practitioner, the first thing to be done is to get his name registered as a medical student; and no medical studies are allowed to be reckoned until this necessary step has been taken. Before he can be registered, the intending student must produce evidence of having passed a preliminary examination in English, Latin, elementary mathematics, and elementary mechanics, and in one optional subject, a choice being given him between Greek, any modern language, botany, or elementary chemistry. This examination is by no means formidable, and many boys pass one that is accepted before leaving school.

The registration is accomplished under the auspices of the General Medical Council, a body charged with the supervision of all matters pertaining to medical education and registration, and the student will have no further official relations with this august body until he presents himself with his diploma or licence to practise, which he must register before he can obtain his full privileges as a duly qualified medical practitioner; before effecting this registration he will have to pay a fee of five guineas (about twenty-six dollars), and he will then, and not until then, be entitled to hold appointments in the public services, sign certificates, and give evidence in the law courts, which an unregistered practitioner, no matter what diplomas or medical degrees he holds, cannot do.

Between the initial and the final registration a period of at least forty-five months must elapse, comprising at least four winter and three summer sessions, and the student must have passed examinations satisfactory to the Medical Council in all the main branches of medical knowledge, and his diploma or licence to practise must entitle him to practise in medicine, surgery, and midwifery. This latter requirement is quite a modern innovation—in fact, it is only of two years' standing. Formerly there were many bodies which could only give what was called a single qualification—*e. g.*, the College of Surgeons, which could only confer upon its members the right to practise surgery. This qualification alone is now not registrable, and, consequently, the College of Surgeons has entered into a combination with the College of Physicians, and the two bodies conduct a joint examination, at the conclusion of which, if successful, the student will have the necessary double qualification and can have his name placed on the register.

There is abundant scope for choice as to the channel through which the qualifying degree or diploma is to be obtained; the decision is not, however, so difficult as it may seem when looking at the list of institutions, and is probably determined in great measure on personal grounds. The bodies which have the power of giving qualifications may be conveniently divided into two groups, viz., those which are educational as well as examining bodies and those which only examine. To the former group belong most of our universities, in fact all but one, They are, in England, the Universities of Oxford, Cambridge, Durham, and the newly created one in Manchester, the Victoria. Scotland boasts of those of Edinburgh, Aberdeen, St. Andrew's, and Glasgow; whilst Ireland has two, viz., Trinity College, Dublin, and the comparatively modern Queen's University. The licensing bodies which only examine, are, the London University, the Colleges of Physicians and Surgeons, and the Society of Apothecaries, in England. In Scotland there are the Colleges of Physicians and Surgeons in Edinburgh and the Faculty of Physicians and Surgeons in Glasgow; these three bodies have amalgamated to hold a conjoint examination in the same way as those of London; and in Ireland there are the Colleges of Physicians and Surgeons, and the Apothecaries' Hall. I believe that the two latter have arrived at some form of conjoint examination arrangement.

The only portal to our register is through one or other of these examining bodies, so that no foreigner, including thereby any one from one of the colonies, can become a legally recognized practitioner in this country until he has submitted himself to the ordeal of examination at one of the above-mentioned institutions; but having once succeeded in getting his name on the register, he can then register his foreign degree or diploma, if obtained at any recognized university. This is a concession that was only obtained two years ago, when the last Medical Act was passed.

In the case of the Scottish universities it is the rule for a student to spend his whole medical career at his university; but in England this is most unusual. At Oxford it would be almost, if not quite, impossible, and at Cambridge it is almost unknown for a medical student to complete his whole medical career, the custom being for the last two or three years to be spent either in London or at one of the chief provincial medical schools; whilst in the case of those who are not entered at one of the universities mentioned in my first list, the choice of a medical school becomes an imperative necessity. Here, again, he has plenty of choice, as in London there are eleven more or less fully equipped schools, whilst in the provinces he can choose between Manchester, Liverpool, Birmingham, Leeds, Sheffield, and Bristol; in Scotland, Edinburgh and Glasgow, and in Ireland, Dublin, offer facilities for the education of those who are unable or unwilling to enter at one of the universities.

ST. LOUIS.

To the Editor of THE MEDICAL NEWS,

SIR: At this season of the year all are interested to know something of the prospects of the medical col-

leges in the various sections of the country. Here in St. Louis we have four colleges of the regular school of medicine, viz., The Missouri Medical College which was founded by the celebrated Joseph Nash McDowell, and which is now a department of the State University; the St. Louis Medical College, with which was identified in its early years the celebrated Dr. Charles Pope, and later the no less distinguished Dr. John T. Hodgen; the College of Physicians and Surgeons, founded by Dr. Louis Bauer; and last, the Beaumont Medical College, named from the eminent physician whose observations upon Alexis St. Martin have made his name familiar to every student of physiology.

Of these colleges "The Missouri" requires the legal "three years of study and two courses of lectures," and the Dean reports two hundred students as having matriculated this year.

St. John's Hospital is adjoining the college building, and supplies material for clinical lectures, the hospital staff being composed of members of the college faculty. The college building is on the northeast corner of Lucas Avenue and Twenty-second Street.

The St. Louis Medical College is situated much farther down town on the northeast corner of Clark Avenue and Seventh Street.

The faculty of this school have long taken an advanced position with reference to the proper requirements for a medical education, and have for several years past required for graduation an attendance upon three courses of lectures and a preliminary examination of all who cannot offer either a college or high school diploma or a first-grade teacher's certificate. The Mullanphy hospital on Grand Avenue is under the control of this school and affords a large amount of valuable clinical material.

The number of matriculants reported from this school is sixty.

The Alumni Association has for the last two years been very successful in arousing and keeping the interest of its members. They have each year a course of lectures by eminent scientists and others.

The College of Physicians and Surgeons, situated on the corner of Eleventh and North Market Streets, was organized in 1878, under the leadership of Dr. Louis Bauer. After continuing for some four or five years most of the members of the original faculty resigned and Dr. Bauer reorganized the faculty, and at present the members are mostly men new to professional honors, though several have been prominent in the councils of the St. Louis Medical Society.

One curious feature of the present organization of the faculty is that an ex-president of the St. Louis Medical Society and one who recently narrowly missed achieving that distinction, sit side by side with a member of the profession whose efforts to secure admission to that society were frustrated, largely by the active opposition of the former.

The number of matriculants reported from this school is about one hundred and twenty-five.

It may be of interest to mention that among the first corps of instructors in this college was Dr. P. H. Cronin, whose murder in Chicago a few months ago has attracted so much attention throughout the country.

The youngest of the regular medical schools in our city is the Beaumont Medical College, which has just entered upon its fourth year of lectures, and has been met on the threshold with a great calamity.

The first step taken by the members of the faculty when they effected an organization four years ago was the purchase of a building on Walnut and Sixteenth Streets, which had been erected for a church some years before, but vacated by the congregation. The site selected was an eligible one and by the expenditure of a few thousand dollars the building was admirably adapted to the purposes intended by its new owners.

The school has prospered and graduated three classes.

On Tuesday night, October 8th, the entire building was consumed by fire, together with the museum of pathological and anatomical specimens belonging to Prof. Waldo Briggs, most of which were prepared by himself, and a costly series of wax models valued at several thousand dollars.

When it became known that the Beaumont College building had been burned, the faculties of the St. Louis College and of the College of Physicians and Surgeons, tendered the use of lecture rooms in their buildings until other permanent arrangements could be made. Both of these offers were, however, declined with thanks and the faculty have arranged to deliver their lectures in the building on the corner of Fourteenth Street and Lucas Place, formerly a private residence. New buildings will shortly be erected, but whether on the old site or farther west has not yet been determined.

The number of matriculants enrolled before the fire was between sixty-five and seventy.

Besides the above mentioned regular medical schools there is the "St. Louis Post-Graduate School of Medicine," some of the professors in which are connected with one or other of the graduating schools.

A rumor is afloat that the faculty of the Post-Graduate School of Medicine would be willing to dispose of their handsome building to the faculty of the Beaumont Medical School, but for the opposition of certain members who are also connected with the Missouri school and who object to the location of a rival but two blocks away.

THE RADICAL CURE OF HAY-FEVER.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of October 12th, your correspondent A. H. L. directs attention to "The Radical Cure of Hay-fever with Chromic Acid."

The article is certainly interesting reading, and the statements of the author inspire one with the conviction that he has made frequent applications of chromic acid, in weaker or stronger solutions, to nearly the entire surface of the nasal passages. What is not at all clear, however, to the careful reader, is upon what basis of accurately observed cases the writer has acquired the right to affirm that he has discovered in the use of chromic acid the radical cure of hay-fever. What the writer of the article has apparently accomplished with chromic acid, has been done, as I believe, with more than one agent by others. I have ameliorated in a marked degree numerous cases of hay-fever by the judicious use of the galvano-cautery. There is nothing new about this, since it is the common property of the profession. I have, on several occasions, effected notable and enduring benefit by applications of carbolic acid and glycerine, or carbolic acid and vaseline, to nearly

all parts of attainable nasal mucous membrane. I have never yet had what I have been able to regard as a *permanent* cure of hay-fever, by any topical agent. My own experience at the present time of writing is, I am convinced, the experience of many of the best observers in our profession—among those who are throat specialists.

It seems judicious, therefore, before any method of treatment, especially if it has merely the aspect of novelty, is relied upon to *reduce*, if not *entirely obliterate*,[1] some of the most difficult cases we, as specialists, are called upon to treat, that forthcoming facts should be numerous and followed up carefully during several spring, summer, or autumnal seasons.

Truly yours,

BEVERLEY ROBINSON, M.D.

NEW YORK, October 16, 1889.

AMERICAN PUBLIC HEALTH ASSOCIATION.

(*From our Special Correspondent.*)

To the Editor of THE MEDICAL NEWS,

SIR: The annual meeting of the American Public Health Association convened on Tuesday, October 22d, at Brooklyn Institute, and probably was the most successful gathering that the Association has ever held. Not only did it bring together representative sanitarians from almost every State of the Union and from Canada, but it also excited general attention throughout the entire country. This was made evident not only by the large number of daily papers which recognized the progress of its proceedings, but also by the unusually great attendance of the public at the general meetings. Owing to the facilities which had been provided by Drs. Raymond and Bell and their associates, everything was favorable to a pleasant and profitable meeting.

The President's Address was worthy of the occasion and of the reputation of its author. After speaking briefly of the increased adoption of sanitary measures, and of the consequent prolongation of life and increase of prosperity, he proceeded to show the social and pecuniary value of preventive and sanitary precautions, quoting from Richardson the actual results which had been attained in England. From these he showed that within a few years the mortality from phthisis has decreased from 12.67 to 9.12 in every 100 deaths; and in zymotic diseases from 23.26 to 20. If the death-rate of New York and Brooklyn were reduced to that of London, it would mean an annual saving of 15,986 lives, not speaking of the vast amount of sickness annually, which is equivalent to 32,000 years. "This lengthening of years, this relief of distress, this saving of public wealth is worth working for."

The address of Mayor Chapin showed an unusual appreciation of the relations of public health to civic and political interests; and following this, the Rev. Dr. Storrs, with his usual eloquence, demonstrated that the American investigator has well nigh reached the precision of research generally claimed for French and German savants.

In the address of President Low, of Columbia College, some very practical comments on the sanitary needs of Brooklyn in its out-lying districts were made, and Dr. Alexander Hutchins welcomed the delegates in so hearty a manner as to receive many congratulations.

The first paper presented to the Association was on the over-shading of our homes, by Dr. Parker, of Newport, R. I., which, unfortunately, added but little on those points where information is most needed. He was followed by Dr. Hibbard, of Indiana, who read a paper on clothing, enforcing the importance of "hardening," to diminish susceptibility to the changes of temperature. Dr. Jerome Walker, of Brooklyn, read a paper on the causes and prevention of infant mortality. He insisted most strongly upon good ventilation, good nursing, and attention to all sanitary details which do so much toward prolonging infant life. As an evidence that such care is not useless, he mentioned the Brooklyn Institute, in which there were 118 children not two years of age, among whom only six deaths occurred in a year. Mr. Alfred C. White, a civil engineer of Brooklyn, furnished a good paper on the relation of the dwellings of the poor to infant mortality, showing the comparative uselessness of partial measures, and the need of radical changes in tenement-houses. He quoted figures received direct from the Secretary of the Improved Industrial Dwelling Company of London, which show a marked decrease of the death-rate among the lower classes in those who were properly housed. In the discussion which followed, Prof. Bartley, of Brooklyn, was disposed to insist upon the evil effects of bad food as having quite as much to do with disease as bad dwellings. Dr. MacDonald stated that, in his opinion, cholera morbus and other causes of infantile mortality depended chiefly upon alterations in temperature.

The session of the second day was opened by a paper upon the "United States Census in Its Relation to Sanitation," by Surgeon J. C. Billings, of the United States Army, who showed the necessity of such an enumeration of population as would give the social condition and occupation of each individual, thereby admitting of a comparison of various districts. Thus, in the case of large cities, deaths occurring in hospitals should be referred to the districts in which they belong and not to the district in which they actually occur, the nationality and birth-place should also be given. In the case of deaths of colored persons the degree of admixture of white blood should be stated. Dr. Billings was followed by Dr. Hunt, of New Jersey, who read a paper upon the prevention of phthisis pulmonalis. Dr. Playter, of Ottawa, then read one upon the prevention and restriction of tuberculosis in man, and Dr. Kretzchmar presented one upon the prevention of pulmonary consumption. The paper of Dr. Hunt claimed that while certain facts as to the bacillus of tuberculosis were established, the proof of the communicability from man to man by inhalation requires investigation. The paper of Dr. Playter adopted the views of Cornet and advocated extreme measures for the restriction of the disease. In the third paper it was pointed out by Dr. Kretzschmar that in ten per cent. of phthisis cases no bacilli were found. In the discussion which followed Dr. Billings said he thought the first paper threw too much doubt upon the conclusions of certain well-known investigations and asserted that in his opinion the necessities of public health require stringent regulations.

[1] The precise words with which A. H. L. terminates his article cannot be conveniently used. The substitution of verbs for nouns will not alter the sense.

The afternoon session was held at the Hoagland Laboratory, which is admirably fitted up for biological and microscopical investigations. During this session a resolution was passed urging the importance of care in respect to the disinfection of diseased sputa.

The second evening was very profitably occupied with papers on "The Art of Cooking," by Edward Atkinson, LL.D., of Boston; on "Recent Researches Relating to the Etiology of Yellow Fever," by Surgeon George M. Sternberg, U. S. A.; a paper on "Pulmonary Observations on the Microörganism of Texas Fever," by Dr. Theobald Smith, Assistant in the Laboratory of the Bureau of Animal Industry, Washington; and another by Dr. D. E. Salomon, Chief of the Bureau, on "Some General Observations on Texas Fever." Dr. Atkinson, with his large fund of information and with simple utensils illustrated the economics of cookery and showed how much is yet to be done for economy and the betterment of health. Dr. Sternberg gave an interesting account of his recent researches on yellow fever which he illustrated by means of the stereopticon. The papers on Texas fever were also well illustrated and the subjects attractively presented by the authors. It is certainly a disease with marked peculiarities and very evidently dependent upon a special microörganism, but its relation to anthrax is as yet indefinite.

On the third day Dr. Benjamin Lee, of the State Board of Health of Pennsylvania, read a paper on the "Annexation of Cuba as a Sanitary Measure," and Dr. S. W. Latta, of Trenton, one on "Railway Sanitation." During the general meeting resolutions were adopted looking toward a representation in future of all the American nations. An encouraging sign was the initiation of a large number of new members. Dr. H. B. Baker, of Michigan, was elected President. The next annual meeting is to be held at Charleston, S. C.

NEWS ITEMS.

Polyclinic Therapeutical Society.—At the last meeting of the Polyclinic Medical Society, a therapeutical section was formed from among the faculty, clinical assistants, and students of the Philadelphia Polyclinic, the object of which shall be the scientific and systematic investigation of the action of drugs and remedies in the cure of disease. The executive committee of this section formulates a programme of practical work for each meeting, decides what drugs or remedies are to be investigated during the following months, devises specific directions in regard to such investigations, and supplies printed blank forms to carry the work into practical effect, with which any member of the profession, who desires to take part in the research, will be furnished free on application. These blank forms are filled out by the observer and returned as soon as the investigation is completed, which will be at the end of one, two, or three months; at which time the reports will be analyzed and presented at the following meeting with due credit to each contributor, results being published in the medical journals. It is believed that a combined effort of this kind will not only benefit those who are engaged in the work, but will be of great value to practical therapeutics.

Dr. Mays read a paper on *Olive Oil in Gall-stones*, and olive oil in this affection was made a subject for investigation during the next two months. All communications in reference to this subject should be addressed to Therapeutical Section, Philadelphia Polyclinic.

ACCORDING to the *Maryland Medical Journal*, New York city employs and pays forty physicians to visit the poor in the tenement houses. This is an improvement over the usual forms of charity.

Sterilized Milk Delivered to Patients in their Dwellings.—Since August 1st, sterilized milk has been furnished to children under treatment at the Philadelphia Polyclinic. The milk is sterilized by the Visiting Nurse Society of Philadelphia, and taken to the child by the nurse in attendance, in the bottles in which it is prepared. Milk and bottles are furnished the parents at cost. The results have been excellent.

The Hudson River State Hospital.—The New York State Hospital, at Poughkeepsie, has received an appropriation of $40,000, with which to build additional accommodations for the resident staff and one ward for the isolation of infectious or suspicious cases.

Diphtheria in Central Illinois.—A dispatch from Chicago states that the public schools at Illiopolis have been ordered closed on account of the prevalence of diphtheria, from which there have been several deaths. The disease has been reported from several other points in central Illinois.

Accident to a Physician.—DR. A. A. CLOUGH, of Denver, Colorado, who has been east to attend the Convention of the Public Health Association, on Sunday last, while walking in the streets of New York, was taken suddenly ill with vertigo, and, falling heavily, suffered concussion of the brain. He was conveyed to Bellevue Hospital.

Foreign Necrology.—DR. LIEDESDORF, the eminent alienist of Vienna, is dead.

DR. PHILIPPE RICORD, of Paris, the authority in venereal affections for fifty years, died on the 22d inst.

DR. IRA HAWLEY BARTHOLOMEW, of Lansing, Mich., died on the 18th instant, at the age of sixty-one years. He was, in 1871, the President of his State Medical Society, and thrice the Mayor of his city, besides holding responsible pension offices under the general government.

Another Continental Anglo-American Society.—In THE NEWS for the 19th ult. an item was published on the Society, in Paris, of English and American physicians. A somewhat similar organization has been begun at Vienna to promote the interests of the English-speaking physicians, who resort to the University in considerable numbers; there were over one hundred American physicians enrolled there last year. It will be named the Anglo-American Vienna Medical Association.

THE American Public Health Association adjourned on the 25th inst., after a successful and interesting meeting.

Suicide of a Physician.—DR. J. A. SHANNON, a practitioner of Canandaigua, New York, was put under arrest

on account of running over a pedestrian, for which he was in part responsible. Filled with alarm and chagrin at the catastrophe, he took some morphine; the amount taken was an overdose, and death ensued. The injured person is said not to have been seriously hurt.

The Bishop Case.—According to the *New York Medical Journal* the board of trustees of the Society of Medical Jurisprudence and State Medicine has taken action that has resulted in the passage of a resolution by the society expressive of sympathy with the medical men under indictment for the part taken by them in the post-mortem examination of the late Dr. Bishop. We are sure that they have the sympathy of the entire profession also. Their action was at most only a technical offense, and the trouble that has already come upon them in consequence of it undoubtedly constitutes as much punishment as any fair-minded citizen would wish to see inflicted on them. We think, therefore, that their further prosecution might be stopped without any disavadntage to the public welfare.

A Report on Cigarettes.—Mr. Willis G. Tucker, in his report to the New York State Board of Health, on the result of his examination of various popular brands of cigarettes, says that careful analysis of tobacco and paper failed to reveal any poisonous ingredients, other than the tobacco itself, and that most cigarettes contain pure tobacco and good paper. The evils of cigarette smoking are due to the fact that cigarettes are cheap, convenient, and can be used in large and excessive quantities, that the smoke is usually inhaled, and that children and immature persons so freely use them.—*Columbus Medical Journal.*

A Dealer in Fraudulent Diplomas.—We learn from the *New York Medical Journal* that the arrest of "Dr." Henry Freeland, the alleged head of seven bogus medical colleges, took place in Maine October 2d. He is to be tried at Portsmouth, N. H. It is not known how long this diploma-mill had been working before its exposure was published in one of the Boston papers, but one of the fraudulent diplomas is known to have been issued early in 1888. The buyers of diplomas were charged from $50 to $300. It is a partial compensation to note that these frauds are brought to book more speedily than was formerly the case; but even now the punishment that will be visited upon this dealer in diplomas—if he is punished—will be only that for an illegal use of the mail, rather than for a crime against his dupes or the public at large. In other words, the General Government must be invited to intervene and prosecute the accused for an act which is not, or might not be, essential to the carrying on of an extensive business in fraudulent credentials. The truth is that comparatively few States have any laws that are competent to the punishment of this kind of iniquity; and this shrewd indirection about the "illegal use of the mail" is a decidedly fortunate circumstance for some of them.

WE understand that the Faculty of the College of Physicians and Surgeons of New York have decided to raise the tuition fee from $150 to $200 a year. It seems to us that this is highly proper. By means of such a change the residents will be given facilities for learning which only a large tuition fee can cover. Further than this, examination of the catalogues of several of the other technical teaching bodies, such as the School of Mines of Columbia College, charge $200, though the expenses of the course are far greater in a medical school than in such an institution. We doubt if any branch of teaching requires more skill and study than that necessary to the thorough medical lecturer, nor one which of necessity forces him to keep abreast of the times so constantly, yet the fees charged and the salaries paid are in many institutions exceedingly small. As long as the teaching bodies of this country are not endowed, it is but fair that they should receive a *quid pro quo* equal to their deserts. So far as we know, the Medical School of Harvard University is at present the only institution charging $200 a year in the country.

A Truly Woman's Hospital.—We learn that under the patronage of the Princess of Wales London is to have still one more hospital, which is, however, to differ very materially from those heretofore founded. Not only are all the patients to be women, but all the physicians, surgeons, and apothecaries connected with the establishment are to be of the softer sex.

Medical Students in Germany.—The *Buffalo Medical and Surgical Journal* states that the number of students attending the medical schools of Germany has increased to such an extent in the past few years, that the Government has been petitioned to open new schools of medicine. The Government refuses to do this, but proposes to remedy the evil by exacting higher tuition fees, and lengthening the course of study required for graduation.

"Flint Disease."—A pulmonary affection peculiar to those who work in quarries received the attention of Dr. Forwood in his address before the Medical and Chirurgical Faculty of Maryland at a recent meeting of that body. He claims that it is frequent and fatal among the quarrymen in Hanford County. Few escape permanent damage to the lungs if they are engaged in the quarries even for one year.—*Memphis Journal of the Medical Sciences.*

Rabies.—The number of dogs in England officially reported during the week ending September 28th, as afflicted with rabies, was eight, against six in the previous week; of these, six were killed and two died. The distribution was as follows: Middlesex (excluding London), three; Surrey (excluding London), two; and Chester, Hertford, and York (West Riding), one each. No cases were reported from London proper.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

ECTOPIC GESTATION.

An Address delivered before the Northumberland and Durham Medical Society, on October 4, 1889.

BY LAWSON TAIT, F.R.C.S.

MR. PRESIDENT AND GENTLEMEN: The subject of ectopic gestation, although rather a special one, occupying in the practice of each individual physician no very large place, is yet of great importance, for when such cases are met they place the practitioner in a position of enormous responsibility, occurring as they do in the most unexpected ways and times; so that perhaps no subject is in reality of more interest to the general practitioner. Ectopic gestation has, too, this additional claim upon our attention, that although it lies in one of the by-paths of practice, still its mysteries have been unravelled in a remarkably short space of time, not only in pathology, but also in the method of dealing with it satisfactorily to the relief of suffering and the saving of human life.

The term *ectopic* gestation should be used to the exclusion of the older term extra-uterine gestation or pregnancy, for several reasons. First, because there is a special variety of this condition which is not covered by the term extra-uterine pregnancy, and it is always well when we change our nomenclature to do so in the direction of greater precision. We are in the habit of altering our nomenclature often enough from mere fancy. With each incoming school of pathology there comes a new system of nomenclature, with the result of confusing those who have just left the schools where the latest doctrines were taught.

I do not, therefore, propose this change without a sound reason for doing so, which is, because the variety of ectopic gestation known as the interstitial is brought within the scope of our term. Then, again, the cornual form of pregnancy was regarded as extra-uterine, which is in reality not the case, and it is undoubtedly ectopic. Therefore, as we have two conditions which are included in the word ectopic, and which are not included in the term extra-uterine gestation, I maintain that the new word ought altogether to replace the older for the sake of precision and comprehensiveness.

It is difficult in dealing with a subject like this, to see clearly the best line to follow. We may take either the pathological or the clinical classification, and I am not sure that the latter is not the best, as I am dealing with the subject for the purpose of helping those who have no time and no opportunity of following out the intricate details of pathological research, men who are engaged at the bedside, but to whom it is important to know what they ought to do. I will, therefore, follow a clinical course, for, although it may lead to some confusion of order, that disadvantage will be compensated for by clearness in addressing those to whom the subject is new, or to whom the term extra-uterine pregnancy simply involves a confused notion of a condition far different from that usually met with at the puerperal bedside.

What, then, is the commonest condition with which we have to deal in cases of ectopic gestation? It is unquestionably a catastrophe so terrible, that nothing can be compared with it short of a railway accident. One of your patients is suddenly seized with pain in the abdomen. The pain becomes more and more severe as the hours advance; she presents a strange, death-like pallor; she vomits as she lies on her back; the pulse disappears; the skin becomes cold and clammy, and though she is clearly dying, there is no very distinct ground upon which you can make your diagnosis, and until you inquire into the history you can be positive of nothing but the pain. So sudden is all this, that most of the men who have seen such cases have seen them pass to the post-mortem table or the grave without a complete diagnosis having been made.

Such are the appearances of a woman who is suffering from rupture of the more common form of ectopic gestation. Your patient dies, if not relieved, probably with the true condition unsuspected. A post-mortem examination is made, the abdomen is found full of blood, one Fallopian tube is found with a small swelling which is the source of the extravasation into the peritoneal cavity. You will find pints of semi-coagulated blood, and when you search for the source of the hemorrhage you discover it in a rent in the Fallopian tube, from the effects of which your patient has died. This is what we call a ruptured tubal pregnancy, and concerning the pathology of which the greatest confusion existed until very recently; in fact, I may say with regard to some of the senior members of the profession the confusion exists at the present time. In support of this assertion I may refer to a clinical lecture which appeared in the columns of the *Lancet* a few weeks since. The lecturer opened his observations with this remarkable sentence: "That only ignorant audacity could presume to make clear the pathology of extra-uterine pregnancy." Now, I do not know whether it is ignorant audacity of the one that can make such a charge, or ignorant audacity of the other for attempting to make clear that which was enveloped in obscurity; but if I can succeed in inducing you to believe that the pathology has been made clear, the treatment and practice successful, then my mission will have been accomplished. We had, until quite lately, an inherited belief that stood in the way of our understanding the pathology of these cases completely, or indeed at all. Many years ago experiments were made by Le Coste with the view of ascertaining the precise position at which the ovum and spermatozoa met and impregnation took place. Unfortunately Le Coste made his experiments upon animals with a bifid uterus, and this has been the source of all the trouble, for the human uterus is single, its bifidity being represented by struc-

tures which are not uterus at all—the Fallopian tubes. He found that impregnation took place high up in the bifid organ and wrongly thought that this was the Fallopian tube instead of the uterus. This led to the mistake that has existed so long. Normally, the Fallopian tube is lined by a layer of ciliated epithelium which was supposed to have for its function the sending of the ovum down into the uterus, and it was assumed that this function was fulfilled after the ovum had been impregnated. We cannot make experiments on human beings as upon the lower animals, but we have an unfortunate habit in many instances in making experiments upon the latter and neglecting a precaution which the physicist and the chemist always adopt, viz., of making sure that the conditions of the experiment are the same. Now, the conditions of the experiment in women would be found on careful examination not to be like those on animals, and the absence of this ciliated epithelium is the precise condition that was neglected. We know now, as nearly as possible, from the investigations of pathologists and from direct observations which will doubtless be completely elucidated before long, that another function of this ciliated epithelium is to prevent the entrance of the spermatozoa into the Fallopian tubes. So long as there is a layer of intact epithelium impregnation takes place only in the uterus. I will not go into the arguments upon this point, for the time will not permit, but some recent researches by A. W. Johnstone and Bland Sutton make the above statement very positive. This is the key-note of the subject which if once grasped makes all perfectly clear. When the Fallopian tube has been denuded of its layer of ciliated epithelium, these observations show clearly that its surface becomes exactly like that of the uterus, to which the ovum would normally become attached. If there has been a destruction of the ciliated layer which is not reproduced, then we have the possibility in the first place of a spermatozoön entering the tube, and, what is still more important, after impregnation the ovum may become attached to the walls of the tube, as it normally is to the walls of the uterus. These points granted, the whole matter becomes clear, notwithstanding the cries of "ignorant audacity."

We will assume, then, that this later pathology is an improvement upon the older, that impregnation takes place in the cavity of the tube, and that the attachment of the ovum takes place upon the wall, in consequence of the loss of the ciliated epithelium. Here, however, let me diverge into the clinical aspect for a moment, and tell you the usual history of these cases. The great majority of the cases occur in women who either have never been pregnant, though married for years, or who have had two or three children, followed by an interval of sterility of some years' duration. This one clinical fact shows clearly enough that the procreating mechanism was out of gear. Then the examination of the tubes will show distinct evidence of mischief. One authority, Dr. Griffith, of St. Bartholomew's Hospital, told me the other day that he was perfectly satisfied as to the correctness of my conclusions, that desquamative salpingitis had been well worked out and proved. In many instances, then, you have a clear history of tubal disease. I cannot go further into this point, because it would take up too much time, but the history generally shows that damage has been done to the tubes prior to the abnormal gestation. Here, then, we have one proof of the correctness of our views. We will now turn to the progress of each condition. Impregnation has taken place, the ovum has become attached to the walls of the tube and is growing. We have now to speak of the conditions based upon divisions of the tube, which are largely artificial, but, artificial though they be, they have many conveniences to recommend them. You are all familiar with the appearances and anatomy of the Fallopian tubes. You know that there is a small part which is buried in the uterine substance, that there is another part which is perfectly free, except that it is kept in place by a meso-salpinx, which is a duplicature of the peritoneum, running up one side and down the other, thus enveloping the tube, but allowing of perfect freedom of movement. Now, as this duplicature of the peritoneum is one of the most important structures in the whole female body, for the purposes of the present discussion I ask you to bear it well in mind. We then come to the division known as the infundibulum, which is supposed, at intervals more or less periodical, to be applied to the ovary for the purpose of receiving the ovum on its way into the uterus. Whether this view is correct or not, remains to be proved. At one time I myself believed that this did take place, but I am now disposed to regard it as mythical. It matters little, however, for our purpose whether it takes place or not.

Another point to be discussed is the view that impregnation sometimes takes place in the ovary, the spermatozoa travelling up the Fallopian tube, spreading themselves out over the ovary, and impregnating the ovum at the moment of its escape. This can be seen easily enough in the lower animals not provided with Fallopian tubes, and the error arose from the application of these observations to the human female. The proof rests upon the answer to this question: Does ovarian pregnancy ever occur? Is there such a variety of ectopic gestation as ovarian? Well, I have examined personally all the specimens to which I have had access, and have investigated every such case that has ever been put upon record, and all I can affirm is that, so far, no such occurrence has been proved to have taken place. The proof which we demand for an occurrence of this kind is, that a cavity be found in the structure of the ovary, the walls of the cyst consisting largely, if not entirely of ovarian tissue, as demonstrated by the microscope, and that the cyst contents consist largely of fœtal structure or placenta. If neither of these three conditions can be substantiated, the case must be put aside and disregarded as evidence. I do not mean to say that the thing is impossible, but I do say that, as yet, it has not been satisfactorily established. Some of the cases published as such, are based on ludicrously erroneous evidence. Not long ago, in the *Transactions of the American Gynecological Society*, a case was recorded which, from the history, was palpably a case of dermoid tumor of the ovary. Yet it is described and put on record as a case of ovarian pregnancy. Great care is therefore required in admitting such cases as evidence. It does not matter for clinical purposes whether it is proven or not. If it is, the subject is all the more interesting, but I do not suppose it would differ in its clinical relations from a tubal pregnancy. The patient would be exposed to the same dangers, and it would have to be dealt with in the same manner.

As regards tubal pregnancy, there is an ample supply

of specimens which prove its occurrence in all the three situations—the infundibulum, the middle part of the tube, and the interstitial part. Now, I may dismiss the interstitial variety with a few words. First of all, it is the rarest; for although I have had perhaps the largest experience of any one man with this curious displacement, I have only seen one such case, and I know of only six mounted specimens in this country in which this lesion indubitably exists. It is rare and inevitably fatal, for we get no notice as to when rupture is going to take place, and the patient dies before anything can be done. The period at which rupture takes place—that is, when the tube gives way—may be deferred as late as the sixth month, and seldom occurs before the fourth. The tissues are then so vascular that it is only a matter of a few minutes before the patient dies. Alluding particularly to my own case, I fail to see how any human power could have saved her, even if we had been there at the time. The condition is simple enough. An attachment of the ovum to the tube has taken place within the structure of the uterus. There it remains, expanding nearly always in an upward direction, and the rupture takes place at the fundus of the uterus. The tear is extensive, usually four or five inches in length, and the hemorrhage is consequently terrific. Nothing could save the patient but hysterectomy, and by the time the diagnosis is made all chance of an operation so grave as hysterectomy proving successful would be gone. The specimens I have seen are all identical in character, and it is very fortunate that a variety in which we can do so little, and in which the consequences are so terrible, should be so rare.

We may then pass on to the consideration of the other two varieties. I will dismiss the infundibulum variety by saying that it too is extremely rare. I only know of two well-authenticated cases—I will not say on record, for such cases are generally recorded by gentlemen who have too little experience with the methods to be followed in establishing these cases, and of the points to be demonstrated. Therefore, when we see figures, except by skilled anatomists or experts in pathology, we have to discount the statements made concerning them. For instance, Dr. Granville is quoted by Dr. Campbell, as having proved ovarian pregnancy up to the hilt, and actually quotes his pamphlet and plate as quite satisfactory. Now Dr. Granville's book is very rare, as it took me four or five years to find a copy. When I did so, I found the description was absolutely incorrect; there was nothing in the plate at all to represent either placental or fœtal tissue, and the text was as follows: "That Dr. Granville was assured by Sir James Clark that, thirty years before, he had seen a fœtus hanging free in the cavity." I have seen the specimen but can make nothing of it. Where the specimen is in a museum, properly put up, you can go back a century, as is the case with the specimens so admirably put up and described by Hunter. Therefore I say that there are only three such examples. It would matter very little, however, if there were more—they would be merely pathological curiosities. Its bearings are precisely the same as the variety now to be spoken of, viz., pregnancy in the middle part of the tube. Let me now remind you of the structure of the Fallopian tube, for this is a fact of the very greatest importance. There is the lining of mucous membrane covered with ciliated epithelium, and outside is the peritoneal investment. Between them are two clearly defined layers of muscular fibres, longitudinal and circular. The mucous surface is of importance, because its denudation, in our belief, is the primary cause of the misplacement. The muscular coat has probably some peristaltic action in assisting the ovum and fluids down the tube. This movement is often seen in operating upon the uterus for myoma, when the vermiform movement follows the removal of the tubes. Of all the layers, however, the peritoneal is of the greatest importance, for according to the way it behaves, or, rather, how it is treated, the ultimate issue depends. The ovum, to start again from the point of its growth, continues developing, and though it is true that the Fallopian tube is capable of a certain amount of distention, provided the walls are not damaged, the distention is limited. The tube is probably capable of the same amount of distention as the gall-bladder or the urinary bladder.

Peaslee narrates a case in which the Fallopian tube was dilated to such an extent as to hold thirty pounds of fluid. I have myself seen thirteen and fourteen ounces of fluid. On the walls of the tube, however, becomes developed an organ which weakens them—the placenta. The formation of large venous sinuses on the site of the implanted placenta diminishes the ability of the tube to distend, and it tears. This coincides with the formation of the "cake" of the placenta. Up to a certain point the placenta is diffused as a villous layer, but in about the eighth week it becomes restricted to one spot, when you get what is called the placental cake. I do not know that the development of this placental cake has an all-powerful influence in determining the rupture, but it certainly exercises some influence. The rupture always take place before the time of the limit of the formation of this placental cake, and the time of the rupture is, therefore, clearly limited to the twelfth week. I have never met with a specimen later than that. Now, the rupture may take place in one of two directions. In one case the placental cake may have formed upon the site where the layers of peritoneum meet, or, on the other hand, it may form upon some part of the wall which is closely surrounded by peritoneum. In the first instance, the rupture takes place into the broad ligament; in the latter, into the peritoneal cavity. Although I have been preaching on this subject for twelve years I have failed to get my professional brethren to see what an enormous difference this makes in the subsequent progress of the case. It means that if this hemorrhage takes place into the peritoneal cavity it is uncontrolled. If you put a bleeding surface under water you remove one of nature's great hæmostatics, coagulation. If you have bleeding into a confined space which is capable of only limited extension, especially if that space be filled by something that is capable of inducing coagulation, such as irregularly distributed muscular fibres, you have a strong means of arresting hemorrhage; whereas if the cavity be indefinite in its capacity there is a corresponding absence of the cause of coagulation. This is an explanation of the different endings of these cases. In rupture into the peritoneum the bleeding practically goes on unchecked. Every one knows that if a vessel has not been properly tied or if a ligature has slipped after ovariotomy, there are no means of checking the hemorrhage, because the blood does not properly coagulate, and a little vessel from an omental adhesion, which would not be of the

slightest consequence in an amputation, would be sufficient to cause death after an ovariotomy. You have thus in the one case every possible condition favorable to the continuation of the hemorrhage, while when the rupture takes place into the cavity of the broad ligament you have all the conditions favorable to the arrest of the hemorrhage. Hence the latter is rarely fatal. Here, then, we have a great natural difference between these two varieties of tubal pregnancy. One has no natural tendencies toward cure, and the other has all. In the one case you have to do with a patient who will die inevitably unless you interfere. In the other you have a condition which you may safely leave alone. In the one case you have hemorrhage into the peritoneal cavity, and in the other you have it extra-peritoneal into the broad ligament, and I think I have made it clear that the prognostic importance of the two is as different as can well be.

Now as to the diagnostic difference between the two. It is very simple, if you think for a moment what the relations of the broad ligament are.

You have to recognize two different varieties, one of intra-peritoneal and the other of extra-peritoneal hemorrhage. Now, intra-peritoneal hemorrhage may arise from various causes, such as injury, or from imperfectly checked bleeding after operation. But excluding such causes, and speaking from my own experience as a gynecologist, it has only one origin, and that is, rupture of a tubal pregnancy. Mark you, I do not say that there are no other causes, but I have never met with them. To my mind, for all practical purposes, intra-peritoneal hæmatocele and ruptured tubal pregnancy are one and the same thing. And now, what are the symptoms and physical signs? Concerning intra-peritoneal hemorrhage I may say, hardly any signs at all. You palpate gently and you have obscure fluctuation, very difficult to make out even when the amount of effused blood is large. Percussion gives nothing very remarkable. You get dulness here and resonance there, but nothing to indicate positively what is the precise condition. Vagially you feel an indistinct boggy swelling in Douglas's pouch, but there is nothing very clear about that either. The relations of Douglas's pouch are practically unaltered. In the extra-peritoneal variety there may be fifty different causes, such as sudden arrest of menstruation by chill, etc., but I fancy the worst cases I have seen of this kind have been caused by a tubal pregnancy rupturing into the broad ligament. Here the signs are positive, and in the first place you have a smooth, tense, rounded tumor in the pelvic region, sometimes reaching almost, or quite up to the umbilicus. This is the broad ligament dissected upward and distended by the effused blood. There is distinct fluctuation. On examination of the pelvis you have a condition which is absolutely distinctive, viz., the whole of the roof of the pelvis is fixed, and coming down from each side of the uterus you have processes of induration extending. You have a more or less flat-topped roof and pillars down each side, which indicate the burrowing of the blood along the pelvic fascia. Then there is another condition almost certain to occur if the case be a severe one, viz., stricture of the rectum. I had such a case yesterday. Remember that the broad ligament comes off from the uterus, it gradually opens one fold on either side of the rectum, and if blood dissects it up, one of the roads will be to the front of the rectum and around it, and you have an annular stricture of the rectum, which will not disappear for many months. Now let us go back to the history. First, the history of sterility, then the suspicion of pregnancy. The patient *thinks* she is pregnant. There may be irregular discharges, sometimes profuse menorrhagia, but not often a clear history suggesting pregnancy. But if you have the acute condition, what you wish to determine is, is the blood in or out of the peritoneum? And this you can determine on the data which I have given you. If the symptoms are negative, then the hemorrhage is *inside* the peritoneum; if otherwise, then outside. I think now you will understand why one gets angry that men should constantly be saying that you are urging them to open an extra-uterine hæmatocele. I do nothing of the kind, except in one particular class of cases, viz., those in which the distention of the broad ligament is such that rupture has taken place into the peritoneum. Here the conditions are the same as in intra-peritoneal hemorrhage. I have never seen such a case, but if I had I would have treated it as if it were a primary rupture of the tube into the peritoneum.

Now, let me discuss the conditions of the second variety, the cases where rupture has taken place into the cavity of the broad ligament. These are most easily indicated and easily disposed of. In the act of rupture, the ovum is destroyed. The case then resolves itself into a simple broad ligament hæmatocele, which is to be left alone—which will be absorbed, though the convalescence will be prolonged. I advise you to leave these alone. Many of my brethren have bitterly regretted having tapped such hæmatoceles, because, if the pressure is lessened, you take away the hæmostatic effect of such pressure, the cyst will refill, and the woman will as surely die from loss of blood as if the hemorrhage had taken place into the peritoneum. The cases that go wrong are those that are injudiciously interfered with. If the blood is absorbed, there is an end of the trouble. Sometimes, perhaps in one among ten cases, the ovum is not killed, the hemorrhage being smaller. Then it goes on developing into a series of conditions which I will briefly run over.

It may go on into the fourth or fifth month, and the ovum die. This is a very common ending of the broad ligament pregnancy. When the ovum dies, it still should be absorbed, or it may suppurate, and then you get those extraordinary cases of abscess bursting into the bladder or rectum or at the umbilicus, with the discharge of fœtal bones at about the fourth or fifth month. These cases prove clearly enough where the fœtus has been; for, if you recall your anatomy, you will see that the places from which the discharge will take place are those of election in cases of abscess in the broad ligament from any cause. Its cavity is in immediate relation to the anterior wall of the rectum, and, therefore, the history of these cases is full of instances of discharge of the fœtal bones *per rectum;* less commonly into the bladder. Then, again, the fœtus may not die, but may go on to full time, distending the peritoneum—and it is extraordinary to what extent this can be carried on. Here is a diagram taken from a frozen specimen, in which the whole peritoneum is lifted off the anterior wall of the uterus and the posterior wall of the bladder, and then comes down about half-way between the umbilicus and

the pubes. After all, there is nothing wonderful about that when we reflect what takes place with the pregnant uterus. The whole of the fœtus, in such cases, is extra-uterine. There is nothing inside the peritoneum: proving that the view I took many years ago was the correct one, viz., that these full-time pregnancies were extra-peritoneal. This looks absurd; but Dr. Berry Hart's specimen proves it completely. One of his actual sections is before you, in order that you may have visible testimony of the accuracy of these views. Now, what must be done if it goes on to full time? The only course open to you is to operate and remove a living child. The older treatment was to give doses of morphia or use electricity to kill the child. But it must occur to all of you that even when they are killed they are not pleasant things to deal with. When suppuration takes place in the dead ovum, it may go on for years. Considering that we have now made five successful removals out of seven operations, I think that the moral question of procuring the death of the child is very serious. I do not pretend to be any better morally than my fellows, but I would not go out of my way to kill a child which had every right and every chance of living if we will only interfere. You must remember, too, that these ectopic children are probably the only children these women have. As to the prejudice of their being deformed, I can only say that I have three of them growing up around me, and they are healthy and well formed in every respect. I have never countenanced the employment of electricity in the treatment of these cases of extra-uterine pregnancy. I would let the electricians and others try their experiments, and when they come forward with better results than mine I will retire. I receive with as much respect as possible the statement as to the value of electricity in the treatment of these cases, but I am content to go on my own way, and await the judgment of my fellows. At any rate, it is perfectly certain that if you attempt to kill the fœtus before the rupture takes place, you may have good grounds for what you say; the idea is feasible enough. Given a case of tubal pregnancy before rupture of the tube: kill the fœtus, and you may save your patient the risk of a rupture. But there is a hitch, and it is this: I have now seen some thirty cases of tubal gestation, and I have had a chance of examining but one before the rupture had taken place. The first we know of these cases is, the patient lying on her back, with her legs drawn up, collapsed, and suffering agony. Of course, if the electricians can spot these women as they are walking along the street, well and good; but if they have to rely on the ordinary methods of diagnosis, then their treatment will not have much of a show. Again, if the bleeding is into the peritoneum, of course no needle, electrical or otherwise, will stop that. And if the bleeding is into the broad ligament, there is, as I have shown, no need for it. After the seventh month the killing of the fœtus does not relieve your patient from the risks of an operation; *toute au contraire*, the risks of suppuration, which is sure to follow, are enormous. If, on the other hand, you wait until full time, you can remove a living child.

Now, then, we come to the most important part. When your patient is dying from the effects of a ruptured tubal pregnancy, what are you to do? The course to pursue was indicated a hundred years ago, and with the utmost precision, and is now embodied in an aphorism of surgery, viz.: In case of hemorrhage, get at the bleeding point and apply a ligature. The same rule applies here. We know now that the source of the hemorrhage is in one of the vessels of the broad ligament. You open the abdomen, and find it full of blood and clots. Do not at first trouble about the blood, but go straight for the broad ligament. Go to where a swelling is felt, and if it is not on one broad ligament it will be on the other. Then pull it up, put on a ligature, and your patient is saved. In order to sum up what I have to say, let me read the account of the last case in which I operated, only a few days ago.

"On the morning of August 7th, at 1 P.M., Dr. Nelson, of Birmingham, called upon me in reference to a married woman, aged twenty-six, whom he had seen that very morning. She complained of a sudden attack of violent pain in the lower part of the abdomen. She rapidly got worse, and when seen by him was already in a condition of collapse. She was acutely anæmic, and presented all the classic symptoms of abdominal hemorrhage. The one point in the history that gave a clew to the case was that she had gone six weeks over her time without menstruating. He made the diagnosis of ruptured tubal pregnancy, and I had but little hesitation in agreeing with him. The patient was brought to the hospital as speedily as possible, and was found to be absolutely pulseless. I opened the abdomen, and, as one of the spectators afterward said to me, the flow of blood was as if I had opened a hydrant. Disregarding the blood and clots for the time being, I went straight for the fundus of the uterus, and in a moment discovered that a tubal pregnancy existed, and had ruptured in the right Fallopian tube. I promptly ligatured it, and then proceeded to remove the blood and clots. I then closed the abdomen, leaving in a drainage-tube. Not another drop of blood was lost, and the further progress of the case is as follows: At 5 P.M. on the same day her temperature was 36° C. (96.8° F.), and no pulse could be felt except deep down in the neck. The pupils were widely dilated, and the only sign of life was some slight movement of the diaphragm. The complexion was waxy and yellow. At 11 P.M., the temperature had risen to 38° C. (100° F.), but still no pulse was perceptible at the wrist; it was only thirty-six hours after the operation that it was possible to count the pulse. In Dr. Thomas's case the pregnancy ruptured outside the peritoneum; in this case it was inside. The trouble in both cases was the same, but in one case the hemorrhage was limited by the hæmostatic influence of the broad ligament, while in my case there were none of nature's efforts to arrest the hemorrhage, and in another hour it must have been fatal. The case was seen and the operation performed in the presence of Dr. Nelson, my assistant Dr. Derchelmann, Dr. Ostrom, of New York; Dr. Arthur Johnstone, of Danville, Ky.; and Dr. O'Callagnan, of the city of Cartow. It constitutes my forty-seventh case of the kind I have operated upon. Dr. Derchelmann made a careful examination of the preparation, and the rent in the tube is not more than a quarter of an inch long, the fœtus not being more than the fourth week. It lies in the membranes in the tube."

Why, then, should we let these women die? Surely, it is some advance if we can remove from the list of catastrophes of our art at least one such, and this we claim to have done.

REST AND EXERCISE IN HEART DISEASE.[1]

BY ALFRED L. LOOMIS, M.D., LL.D.

RECENTLY physical exercise in the treatment of diseases of the heart has been much discussed, and the statement has been made by distinguished observers that it is a most valuable therapeutic agent in their successful management. Such a statement, however, is misleading and dangerous, unless accompanied by a definite description and classification of those pathological changes in the heart which allow of exercise, and those in which rest is essential to the prolongation of life. I venture to offer a few clinical experiences on this important subject, and to formulate, as far as possible, the rules which now govern me in advising rest or exercise to those suffering with heart affections. Clinical experience makes it evident that while one case of heart disease is benefited by rest, another is benefited by exercise, and the question is constantly coming to us in our management of cardiac cases, What pathological changes in the heart render exercise dangerous and what demand rest?

If we turn to the older writers on heart disease for an answer to this question, it will be found that the plan advised in the treatment of all valvular lesions was to diminish as much as possible the work of the heart, and in most instances absolute rest was insisted upon.

Until quite recently valvular murmurs were the important clinical phenomena in cardiac disease, and decided its diagnosis, prognosis, and treatment. But as our knowledge of cardiac pathology has advanced, murmurs have assumed a secondary place. Within the last few years we have gone a step further, and to-day no intelligent observer regards a cardiac murmur as anything more than a sound indicating the seat and character of a valvular lesion. The great problem to be solved in every case is, What is the condition of the heart-muscle and the heart-cavities? We know that so long as full nutrition is maintained in the cardiac walls the heart meets every obstacle to its activity with added force, and only when the walls are weakened do we find the clinical evidences of cardiac insufficiency. To maintain the integrity of the heart-walls and cavities the muscular tissue of the heart must be healthy. The heart-muscle must receive a sufficient supply of healthy arterial blood. The products of muscular waste must be rapidly removed from the body, and the trophic nerve apparatus of the heart must be in a normal state.

Any essential deviation from these normal conditions leads to weakening of the heart-walls, and favors dilatation of its cavities. It is evident that when the physical organism, as well as the heart itself, is healthy, abnormal increased stimulation of the cardiac muscle from any cause results in the production of hypertrophy, while, on the other hand, if the vitality of the organism is below par, and the heart-muscle imperfectly nourished or diseased, it does not respond to the increased stimulation, and instead of becoming hypertrophied, the walls of the heart yield to the intra-ventricular blood pressure, and dilatation of the cardiac cavities is the result. Whenever there is dilatation of the heart-cavities, with weakened heart-walls from any cause, physical exercise is contra-indicated whether valvular lesions exist or not.

It seems hardly necessary to insist upon the importance of absolute rest in the treatment of all acute inflammations of the heart and its appendages, for no one, I think, will claim for a moment that it is safe for a patient with an acute pericarditis, endocarditis, or myocarditis to take even moderate exercise. It is a well-recognized therapeutic principle that for the successful management of any one of these acute affections, patients must be kept at rest in bed, freed from all those influences which tend to accelerate the heart's action or increase its force; in fact, the remedial agents on which we rely most in such cases are those which tend to quiet the heart's action and lessen the force and rapidity of the circulation.

The question, therefore, which naturally meets us first in this discussion is, In which chronic valvular lesion (while the heart is still competent, there being as yet no signs of heart insufficiency) shall we advise or permit physical exercise, and in which shall we enjoin rest?

I maintain that no chronic valvular lesion is to be regarded as absolutely contraindicating physical exercise, unless it is associated either with hypertrophy or dilatation of the heart-cavity which it obstructs. The fact that an obstructive or regurgitant murmur is heard at the mitral or aortic orifice is not conclusive evidence that an individual may not without risk engage in the most violent physical exercise; but when a valvular insufficiency at either of these orifices is associated with extensive hypertrophy and dilatation of the left auricle or ventricle, then the question of exercise or rest is to be determined, not so much by the heart condition, as by the age, habits, and general nutrition of the individual. A stenosis or valvular insufficiency after fifty years of age is a very different affair from the same condition at twenty or thirty. Chronic alcoholism and the evidences of general fibrosis render a heart crippled by valvular lesions far less able to resist the strain of physical exercise, than if the same valvular insufficiency exist in one who is free from these general degenerative changes. The

[1] Read before the American Climatological Association, June, 1889.

two following histories will serve to emphasize these statements:

Case I.—A gentleman, forty-three years of age, with no rheumatic or gouty tendencies, consulted me in June, 1887, for an opinion if it would be safe for him to join a hunting and fishing excursion to the northern part of Minnesota during the summer. He had been told that he had heart disease, the result of a single attack of acute rheumatism when he was eighteen years of age.

On examining him I found the evidences of extensive mitral insufficiency, with well-marked hypertrophy and dilatation of the left ventricle; his cardiac rhythm was perfect, and he gave no cardiac symptoms. He had led a moderately active life, his habits having been most abstemious, using neither alcohol nor tobacco. I tested him in every possible way, but could not detect the slightest indication of heart insufficiency, and gave him the opinion that it would be perfectly safe for him to take the proposed trip, requesting him to call upon me on his return. During the following November he visited me again, much improved in general physique, and, as he said, stronger than he had been for years. He stated that for three months he had camped out, taking a great amount of physical exercise in rowing and tramping. I could find no change in his heart, except that the apex beat was more forcible than at any previous examination.

Case II.—In May, 1888, a gentleman, forty-six years of age, of very intemperate habits, who had had a severe attack of acute rheumatism at twenty, consulted me for dyspeptic symptoms and pain in the epigastrium. I found on examination the evidences of mitral regurgitation, with well-developed hypertrophy and dilatation of the left ventricle and auricle; he gave no cardiac symptoms, and was not aware that he had a cardiac lesion. I advised him to stop the use of alcohol and tobacco, and to live an out-of-door life in the country during the coming summer.

The following December I saw him again with his attending physician, and found him in a condition of general dropsy, with all the signs of advanced cardiac insufficiency. He reported that when he went into the country the preceding June, he stopped the use of alcohol and tobacco, and immediately began a very active out-of-door life, rowing some days five or six miles without resting; for a time he seemed to improve, but early in September, after rowing a race of two miles, he became short of breath, and had a violent paroxysm of dyspnœa which lasted several hours. After this attack, he found that a short row would bring on a paroxysm of dyspnœa; soon his feet began to swell, and he steadily grew worse, until now he was compelled to assume a sitting posture night and day, and was constantly in a condition of great distress.

The important difference to be noticed in these two cases is in their habits of life. At the time of my first examination, physical signs gave little or no appreciable difference in their cardiac lesions. Both had well-marked mitral regurgitation, with the usual accompanying hypertrophy and dilatation of the left ventricle and auricle; but the abstemious habits of the first gave assurance that the cardiac muscle still retained its normal integrity, while the alcoholic history of the second left little doubt that the cardiac muscle was not in a condition to respond to prolonged or severe intra-ventricular tension, and that under such tension sudden and extensive dilatation of the ventricles occurred, which was never recovered from.

I erred in not appreciating this condition more fully at my first examination, and not guarding my patient against the violent and prolonged physical strain which initiated his heart insufficiency.

The object to be aimed at in the treatment of every case of mitral stenosis is to favor the process of self-adjustment in the heart, by the avoidance of excessive intra-auricular blood-pressure. While gentle and healthful exercise may be of service in relieving hepatic and portal congestion, sudden or prolonged physical exertion sufficient to cause muscular and circulatory exhaustion tends to increase intra-auricular tension, and may lead to extreme dilatation of the auricle and permanent crippling of the cardiac circulation.

The following experience impressed upon me the importance of being very careful about excessive physical exertion in these cases:

Case III.—A few years since a girl, eighteen years of age, was brought to my office by her brother to obtain a permit of admission to the hospital. As she entered my office I noticed that she was very much out of breath. On examination I found the evidences of advanced mitral stenosis. I gave the brother a permit to the hospital on condition that he would take the patient there in a carriage, as there was a strong wind blowing from the east, and she would be compelled to walk a mile against the wind. He promised, but after leaving my office forced his sister to walk. She fell by his side as they entered the hospital gate, and died in a few moments. The autopsy showed an enormously distended left auricle, intense pulmonary hyperæmia with œdema, and a mitral stenosis that would not admit the end of the little finger.

The treatment of mitral insufficiency is directed mainly to the prevention of weakening of the ventricular walls and consecutive dilatation of the ventricular cavities. Muscular exertion, especially such as increases intra-ventricular tension and causes temporary interference with respiration, favors the development of both these dangers. A safe rule is to avoid everything which throws extra strain upon the heart, especially if the evidences of commencing dilatation exist. The amount of exercise which may safely be taken is determined by the special circumstances of each case; in most instances there

is little difficulty in deciding this point, for any exertion on the part of the heart which makes itself immediately felt by shortness of breath, with slight irregularity in the force of the radial pulse, cannot be safely indulged in. Whenever, from any cause, there is with a mitral insufficiency a defective, irregular, or in any respect an uncomfortable action of the heart, rest must be insisted upon until the heart regains its rhythmical power; as soon as its rhythmical power is regained, gentle exercise is useful in improving not only the general condition of the patient, but also the contractile power of the heart itself, for muscular movements act as a gentle stimulant to many of the secretions, and thus improve cardiac nutrition. We must, therefore, recognize in mitral insufficiency with an imperfectly compensating heart, that there is a period for rest and a period for exercise; a period when exercise acts favorably by inproving general nutrition, relieving the system of excrementitious products, and furnishing a more abundant supply of oxygen, as well as a period in which it acts unfavorably by calling upon an already overworked heart for still greater power, bringing it nearer the point where forced expenditure overbalances nutritive repair.

The treatment of aortic stenosis and regurgitation has for its object the postponement of tissue degeneration of the heart and arteries by maintaining all the tissues, especially the cardiac muscle, in the highest state of health. Before the period of ventricular incompetency is reached more exercise can safely be indulged in than in mitral disease; in fact, patients with aortic valvular disease should lead active out-of-door lives, and any exercise may be indulged in which does not involve strain or overtaxing the heart; but if the valvular lesions are associated with atheroma of the vessels the individual should lead a quiet life. The indications for rest or exercise in this class of cases are determined by the character of the murmur, the integrity of the heart-muscle, the extent of the ventricular dilatation, and the condition of the arterial walls. A long murmur indicates far less aortic incompetency than a short gushing one, and, as a rule, will admit of much greater physical strain without damage to the heart. Commencing failure of the heart-muscle and non-compensating dilatation of the ventricular cavity, will not, as in mitral disease, be indicated by shortness of breath, but by headache, vertigo, or actual fainting, throbbing of the peripheral vessels, cardiac palpitations, and carotid pulsations. The condition of the arterial walls will be determined by the age, habits, and hereditary tendencies of the patient, and by the appreciable changes in the surface vessels. In any case, therefore, of aortic valvular disease, if the murmur is short and gushing, the cardiac rhythm easily disturbed, the left ventricular area much increased, the cardiac impulse diffused, and the age of the patient, his habits, and his hereditary tendencies, such as to render it probable that extensive arterial degeneration exists, active physical exercise becomes dangerous, and the effects of even moderate exercise must be closely watched.

The important things to be accomplished in the treatment of either primary or secondary cardiac hypertrophy are to diminish, as much as possible, heart strain, to avoid accelerating the circulation of the heart-muscle, so as to enable the heart to compensate perfectly for the defects it has to overcome without exhausting its contractile power. We cannot, and we would not if we could, prevent the compensating hypertrophy which follows obstructions to the normal blood current, which may have their seat either in the heart or bloodvessels; but we may, by forbidding excessive muscular exertion, or other provocatives of increased cardiac action, prevent such hypertrophy from becoming excessive and consequently injurious.

A mode of life must be adopted which will prevent continuous or repeated excitement of the heart, and which, at the same time, will tend to promote the renovation of tissue and maintain the general state of nutrition as well as the vitality of the cardiac muscle, so as to enable it to meet the extra demand which is required of it in compensating for the lesion which has led to its development, and thus delay as long as possible the degenerative changes in muscular fibre which are certain to occur in excessively hypertrophied heart-walls. To this end moderately active exercise may be taken in the open air, but within the limits of slightly quickening the circulation, great care being exercised that occasional or sudden strain shall not be put on the heart by injudicious exercise or violent muscular effort; active prolonged physical exertion with the idea that it will reduce the volume of an enlarged heart, is calculated to exhaust muscular power, and leads to degeneration of muscular fibre. If a feeling of cardiac oppression, difficult breathing, headache, and vertigo exist, even moderate exercise will be found harmful.

The indications for treatment in cardiac dilatation from any cause are to diminish intraventricular and arterial blood pressure, and relieve venous engorgement: the heart, as far as possible, must be placed at rest, for it is well established that physical exertion increases both cardiac and arterial tension. There is no condition in which cardiac dilatation occurs that active physical exercise is safe, except when the dilatation is secondary to valvular lesions, the integrity of the muscular tissue of the hypertrophied walls being fully maintained, so that the heart fully compensates for both the valvular lesions and the dilatation. The question of exercise or rest in any form of degeneration of the heart-walls is to be determined by the extent and nature of the degen-

eration, as well as by the constitutional conditions under which it occurs. My experience leads me to the opinion that extensive fibroid change in the cardiac walls, occurring, as it usually does, in those of an hereditary or acquired fibroid diathesis, admits of less intracardiac tension than extensive fatty degeneration of the muscular fibre. Sudden death may occur in such cases as the direct result of sudden and violent exertion. In some instances an extreme dilatation of the ventricular cavities takes place at the time of the physical strain, which is never recovered from, and marks the beginning of a heart insufficiency which terminates life after a few weeks or months of cardiac distress.

The following history emphasizes this statement:

Case IV.—In November, 1888, a gentleman, fifty six years of age, with a gouty history, consulted me for slight attacks of dyspnœa, which followed exertion, stating that within a few weeks he had become so short of breath going up the stairs to the elevated railroad, that he was compelled to rest once or twice during the ascent. I found on examination the normal area of precordial dulness much increased, the apex impulse diffused and feeble, the cardiac rhythm irregular in force, and the heart sounds indistinct, but no murmur could be detected. From his history and general condition taken in connection with his heart symptoms, I was quite certain that extensive fibroid changes in the heart-walls existed, and I cautioned him against making violent or prolonged physical exertion.

On the 15th of the following month the elevator in the building where he had his offices having temporarily stopped for repairs, he attempted to walk up four long flights of stairs; when about halfway up the last flight his breathing became so difficult that he sank on the stairs and called for help. He was carried into his office, and after resting a few hours, took a carriage for his house in Fifty-first Street. A few moments after he reached it he died.

The autopsy showed an extremely dilated heart distended with blood, with somewhat thickened ventricular walls, which everywhere showed extensive fibroid changes. At the apex of the left ventricle the muscular tissue had entirely disappeared, and its place was occupied by firmly organized fibrous tissue; there were also evidences of both visceral and parietal interstitial pericarditis. It was evident that the fibroid changes in the heart walls were so extensive in this case that they had not sufficient contractile power to overcome severe intracardiac tension.

In the early stage of fatty degeneration of the heart walls, a moderate degree of vigor may be maintained for a long time, if patients are restricted to an animal diet, and adopt a life of daily systematic out of-door exercise, provided the exercise is never carried to fatigue or to such a degree as to cause dyspnœa. Often such patients after a time will be able to undergo an amount of physical exertion with advantage, which they could not at first safely have attempted, on account of the dyspnœa and anginal pain which it produced. Muscular exercise under these circumstances is far more likely to be of service in the young than in those past middle life. I have frequently found that in young subjects the signs of heart insufficiency would entirely disappear during a carefully regulated course of gymnastic or pedestrian exercise. But in those advanced in life, atheromatous disease of the aorta and secondary affections of the lungs and liver render even slight physical strain dangerous. If a fatty heart has once become dilated, as is indicated by recurring attacks of anginal pain, syncopal seizures, and paroxysmal dyspnœa, general enfeeblement takes place rapidly, and the most gentle exercise becomes dangerous.

The only heart affections which I have found uniformly benefited by vigorous physical exercise, are fatty infiltration, or, as it is sometimes called, fatty overgrowth of the heart, and weak hearts in anæmic and neurotic subjects.

The treatment of fatty infiltration of the heart differs in no respect from the treatment of general obesity; if the fat can be removed from the muscle of the heart, the organ will regain its normal contractile and resisting power. If the subject is young, the pulse regular, the heart free from valvular lesions, and its cavities not dilated, the aorta healthy, and the kidneys free from disease, the most active exercise may be undertaken without danger and usually with benefit. It is claimed that Oertel's plan of treatment is applicable to all cases of heart disease where there is a disturbance of the hydrostatic balance, but usually there is no disturbance of the hydrostatic balance in heart disease until after failure of compensation, except in those cases where there is general obesity with fatty infiltration of the heart.

The principal and primary pathological factor in obesity is faulty oxidation, and as the heart becomes implicated the power of oxidation is still further lessened. The object of treatment in these cases is therefore to get rid of the fat by increasing oxidation, and thus improving the nutrition of the heart muscle.

There is no question that the most effective means of accomplishing this is by active physical exercise in the open air, such as is obtained by mountain-climbing.

This is no new proposition, for Dr. Stokes, in his work on *Diseases of the Heart* (page 373), states that pedestrian exercise in mountainous countries such as Switzerland and the Highlands of Scotland, will enable patients with fatty hearts to undergo active and prolonged exercise without signs of heart failure, and that the effect of pedestrian exercise is

twofold: it not only increases muscular energy and development, but by augmenting the secretions of the skin it assists in conveying off a large quantity of the oily constituents of the system; "and," he adds, "I have seen most remarkable examples of this in young persons who have spent summers walking through the Alps, when during exercise they were under constant perspiration."

No one, I think, will doubt that a life of activity, which favors the oxidation of waste products and accelerates their removal from the body, tends to lessen the work of the heart; but if the heart-muscle is not in a condition to respond to the exercise, dilatation of the right heart must occur, and as its muscle becomes more and more exhausted, systemic capillary obstruction and increased arterial tension follow. When under such circumstances the imperfectly nourished left ventricle is unable longer to meet the demand that is now made upon it, it becomes dilated. Therefore even in a heart that is the seat of fatty infiltration, exercise must be carefully graduated, so that it shall at no time exceed the nutritive supply to the heart muscle. In every case where the heart muscle is not in a condition to respond fully to graduated exercise, the heart work must be reduced to its minimum, until by rest, forced nutrition and alimentation, its contractile power shall be regained. Certainly no case of fatty infiltration should be subjected to Oertel's plan of treatment unless there is unmistakable evidence that the cardiac muscular fibre is healthy. The weak hearts which are so often met in anæmic and neurotic subjects, I have usually found benefited and in many instances cured by judicious exercise and a carefully regulated diet, but the danger of cardiac exhaustion in these cases is very great and must constantly be borne in mind. My studies of the effects of violent physical exercise on the heart convince me that the morbid changes which lead to irreparable cardiac incompetency in a large number of cases commence in the left ventricle, and that their order of development is as follows: It is well established that during violent and prolonged physical exercise the cavity of the left ventricle becomes dilated and its walls hypertrophied to meet the greater demands of the general system for an increased blood-supply; this increase in the ventricular capacity and power gives rise to high arterial tension and increased aortic recoil; as a result degenerative changes are initiated in the walls of the aorta which diminish their elasticity and contractile power; as a consequence the force of the coronary circulation is diminished, and the nutrition of the heart walls interfered with. Excessive dilatation of the left ventricle is now liable to occur during any severe intra-cardiac tension, and the resulting overloading of the pulmonary circulation leads to right ventricular dilatation and finally to insufficiency at the tricuspid orifice. The general venous systemic engorgement which follows marks the advanced stage of cardiac incompetency. Therefore if we advise one who has passed middle life or who has an acquired or hereditary fibrous diathesis to enter upon mountain-climbing, or any other prolonged physical labor, we find when too late that our advice has been followed by irreparable dilatation of the right ventricle.

I would urge that before advising exercise to patients with cardiac affections, or even to those who have entered upon the degenerative period of life, who furnish none of the usual signs of cardiac disease, we carefully investigate their cardiac resisting power as well as the condition of their general arterial system.

TWO CASES OF LITTRE HERNIA.

By CHARLES B. PENROSE, M.D., Ph.D.,
OUT-PATIENT SURGEON TO THE PENNSYLVANIA HOSPITAL.

Littre hernia, or a hernia involving only a part of the circumference of the intestine, is of unusual occurrence and of great interest from a surgical point of view. In such cases, intestinal obstruction may exist though the constricting ring does not completely occlude the lumen of the gut. The cause of this obstruction is due either to a kink or sharp flexion, or to paralysis of peristaltic motion induced by the strangulation.

The diagnosis is obscure, for no tumor may be present, and no local tenderness or localized pain; all the pain being referred to the umbilicus, as in many other forms of intestinal obstruction.

In such cases of concealed hernia, where all symptoms of intestinal obstruction are present without any indication that the trouble is due to strangulation through a hernial opening, operation should be performed by median abdominal incision as in intestinal obstruction from an intra-abdominal cause. In Littre hernia median abdominal section not only serves for exploration, but often may be sufficient for treatment, as reduction can be accomplished by traction on the intestine from within the abdomen without division of the hernial ring.

Case I.—A female, forty-eight years old; general appearance cachectic, and that of a woman of seventy; admitted to the medical wards of the Pennsylvania Hospital under the charge of Dr. A. V. Meigs. She had suffered with abdominal pain for one week and with persistent emesis for thirty-six hours before admission. The attack was not acute in character, and she had on previous occasions suffered with similar symptoms. Emesis became feculent on September 16th; abdominal pain continued, and constipation was absolute. Dr. Meigs decided upon operation, and she was examined by the writer on September 17. She was then in a sinking condition; there was a moderate amount of abdominal distention, and the move-

ments of the coils of intestine were plainly visible through the abdominal parietes. There was general tenderness over the abdomen—most marked in the right iliac region. She had a previous history of right inguinal hernia, but there was no tumor present, and no tenderness in the region of the inguinal canal. Laparotomy was performed by median abdominal incision. A small quantity of sanguinolent serum was found in the peritoneum, and the presenting loops of ilium were distended and congested. The most distended loop was traced to the right iliac region, where there was a mass of adherent intestine; one loop about eight inches in length was bound by adhesions in a position of sharp flexion. The adhesions were separated with the fingers and the right internal inguinal ring was examined. A loop of intestine was found firmly attached to the ring by a diverticulum which entered the inguinal canal and was bound there by such old, organized adhesions that its removal by means of the abdominal incision was impossible. There was, however, no strangulation of the diverticulum and no occlusion of the intestine from which it sprang. No other pathological condition was found in the abdomen, the obstruction being caused by the adherent loops of intestine in the right iliac region. There was no shock after operation and she passed a comfortable night. Six days later she had obstinate diarrhœa.

She died from exhaustion, due to a combination of intercurrent diseases, thirty days after the relief of the obstruction.

At the autopsy a conical diverticulum was found situated on the ilium at a distance, from the mesenteric attachment of one-fourth the circumference of the intestine, and eighteen inches from the ileocæcal valve. It was one inch long and one-half inch in diameter at the base. In structure it was composed of all the intestinal coats. It was so firmly adherent to the inguinal canal that it could not be torn out. It occasioned no obstruction.

There were also present general atheroma, disease of liver, lungs, kidneys, and vertebræ, and cancerous ulceration of the cæcum.

CASE II.—A woman, sixty-four years old, was seized with sudden pain in the right inguinal region after heavy lifting, on July 26, 1889. This was followedby prostration, repeated vomiting, and intense umbilical pain. She was admitted to the surgical wards of the Pennsylvania Hospital twenty-four hours after the beginning of the attack. Her condition was then good. The temperature was normal, the pulse 90. There was no abdominal tenderness and but slight distention. The vomiting had ceased, and the tongue was clean. There was a cystic tumor, the size of a pigeon egg, over the right external inguinal ring, which had been there for many years. There was no tenderness on pressure, and no pain in the region of the inguinal canal. All her present pain was referred to the umbilicus. Before admission to the hospital unsuccessful attempts at taxis had been made on the cystic swelling in the right groin. When admitted, the tumor, except from its position, presented none of the signs of hernia. It was painless on pressure, and freely movable under the skin, and of the same size which it had had for many years.

A large rectal injection of turpentine and water was administered, and was followed by a very small fecal movement.

Early the next morning the abdominal pain and distention increased, and the vomiting began again and became fecal. As there was undoubted obstruction and no symptom to indicate the position of the lesion, a median abdominal section was made at 9 A.M. for the purpose of exploration. A loop of ilium was found caught in the right internal inguinal ring. The whole lumen of the gut was not involved, but a portion on the convex surface, about one inch in circumference, had slipped through the ring and was firmly constricted, requiring considerable traction for its removal. It was not necessary to divide the ring. The strangulated portion was brought to the abdominal opening and examined. It presented the appearance of a livid circle of one inch diameter on the convex surface of the ilium. It was restored to the abdomen and the incision closed. The cystic tumor in the groin was unaltered by the operation. Recovery was uninterrupted.

It is probable that the hernia in the case first described began in the same way as in Case II., without, however, producing strangulation and acute obstruction, and the false diverticulum was caused by constant, long-continued traction on the adherent portion of the circumference of the intestine.

DIPHTHERIA AT HIGH ALTITUDES.

BY S. S. TURNER, M.D.,
A. A. SURGEON U. S. ARMY.

ASIDE from its professional interest, it is seldom that one finds anything so entertaining in a medical journal as Dr. S. H. Chapman's "Notes on the Prevalence of Diphtheria at High Altitudes," published in THE NEWS of September 28th. The Austrian surgeon's brief summary of the epidemic in Tyrol, as of "atmospheric" origin, "non-contagious, and uninfluenced by treatment of any sort," is somewhat startling; but his statistics—"sixty cases and forty deaths"—correspond so nearly with my own observation of the disease in the high and dry northwest, that a great load is thereby lifted from my mind.

Approximately we may say that Dakota extends from the 43d to the 49th degree north and from the 97th to the 103d west, and that its elevation varies from 1000 to 3000 feet above the sea. Within this territory many cases of diphtheria, treated by many physicians, have come to my knowledge, and to place the mortality at 60 per cent. is to do no injustice to any practitioner of my acquaintance, whether we admit or not that the disease is "uninfluenced by treatment of any sort."

In the southwestern part of the Territory, ten or

twelve years ago, I saw two fatal cases, in consultation with other practitioners. Within a radius of twelve miles I also attended five cases personally, of which three died—seven cases, five deaths. I mention only the cases seen personally, but they do not differ from the general results.

I next encountered the disease about six years ago at Fort Buford, which is nearly upon the 48th degree north, with an elevation of 2000 feet or more. Like all "well-regulated" military posts, its slops are removed daily, its grounds "policed" weekly, the whole being inspected monthly by the commanding officer and his staff, and as much oftener by the chief medical officer as he may deem advisable. Whether due to this fact or not, there is very little disease of a serious character at this or any other of the posts in Dakota or Montana. Once in a while, however, we encounter a typical case of typhoid, such as in England comes only from dunghills and dairies, or in Philadelphia from defective plumbing, or more often a typical pneumonia, neither of which diseases gives rise, in my experience, to other cases, though treated in the same wards with tonsillitis, lumbago, and gonorrhœa.

At the time I speak of, Fort Buford was 160 miles from any considerable village and 80 miles from the nearest railroad station. It was midwinter, with a foot or two of snow, and a temperature ranging from about zero to 40° below. In some winters the temperature is rarely above zero between December 1st and March 1st, and never above freezing point, while in other years there may be an occasional thaw within this period.

A few hundred yards north of the main garrison, on the open prairie, is a structure containing four sets of "laundress quarters," each consisting of two rooms and an enclosed shed, the latter being used for water barrels in the winter and for laundry work, while the kitchen, and often the sleeping-room, is used for drying purposes. Yet these families are healthy as a rule. Beginning at the east end of the row facing south, one of two children in the family was attacked with what appeared to be a catarrhal tonsillitis, but on the second or third day I discovered that I had to deal with diphtheria, and that the second child was coming down.

In the adjoining quarters were five children who had been playing in the infected quarters, apparently with as much freedom as at home; and, in fact, the partitions were of such an open and flimsy character that ordinary conversation could be heard from one room to the other. However, I quarantined the five children upon their own side of the partition, and made a thorough inspection of the entire premises. Inside and out everything was clean. Suds had been carried away and poured upon the snow. The floor of the shed was damp, but clean. To all appearances the quarters were as good as any in the garrison, and all were as they had been for ten years. I had not heard of the disease being at any time nearer to Fort Buford than Bismarck—250 miles east. On the opposite side of the garrison were a larger number of laundress quarters, to all appearances in a similar condition, but no disease appeared there, although the women, as is usual, showed their sympathy by frequent visits.

In a few days both children were dead. About a week after their burial I was called to see the oldest of the five in the other family. It was said that he had been ailing for some days—had appeared weak and pale, but had continued to play about the house.. That morning, however, he had fallen down from sheer weakness while going to his breakfast. I examined his throat and found both tonsils diphtheritic, but apparently in a state of beginning resolution. I prescribed iron and chlorate of potash, without local treatment, and directed that the boy be kept in for a few days longer. He continued to improve, and recovered without confinement to bed, but later nearly starved from paralysis of the muscles of deglutition. The four younger children escaped the disease, as well as all of those in sets three and four.

Two months later a band recruit arrived with wife and three children from West St. Paul, where virulent diphtheria was prevailing. They occupied an isolated cabin, distant from the scene of the late outbreak nearly half a mile. A few days after their arrival one of the children was prostrated by the disease and died. The rest of the family escaped. Two months later a lad arrived from the far south to visit an aunt near the cabin of the band man. A few days after arrival the boy was stricken in the morning and died before sundown. Five cases; four deaths. I do not think the last two cases bore any relation to each other, or to the former three.

Some five years later—last winter—Fort Buford was revisited by the scourge, but, happily, I was not there to see it. Nearly the entire garrison had been changed in the meantime. The disease did not appear amongst the laundresses' children, but in the family of a non-commissioned staff officer, who lost his wife and three out of four children. One of two children in the nearest neighboring family was attacked and died. In a distant part of the garrison two of three children in the family of an officer were attacked and died. Two children of another officer were attacked, but recovered, the youngest suffering alarmingly from paralysis of the throat. Eight cases with six deaths. Total, twenty cases, with fifteen deaths, or a mortality of 75 per cent.

These cases "militate" strongly against the "atmospheric" theory of the Austro-Tyrolean, and, further, they prove that in a northern atmosphere

of great rarity and purity, with only moderate elevation, diphtheria is the most fatal of prevailing maladies.

While all the cases observed by me appeared to be of strictly local origin, I do not wish to account for the appearance of the microbes in any case, or for their sudden disappearance in the presence of so many exposed children; for future students may wish to prove that all microbes are pathological *results*, which may reproduce disease when transferred to a healthy body.

Camp Sheridan, Wyoming Territory, Oct. 16, 1889.

HOSPITAL NOTES.

STRANGULATED INGUINAL HERNIA.

Abstract of a Clinical Lecture
Delivered at the Buffalo General Hospital, October 10, 1889.

By ROSWELL PARK, M.D.

Dr. Park showed a man aged forty years suffering from an inguinal hernia which three and a half hours previously had become strangulated. Taxis having failed, he was brought to the hospital for operation. The hernial tumor was the size of a child's head, irregular in shape and distending the scrotum. It had also dissected between the superficial tissues of the lower part of the abdomen, which was considerably swollen in consequence. Previously to operating the surface was scrubbed, shaved, and washed with a mixture of turpentine and alcohol, which on account of its penetration Dr. Park prefers to other antiseptics for the skin. On opening the sac in the usual manner, about four ounces of blood-stained serum escaped. The walls of the sac were much thickened, and in some places adherent to the intestines, of which about twenty inches were found in the cavity. Several of the adhesions were torn, but no oozing followed and sutures were not necessary. The internal ring was nicked and the bowel readily replaced. A portion of the sac was continuous with the meso-cæcum, but the remainder was removed. A counter-opening was made for drainage, the wound irrigated and the internal ring united with silver wire sutures, catgut sutures being used superficially, and the whole dressed with an antiseptic pad.

Note.—Four days later the patient died, and at the autopsy an area of meningitis over the leg centre was found, under which the brain was œdematous.

CLINICAL MEMORANDA.

THERAPEUTICAL.

Clinical Reports on Arsenite of Copper.—There lie before me nearly fifty letters from physicians residing in different sections of the country, who have lately been observing the action of arsenite of copper in the treatment of various bowel affections, including cholera morbus, cholera infantum, diarrhœa, and dysentery. To sift this mass of correspondence and correctly estimate the value of the remedy is a work of no small magnitude, and the space required for such an elaborate study would tax the ournal that should undertake to publish it so severely, that I have decided to give an abstract of the communications, together with some illustrative cases, in the hope that further investigation will result as satisfactorily as has that which I have undertaken.

As a preliminary to the reports which follow, I may add a few words concerning the indications for the use of this comparatively new remedy, and some instructions regarding its administration. In addition to the above-mentioned diseases, Dr. Broughton, of Reidsville, N. C., has found it of great value in the treatment of chlorosis and allied affections, the dose in such cases being 1-25 grain three times daily. The best method of administering the drug is in small and frequently repeated doses. Thus, in the treatment of a case of cholera morbus, the dose for the day (1-100 grain) is dissolved in from four to six ounces of water, and a teaspoonful of this given every ten minutes for the first hour, and afterward at intervals of one hour, or, should the circumstances warrant, every half hour. To meet those cases where the use of water is contraindicated, I have had prepared for use tablets containing grain 1-100 and grain 1-5000, which enable the physician to graduate the dose, and repeat it at as frequent intervals as may be deemed necessary.

I had some hesitancy in offering to the medical profession a drug which was to be used in such small doses, and asked the manufacturers if it were possible to detect so small a quantity of the remedy as one part in five thousand, to which they replied that it was quite possible to detect *one part in ten thousand*, of either the arsenic or the copper. My later observations have been very favorable to the continued use of the drug, though I should add that there seems to be greater benefit derived from its administration in the early stages, before the inflammatory action has extended to adjacent or contiguous structures. When adjacent structures are involved, it is advisable to combine with it some suitable opiate in small doses, and as this method is the one that I have adopted, it will appear that I have not advocated the arsenite of copper as a specific.

In my attempt to present an abstract of the correspondence, some cases, of course, will have to be overlooked, but I wish to represent the true condition of affairs as nearly as possible, and I desire here to return my sincere thanks to the gentlemen who have favored me with an account of their experience.

Dr. J. W. Long, of Russell, Kansas, writes as follows: "At the time the samples were received, I had a very severe case of summer complaint under treatment, of three weeks' duration, in a child six months old. The usual remedies in such cases had been tried in vain; after I began with the arsenite of copper, there was within twenty-four hours a decided improvement, and after the third day the child was well." Dr. Long says that he has also used the drug in the diarrhœa of malarial and typhoid fever, and in other affections of the bowels, with good results.

Dr. W. H. Rees, of Trading Post, Kansas, writes as follows: "I have had occasion to use arsenite of copper in four bad cases. The first case was a child, æt. two and a half years, with a severe attack of cholera infantum. Vomiting was almost continuous, the bowels had moved fifteen to eighteen times in the course of seven hours, the nose and extremities were cold, with the usual pinched appearance of face, and shrunken limbs. I had been in attendance twenty-eight hours when the arsenite

of copper arrived, and had freely used the usual remedies, but the patient was worse than when first seen. I then began with the arsenite of copper and withdrew everything else, except small quantities of water. The child vomited but once after the first dose, and the bowels moved but three times in the following twelve hours. Improvement was steady and permanent, and I made but two subsequent visits. To-day the child is as rugged as you could wish to see."

Dr. R. D. Boggs, of Marquez, Texas, says: "In cholera morbus, the effects of arsenite of copper have been prompt, ameliorating the symptoms and perfecting a cure without other medication, in almost every case. In cases of longer duration, I have generally been unsuccessful with it, and have had to resort to other treatment, although I regard it as a valuable remedy in bowel troubles, if used early."

Dr. J. B. Burroughs, of Shortsville, N. Y., writes that he has been successful in the treatment of four cases out of five, and that the fifth case was much benefited by the treatment.

Dr. R. B. Root, of Georgetown, Mass., says he has used it in six cases, three of which were successful, but that in cholera infantum he dared not continue its use longer than twelve hours.

Dr. P. D. Carpenter, of Pittsford, N. Y., says although he used it in both infants and adults, his experience was not favorable, and that he was forced after a sufficient trial to resort to other remedies.

Dr. John L. Heffron, of Syracuse, N. Y., has also failed to see good results following its use, although he says it is worthy of a more extended trial than he gave it.

The experience of Dr. A. H. Thomas, of Ironwood, Mich., is in marked contrast with that which has just been related. Speaking of its use in cholera morbus, he says: "In every case I have used it, it acted like a specific. I gave a few tablets to Dr. Nivens, of this place, for trial. He was called to a very severe case, and would have used his hypodermatic had he not forgotten it. He prescribed the arsenite instead, with the happiest results."

Dr. H. S. Crockett, of Rural Retreat, Va., reports that he has used the remedy in a number of cases of cholera infantum and in cholera morbus, but that as other remedies were used at the same time, he is unable to say what influence the arsenite of copper had, "except in a case of dysentery, which yielded to this drug after the disease had resisted the ordinary remedies, and also one case of cholera morbus which was relieved without resort to any other remedy."

Dr. F. C. Ard, of Pomeroy, Ohio, has used this drug in two cases only, one being a child of fourteen months with diarrhœa, the other a child of eighteen months with acute dysentery, engrafted upon a chronic diarrhœa. The first case was promptly relieved, but in the second recourse was necessary to other methods of treatment.

Dr. J. W. Chamberlain, of Wyalusing, Pa., has used the drug in various instances, and thinks the results have for the most part been favorable. Some of his patients have not again reported, and these cases are set down as successful, while in others he has seen relief follow within twenty-four hours.

Dr. J. H. Freeman, of Lexington, Va., reports that the results were very satisfactory. "Three cases of enterocolitis were promptly relieved of the diarrhœa and tenesmus, and, as no other medicine was given during the time, I am satisfied that the results were due to the arsenite of copper. Other treatment which had been adopted was discontinued and the arsenite alone used, when the patients recovered in a few days." He says also: "The arsenite was tried in a case of tubercular laryngitis with diarrhœa, with very great relief. I also gave it in a case of pulmonary phthisis, with profuse diarrhœa, and the discharges were reduced from twelve to two per diem."

Dr. A. D. McDonald, of Wilmington, N. C., reports having used the remedy in eight cases of typhoid fever, and that it acted like a charm in six and did moderately well in the other two. He has used it in about forty cases, and is well pleased with it.

Dr. E. L. Harriott, of Jacksonville, Ills., gives an account in detail of four very interesting cases, and closes as follows: "I think in genuine, uncomplicated cases of cholera morbus, especially where there is a tendency to dysenteric discharges after the first onset, of which I have had a number previous to obtaining this remedy, it would be invaluable, as it seems to relieve promptly."

Dr. D. Sinclair, of Tonawanda, N. Y., reports "that he has used arsenite of copper in the treatment of summer diarrhœa of adults and children, in chronic diarrhœa, typhoid fever, irritable stomach, and in anæmia with gastric and bowel trouble with good effect. In the bilious attacks which are so common to children in the hot season, the children tolerated large and often-repeated doses, and especially where the symptoms were severe, the vomiting and other symptoms generally ceased as if by magic, and improvement commenced with the first dose. . . . . In anæmia, with irritable stomach and bowels, the patients were soon able to tolerate more food, the body increased in weight, the lips became rosy, and, when the monthly periods had ceased, they were re-established."

The report of Dr. A. I. Lawbaugh, of Opechee, Mich., so accords with my own observations that I transcribe the following: "My first case was an infant of eleven months, suffering from cholera infantum, bordering on the stage of collapse. After the arsenite was administered, the child vomited but once, the stools became less frequent. and in three hours the child was on the way to recovery. I treated a number of similar cases almost invariably with the same success. When failure occurred it was either because the medicine had not been given according to directions, or else too late.

"My first administration of the drug to an adult was in a case of cholera morbus, where the patient had been under other methods of treatment for twelve hours without benefit. After the first dose he vomited but once, the bowels moved no more, and in twenty-four hours after beginning the treatment he considered himself well. I used it in many similar cases with equally good results."

Dr. C. C. Stockard, of Columbus, Miss., has given the drug a fair trial in various disorders: in cholera morbus it has given prompt relief; in some cases of diarrhœa in children it has been less satisfactory, but in a number of cases which threatened to develop into typhoid fever relief has followed in the course of a few days.

Dr. E. C. Dupont, of Grahamville, Beaufort County, S. C., says his experience has been somewhat limited, but he has used the arsenite in two cases of cholera mor-

bus, and in each instance the medicine acted promptly in checking the vomiting and purging.

Dr. F. F. Field, of Elroy, Wis., has had the misfortune to meet with quite a number of very obstinate cases of dysentery which failed to yield to any of the ordinary remedies, and has not been successful with arsenite of copper. He has used it in but two cases without the aid of other medicines, but was compelled to discontinue its use after a day or so, an observation which should not be overlooked in connection with the suggestion made regarding the use of opiates.

Dr. John Swain, of Ballardsville, Ky., writes for himself and his partner, Dr. Weeks, giving an instructive account in detail of no less than twelve cases, covering diarrhœa, dysentery, cholera morbus, and cholera infantum, in which the arsenite was used with great satisfaction. This communication, I hope, will soon be published, and it will be sufficient to say that both these gentlemen "are thoroughly convinced of the efficiency of the remedy."

Dr. E. C. Linn, of Monmouth, Ills., writes that he has used the tablets in a number of cases of typhoid fever where there was diarrhœa, and in the majority of instances it acted very promptly. In other bowel affections it has not always been successful, although he records one severe case "where it acted like a charm." The patient had been suffering all the morning from cramps and active purgation, and the arsenite was exhibited about 2 P.M., but when he called again about five o'clock, the patient had recovered and gone out.

Dr. W. F. Spragins, of Aberdeen, Miss., reports in detail a series of six cases in which the use of this drug was attended with most excellent results. One case was that of a man æt. thirty-three, who complained of having an annoying, griping pain about the umbilicus. He says: "Here the arsenite of copper acted like a charm, one tablet being all that was required to bring about permanent relief . . . . ."

Dr. John M. Buckingham, of Springfield, Ohio, sends a general report, in which he mentions that he has succeeded admirably with the preparation in the treatment of several cases of typhoid fever. "I purpose adding the remedy to my regular armamentarium, and have every confidence that future use will verify what is claimed for it." The statement of Dr. Buckingham is one that I can fully indorse, especially in the matter of treating typhoid fever, and now that I understand its action so well in this disease, it would seriously embarrass me were I compelled to eliminate this drug from my list.

Dr. L. G. Broughton, of Reidsville, N. C., sends a lengthy report which I shall advise him to publish, as it covers the treatment of the diarrhœa of phthisis, that of dysentery, and also that of chlorosis, already referred to, and is on the whole an excellent testimonial to the great value of the drug in this class of cases. Dr. Broughton is very positive that the good results he has witnessed are due to the influence of the remedy.

Dr. W. E. Shelton, of Appleton City, Mo., writes that he has used it in a number of cases, with very satisfactory results; the cases he reports include five cases of diarrhœa in children, ranging in age from six weeks to three years, and two cases of dysentery. He adds: "I must say that I had but little faith in the remedy in such small doses, but am now satisfied that it will prove to be one of the best remedies in diarrhœa and dysentery."

Dr. J. F. Escher, of San Diego, Cal., says he has used the remedy in ten cases, ranging in age from six months to forty-six years, and in most of the cases the bowels were checked after giving six doses at intervals of ten minutes, and in every case the diarrhœa was checked before one full tablet had been taken. In only two cases was there a disposition for the bowels to become loose again after a day or two, and these were in children fed on fresh, unboiled milk, which the stomach failed completely to digest.

In concluding this somewhat imperfect epitome of my correspondence upon an important topic, I may add that I still have a large number of cases included in reports which have not been mentioned, but space and time forbid, and the foregoing is submitted with the hope that the readers of this journal will properly estimate the value of the testimony in favor of this drug. Should there be any doubt in the minds of some, I can only refer them to the remedy itself, the use of which will furnish the best evidence of its great advantage over the methods of treatment usually practised.

JOHN AULDE, M.D.
4719 FRANKFORD AVENUE, PHILADELPHIA.

MEDICAL PROGRESS.

Gonorrhœal Ophthalmia.—In gonorrhœal ophthalmia M. HIGGENS first washes the conjunctiva with a 5 per cent. solution of boric acid, then uses the following ointment spread upon linen and placed over the eye:

℞.—Hydrarg. ox. flav.	. .	gr. jss.
Cocaine.	. . . .	grs. vijss.
Acid. boric.	. . . .	grs. xvij.
Vaseline	. . . .	℥j.—M.

—*Monatshefte für praktische Dermatologie*, Oct. 1, 1889.

Excision of Rectal Cancer.—At a discussion in the Surgical Section, British Medical Association, on the treatment of rectal cancer, MR. W. HARRISON CRIPPS formulated his views on excision as follows: Probably not more than 15 or 20 per cent. of cases are in any way benefited by the operation, and such cases are difficult to select from among those in which excision is not indicated. The operation should not be undertaken unless the patient's constitutional condition is good, or unless the entire neoplasm can be removed; hence it is important to determine whether or not the bladder, upper part of the vagina, or uterus are involved, and whether the growth is confined to the lower portion of the rectum. If the finger cannot reach healthy mucous membrane removal is not justifiable. Implication of the ischio-rectal fossæ or of the lower part of vagina does not necessarily contraindicate excision.

For the operation the patient should be prepared by a dose of oil twenty-four hours previously, and within two hours of the operation, a warm-water enema. The patient is then anæsthetized and arranged in the lithotomy position with the buttocks raised by a hard pad. A strong sharp-pointed curved bistoury guided by the finger or speculum is passed into the bowel and by transfixion made to protrude through the skin at the side of the coccyx. The intervening tissues from this point to the anal margin are then cut through. If the incision is cleanly made and as nearly as possible in the median line

the hemorrhage will not be great and can be controlled by the pressure of a sponge.

A crescentic incision is now made, extending from the margin of the first cut to a point in the middle line in front. This cut should be made boldly and sufficiently deep to extend well into the fat of the ischio-rectal fossa. If the skin around the anus is healthy, the cut should be confined to the mucous membrane. The forefinger thrust into the incision will now readily separate the bowel from the surrounding tissue except at the insertion of the levator ani, where scissors should be used. A piece of sponge is now thrust into the cut to control bleeding, while the opposite side is treated in the same manner, when the vessels of both sides should be clamped.

The anterior wall is next separated by a careful dissection, which in the male is facilitated by a sound in the bladder. When the dissection is carried beyond the disease the bowel is drawn down with moderate force by a vulsellum forceps. The diseased bowel should then be cut off with strong curved scissors, clamping all vessels that bleed. Stitching the cut edges of the bowel to the anal margin should not be attempted, as it forms pockets in which discharges collect. A piece of rubber tubing five or six inches long is then passed into the bowel. Next a square of lint with a central hole to pass over the tube, is smeared with eucalyptol ointment and gently pressed into the wound, the space between the lint and the tube is packed with iodoform wool, and the whole retained with a T-bandage.

Thirty-six hours after the operation the wool is removed, the lint being left in position and syringed with carbolic solution.

As the wound heals it is important to guard against contraction, which would cause an intractable stricture. If contraction is noticed during cicatrization, a full-sized conical rectal bougie should be daily passed until the wound is healed.—*British Medical Journal*, October 12, 1889.

Turpentine in Whooping-cough.—DR. VASCENCELLOS DES POST employs turpentine in whooping-cough by dropping it upon the child's pillow, thus causing constant inhalation of the vapor, as an enema, in capsules, or with belladonna in the following formula:

℞.—Tinct. belladon. . . .	♏ xx.
Ol. terebinth.	f ʒij.
Syr. althææ	f ʒiij.—M.

Of this a tablespoonful may be given every two hours.—*L'Union Médicale*, October 12, 1889.

Ichthyol in Skin Diseases.—DR. KARL KOPP has used ichthyol in a number of different skin diseases and with varying results. He prefers the ammonium sulphichthyolate, which he not only applies externally in ointments and solutions, but also administers internally in the form of pills. He finds that patients can take more than a drachm daily without harm.

Dr. Kopp's results were as follows:

In acne rosacea and pustulosum, the external and internal use was of great benefit after seven months' treatment. Applied externally only, the results were less marked than when given internally alone.

In acne vulgaris, ichthyol combined with daily applications of sublimate solutions, occasionally produced good results, but oftener not.

Angioma was not influenced by the drug.

Facial erysipelas was usually cured in from three to five days by a 30 to 50 per cent. ichthyol ointment spread upon linen.

Acute eczema was, in a few cases, improved, but in many more aggravated; and in chronic eczema the effect was in no instance curative.

Prurigo mitis improved under the local application of a 10 per cent. solution, but the improvement was invariably temporary. In prurigo ferox the results were even less satisfactory.

In a few cases of senile, neurotic, and idiopathic pruritus, the internal administration of ichthyol, combined with the external application of a 30 to 40 per cent. ointment, diminished the itching, but in others this effect was not apparent.

Seborrhœa sicca capitis was uninfluenced by the drug, The statement of Unna that after the scraping of lupus or removal of papillomata, the application of pure ichthyol caused satisfactory cicatrization, Dr. Kopp is unable to confirm.—*Monatshefte für praktische Dermatologie*, October, 1889.

Herpes Genitalis.—The *Gazette de Gynécologie* of October 15, 1889, gives the following directions for the treatment of this condition: When the skin has a considerable tendency to dryness, frequent applications of vaseline should be made; or if, on the other hand, moisture is present, this powder should be used:

Subnitrate of bismuth . .	15 grains.
Tannic acid	75 "
Powdered starch . . .	3 ounces.

When the surface is washed, the water used is carbolized, and, if ulcerations occur, they are to be treated by astringent dressings, but never by cauterization.

Suspension in Locomotor Ataxia.—In the *Lancet* of October 19, 1889, the results of treatment by suspension in fourteen cases of tabes are tabulated by Drs. Russell and Taylor. Three of the cases improved while undergoing the treatment. One improved at first, but during the last three weeks he had a relapse, and when he left the hospital was certainly worse than he had been a month before. Another case had, between April and June, a course of twenty-five suspensions, but experienced no improvement. A month after this the ataxy became much more marked, and the suspensions were resumed. After ten suspensions he began to improve, and this improvement was maintained until he left the hospital. Considering the negative result of the first course of suspensions in this case, the improvement during the second course can scarcely be regarded as anything more than a coincidence. One case said that he thought he walked better and was more steady, but neither Dr. Ormerod nor the house-physicians, observing independently, could say that there was any improvement to be seen. In another case commencing optic atrophy was the prominent symptom, and although the patient himself said he thought his vision was better, careful testing did not confirm this.

In the cases in which improvement did occur, this consisted in a less ataxic gait and a greater steadiness in standing. In no case, however, was there ability to stand with the eyes closed, nor was there a return of the knee-

jerk or of the pupil reaction to light. In one case the shooting pains were relieved somewhat, but in none of the cases had they been either a recent or a prominent symptom.

In the greater number of the cases it will thus be seen that there was no improvement. Most of them remained practically in the same condition, but in more than one there was an evident retrograde tendency.

Injection for Uterine Cancer.—In the *Gazette de Gynécologie* of October 15, 1889, we find the following treatment, as recommended by CHERON:

Salicylate of soda	100 grains.
Salicylic acid	15 "
Tincture of eucalyptus	2½ fl. oz.
White vinegar	1½ pints.

Add one or two tablespoonfuls of this mixture to two pints of warm water, and inject into the vagina several times a day until the disagreeable odor is destroyed.

The Use of Naphthol in Typhoid Fever.—BOUCHARD, in the *Gazette Hebdomadaire* of October 4, 1889, recommends the use of this substance in the treatment of typhoid fever. The method carried out is as follows:

As soon as the disease is discovered to be present, calomel is given amounting to from four to eight grains, divided into two doses. On the next day the naphthol is administered, either alone or with the salicylate of bismuth, or, better still, with the salicylate of magnesia. If the diarrhœa is severe, the following treatment is to be employed: β-Naphthol thirty grains; made into ten powders, and one of these given every few hours. If the looseness of the bowels persists, salicylate of bismuth is to be added to the dose, three grains every two hours.

On the other hand, if constipation is present, salicylate of magnesia is to be employed in the same dose.

Treatment of Pigment Spots in Pregnancy.—MONIER, in the *Monatshefte f. praktische Dermatologie*, recommends the following formula for the treatment of this annoying condition:

White precipitate	1½ grains.
Oxide of zinc (pure)	4½ "
Castor oil	2 ounces.
Cacao butter	2 "
Essence of roses	q. s.

To be applied night and morning.

Butylchloral in Facial Neuralgia.—LIEBREICH recommends butylchloral in facial neuralgia, using doses varying from fifteen to forty-five grains a day. The formula employed is as follows:

Butylchloral	45–75 grains.
Alcohol	2½ fluidrachms.
Glycerine	5 "
Distilled water	4 fluidounces.

Of this the patient is to take a tablespoonful at a dose.

Surgical Treatment of Peritonitis.—At the recent French Congress on Surgery the following views were announced:

PROFESSOR DÉMOSTHÈNE, of Bucharest, advised that in tubercular peritonitis the abdomen be opened, the cavity washed with boric solution, and drainage continued as long as there was discharge. By these measures he believes that the patient is rendered more comfortable and life prolonged. In purulent peritonitis, he thinks the same treatment should be adopted if the case is seen early and is in fairly good condition. If in this disease operation is delayed the results are unsatisfactory. Localized purulent peritonitis should be treated as an abscess in any location. Professor Démosthène does not consider sublimate or carbolic solutions inadmissible, but seems to prefer boric acid.

M. DEMOUS, of Bordeaux, believes that if laparotomy is undertaken in peritonitis it should be done early, and thinks that physicians are too tardy in summoning the surgeon.

M. BOUILLY insists that in purulent peritonitis a large incision is unnecessary, but the peritoneal cavity must be thoroughly washed out with a boric solution or a 1 : 6000 sublimate solution. This should be done with a canula sufficiently long to reach all parts of the cavity.

M. DENUCÉ washes the peritoneal cavity with sterilized water and sponges, and for drainage uses iodoform gauze.—*L'Union Médicale*, October 12, 1889.

Belladonna in Renal Calculi.—In the *Provincial Medical Journal* for October, DR. W. MURRAY reports three cases in which the passage of renal calculi was hastened and pain quickly relieved by the free administration of belladonna. In all cases the drug was pushed until the well-known toxic symptoms were marked. Dr. Murray believes that the action of belladonna here is analogous to its action in intestinal obstruction, a belief that seems entirely rational.

Hypodermatic Use of Mercury in Syphilis.—The Berlin correspondent of the *Medical Press and Circular* writes that DR. HEBRA still pursues this course of treatment of syphilis at the Polyklinik, but admits that it is not so successful on outdoor patients as those under special care, as one has not the opportunity of modifying the dose to the individual wants.

He uses one injection daily of a 90 per cent. solution of sublimate with 6 per cent. of sodium chloride added. Of this solution, one centigramme of the sublimate is injected, or 0.15 of a grain. The injection is made in the nates, going deep into the gluteal region on the right and left side on alternate days.

Twenty injections during three weeks are the usual number allowed for complete recovery. Infants and adults are treated on the same principle, with the dose modified according to age. Exceptions to this rule are found, however. Hebra mentions a case that he is now treating at the clinic as an example of difficulty. The case has been under his notice for three years, and been injected 350 times. No effects of the drug can be obtained, but severe sickness when pushed.

The danger of abscesses forming at the site of injection is small, as he has used it for five years and now says he never had a single untoward case, although he has treated 800 such cases, and at an average of 20 injections that would be 16,000 injections. The pain of injection may be raised against the treatment, but this seems to the patients a trifle.

The advantages gained far more than counteract the disadvantages. The drug immediately enters into the circulation, where the mercury seems to combine with the albumin and form a very stable compound, as it is long before it is thrown off from the kidneys. Accord-

ing to Bockhart's experiments, it is three weeks before anything is seen after commencing the use of this chloro-soda-mercuric compound.

The drug administered thus is observed to act rapidly and last longer than in any other method. As to the period of delay before any sequelæ appeared, he could not give figures, as many of the patients would go to the nearest attendant for medical advice.

Electrical Stimulation in Apnœa during Anœsthesia.—DRS. H. A. HARE and EDWARD MARTIN, in an exhaustive study upon stimulation of the diaphragm in apnœa, conclude that by far the most important practical point to be gained from their observations is in regard to the methods commonly used in the application of electricity to persons who have ceased breathing, particularly during the action of an anæsthetic. While few text-books give any specific directions concerning the practical application of such methods, those that do so force the physician to a method at once dangerous and impractical, for the directions usually given are to place the positive pole on the phrenic nerve as it crosses the anterior scalene muscle at the root of the neck, the negative pole being pressed against the lower margin of the ribs, and a rapidly interrupted current being used with the purpose of causing contraction of the diaphragm by the direct action of the electricity upon the nerve. Even theoretically this is a possible source of danger, and practically they have proved danger to be an ever-present fact under its use. The cardiac inhibitory nerves run so closely to the phrenic fibres, and respond so readily to electrical stimulation that it is hard to imagine how they can escape stimulation if a current be used of sufficient strength to excite the phrenic nerves near by. By practical experiment they have proved that inhibition of the heart may not only be possibly brought about by this method, but that it is nearly impossible to avoid its production if the phrenics are to be reached at all.

The electric brush produces a more powerful effect upon the terminal extremities of the sensory nerves than any known method of stimulation. Far more powerful than the douche and than abdominal applications of ether, as recommended by Hare, it should be used under all circumstances when death threatens from respiratory failure. It should not, however, be applied to the neck, but a sponge electrode being placed at the base of the ribs the brush should be applied at intervals to the epigastrium, to be removed when inspirations result, and reapplied when breathing movements cease. If artificial respiration is being carried on by Sylvester's or other of the recognized mechanical methods, the wire brush should be applied during the inspiratory movements.

It would seem probable that in those cases where the use of electricity has been resorted to, the return to life has been the result of reflex stimulation rather than a direct effort on the phrenic nerves.—*University Medical Magazine*, November, 1889.

Sulphate of Copper Injections in Dysentery.—In the *Lancet* of October 12, 1889, DR. W. EASLEY reports a case of dysentery cured with rectal injections of sulphate of copper. The patient had been suffering for about a month with the usual symptoms of the disease, and had been treated to little purpose with bismuth, gallic acid, and ipecacuanha. Finally, when he was growing worse, a solution, consisting of ten grains of sulphate of copper and one drachm of tincture of opium, in four ounces of water, was injected high into the rectum by means of a soft-rubber catheter. The injection caused no pain, in a few hours tenesmus was relieved, and blood ceased to pass. On the two following days a small amount of blood reappeared, and the injections were repeated, but from that time convalescence was rapid.

Intestinal Obstruction.—DR. GELPKE reports in the *Correspondenzblätter für Schweizer Aerzte* four cases of intestinal obstruction, of which two had been operated on—one with success—and two had been successfully treated with metallic mercury. From these cases he concludes that quicksilver is a valuable remedy in cases of obstruction, and that the metal seems to be quite innocuous to the system if not too long retained. It had been so retained in one of the two cases in which four teaspoonfuls of quicksilver had been given, and the feces and urine of the patient contained the drug for twelve weeks. There were other distinct symptoms of mercurial poisoning, such as great emaciation, excitement, loss of hair, and some stomafitis. The other patient, on the contrary, showed no signs of mercurialism whatever. He considers that in hernia it is generally advisable to commence the abdominal section from the orifice of the sac. Finally, considering the uncertain and not very successful attempts of laparotomy, he would not operate before other means, such as quicksilver, have been tried for from four to six days.

DR. S. V. REITZ, in the *Centralblatt für Chirurgie*, reports the case of a laborer suffering from obstruction of the bowels who, after three days' fruitless administration of purgatives, was brought to the hospital. Fecal vomiting was present, and a tumor could be felt on the left side of the umbilicus. Enemata of water by the long tube, though as much as six pounds of water were injected, were unsuccessful, but the vomiting and sickness improved after repeated washing out of the stomach. The next day the patient was considerably worse, and fecal vomiting returned, with cold perspiration, restlessness, meteorismus, a pulse of 120, and a temperature of 100°. After the enema with the long tube had been again used, and the stomach repeatedly washed out, without any improvement, seven drachms of bicarbonate of soda in five ounces of water were injected into the rectum, followed by three drachms of tartaric acid in the same amount of water, and the anus closed. The patient, who was on his knees and elbows, complained at once of severe abdominal pains, and in five minutes the injection came away with exceedingly offensive flatus. Shortly afterward the patient felt considerably better. In three hours the enema was repeated with half the previous doses, and was shortly followed by a large loose motion, and by a second later on. The patient completely recovered.—*Lancet*, September 21, 1889.

Sulpholeinic Acid has been called "polysolve" by Mr. H. Wilson, of Manchester. This product is produced by the action of sulphuric acid upon any kind of vegetable oil, and when concentrated is a yellow viscid liquid. It is capable of dissolving a large number of organic and inorganic substances, two per cent. of sulphur, three per cent. of iodoform, twenty-five per cent. of camphor, etc. —*The Pharmaceutical Journal of New South Wales*, September 16, 1889.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 9, 1889.

THE CHOICE OF ANÆSTHETICS IN LABOR.

ALTHOUGH there are still a few aged practitioners who assert that it is wrong to use anæsthetics in labor, chiefly on the ground that the Almighty intended women to suffer in childbirth, the majority of the profession recognize the fact that the proper employment of some transient pain-relieving agent is a procedure almost as much in the line of duty to the parturient woman as the safe delivery of her child. That these drugs are often abused there can be no doubt: either they are pushed to such an extreme that the uterine muscle is relaxed and does not expel the fœtus, or fails by its contraction to prevent post-partum hemorrhage; but such objections hold good in every case where a drug is wrongly employed, and should not militate against a proper use of a medicinal substance.

With a regularity equal to a quotidian malarial paroxysm, the medical journals of the world, and more particularly of the English-speaking peoples, break out into long discussions as to the values of the various anæsthetics, the dangerous effects of chloroform and ether, and the assertions of masses of professional men arranged in opposing lines, which on the one hand support chloroform with a fervor only equalled by their opponents, the advocates of ether. The questions concerning these facts are now under study and discussion, and we cannot forbear the opportunity of pointing out what we believe to be the true aspect of the case.

The most enthusiastic supporters of chloroform for professional favor cannot, and do not, deny that the drug has a far larger list of deaths than has ether, even when the administrators were skilled physicians; and on the other hand, the advocates of ether cannot take exception to the statement that it very commonly produces nausea and vomiting with irritation of the lungs, all of which symptoms are peculiarly distressing in abdominal diseases or wounds. No one, we believe, will assert that death occurs as suddenly from ether as chloroform. The one is essentially a cardiac and respiratory paralyzant, the other a cardiac stimulant, except in overwhelming doses, and a respiratory stimulant until large amounts are given. As a consequence of this it at once becomes evident that in the hands of any person chloroform is the more dangerous drug of the two, and when employed by the unskilled nurse or physician possesses power for the greatest harm. Further than this, chloroform acts dangerously upon the heart in two ways, both of which may be present at once, and act immediately after the first whiff of the drug. It may stop the heart by stimulation of the vagus nerve or by paralysis of its muscular fibres. Indeed, many deaths from chloroform have occurred after the earliest inhalations and not after its prolonged employment. Idiosyncrasy has also a prominent part in its lethal power, and no number of previous anæsthetizations can be regarded as evidence of safety in an individual case. Ether kills by a slow failure of respiration, or very rarely, probably never in those cases where it is given to a healthy man, by failure of the heart which is progressive and not sudden. The one shows its danger signal, the other strikes its death-blow as does a bullet in the heart.

We do not wish to be understood as universally condemning chloroform; far from it. We believe that in many cases it is preferable to ether, but in the case of a healthy man there can be little doubt that the latter is the safer drug. Neither of them is to be condemned, for both have their parts to play. The surgeon and accoucheur should not be asked whether he uses chloroform or ether for all cases, any more than whether he employs morphine for all patients suffering with insomnia. There should be no factions in the profession in this respect, and no preference be shown to either drug by any body of men. The laws which are to be laid down are founded on therapeutic reasoning, not on dogmatic preference. No one has a right to

take the patient's life in his hand where it is so lightly balanced that nothing can save it should it suddenly fail, and for this reason ether is to be the more generally employed. On the other hand, the presence of acute or chronic bronchitis, of acute or subacute renal disease, of dilated or fatty heart, seems to us to call for the employment of chloroform.

In the former states the large amount of ether given is apt to irritate the lungs and the kidneys, or in the state of excitement and struggling so to strain the heart that the danger of cardiac failure is imminent. The same reasons hold good where atheromatous bloodvessels exist, and where, in consequence, apoplexy is feared from the struggles and increased blood-pressure produced by ether. The number of deaths during labor due to chloroform inhalations have been surprisingly few, for what reason we know not, unless it be that only a very little of the drug is generally given. There are no deaths from ether in the same state. The disagreeable preliminary signs of the inhalations of ether may be avoided if it is given so diluted with air as to anæsthetize the fauces before it is pushed in a concentrated form, and the after-symptoms of nausea and vomiting are rarely seen in parturient women, unless its use is excessive. Finally, we may be allowed once more to insist upon the statement already made, namely, that each has a field of its own and that neither one can be used to the total exclusion of the other.

HYPODERMATIC MERCURIAL INJECTIONS IN THE TREATMENT OF SYPHILIS.

The modes of administering mercury are, fortunately, numerous. In many cases in which the need of this drug is most imperative, the gastro-intestinal tract is so irritable as to preclude its administration *per os*, and compel recourse to inunction or fumigation. Both these methods are open to objection: the first on the score of cleanliness, the second on account of the elaborate nature of the proceeding and the publicity which it is almost sure to involve. For these reasons the addition of mercury to the long list of hypodermatic medicaments was a welcome and, there is good reason to believe, a permanent one. This opinion may be maintained in spite of the fact that the latest report on the treatment of syphilis by hypodermatic mercurial injections is rather unfavorable.

Leloir and Tavernier (*Journal des Maladies Cutanées et Syphilitiques*, No. 3, 1889) have practised 1573 mercurial injections in syphilitic cases of all grades of intensity, and in every stage of the disease. Of these injections, 875 were made with calomel suspended in vaseline; 642 with yellow oxide of mercury suspended in vaseline; and 56 with "gray oil," as in the following formula:

Vaseline	40 grammes.
Ethereal tincture of benzoin .	5 "
Purified mercury . . .	20 "

Of this mixture one-third of a Pravaz syringeful was injected every ninth day.

The authors believe that this method of treatment can never come into general use, and state that a number of their hospital patients preferred discharge to submission to it.

Its sole advantage is, in their opinion, the rapidity with which it causes erythematous and other syphilides to disappear from the integument, its action upon mucous syphilides being slight. Of the three substances employed, calomel is the least, and "gray oil" the most effective.

The objections to the method are: violent pains, lasting, on an average, from one to three days, sometimes much longer; paresis of the lower extremities; vertigo and cephalalgia; diarrhœa, etc. In no instance did the injections cause suppuration.

In conclusion, Leloir and Tavernier state that in the immense majority of cases they prefer mercurial inunction to hypodermatic injection of mercury. They found that cutaneous eruptions disappeared quite as rapidly under treatment by inunction, and mucous eruptions much more so. The eruptions having disappeared, they keep their patients in a condition of "mercurial impregnation," by means of pills of bichloride or protiodide of mercury, and repeat the frictions at variable intervals. This treatment is continued during one or two years, and iodine is withheld until the second year. They believe that by such a plan of treatment the best results are to be secured, and their great experience entitles these views to the most respectful consideration.

REVIEWS.

A Treatise on Gout. By Sir Dyce Duckworth, M.D. Edin., etc. With Frontispiece and Illustrations. 8vo., pp. 476. Philadelphia: P. Blakiston, Son & Co., 1889.

"I have bin very careful to write nothing but what was the product of careful observation. Soe when the scandall of my person shall be layd aside in my grave,

it will appear that I neither suffered myselfe to be decieved by indulging in idle speculations, nor have decieved others by obtruding anything to them but downright matter of fact."

With these quaint words we find the opening page of this interesting book strewn; words which, arising as they did from the immortal Sydenham, represent a desire too little seen in scientific and clinical studies nowadays; and which form with other abstracts a proper prelude to a thorough study of a condition little understood in any of its parts, and one which, with its sister, rheumatism, stands as a rebuke to the medical progress of the day.

While recognizing the complexity of the subject in hand, the writer seems to us to have written an unusually clear exposition of a state usually hopelessly confused and unreal, and apparently has followed, almost everywhere, the quotation just given. He has pointed out the relation between gout and other morbid states, and adheres closely to the theory concerning the dependence of disease upon the existence of distinct diatheses; an adherence which he himself recognizes as one which, at the present time, is apt to bring a storm of adverse criticism upon his head. It is impossible in these pages to review thoroughly so complete a study and one upon which the author has expended so much care and clinical research. The disease is defined, its pathological nature is studied, and its pathogeny followed with the care of an accurate clinical student of medicine. The question of its hereditary transmission is fully considered, and an interesting chapter is devoted to the states which are believed to be similar in the lower animals. In the last chapters the question of therapeutics is thoroughly discussed, and we are glad to see that no less than one hundred and six pages are devoted to this subject.

The only chapter which we are disappointed in is that upon "Pyrexia in Gout." We turned to these pages with the hope that we might at least find some careful study of the manner in which such variations in temperature may occur. No such observations are made and nothing is said concerning the hyperpyrexias which sometimes come on suddenly in gouty people. Even under the heading of "Retrocedent Gout to the Brain," no mention of such a state is to be found.

Sir Dyce Duckworth has written a very useful and interesting work on gout. He does not seem to have drawn about it a vast amount of contemporaneous literature nor of experimental study, but has brought forth a book which typifies its author in its careful and perhaps laborious treatment of a disease concerning the character of which clinicians must know more than those given to original research. Written on the soil where gout in all its forms delights to revel, a wealth of cases naturally adorns its pages and a colored figure shows a state common enough in England, but more rare in this country, *i. e.*, gouty deposits in the eyelids.

To those who are interested in these troubles and who find patients with sufficient English blood to possess the ailments of their grandsires, we heartily recommend the book. Written in an unusually interesting style, it is easily read and will give such information about the treatment of gout as will enable the ordinary practitioner to benefit his patients by its perusal.

A COMPEND OF PHYSIOLOGY. By ALBERT P. BRUBAKER, A.M., M.D. Fifth edition. Revised and enlarged. Illustrated. Philadelphia: P. Blakiston, Son & Co., 1889.

WITH such a book as this one before us it is almost impossible to give anything more than a notice of the fact that a fifth edition has appeared.

To review a quiz compend is an unnecessary task, since it is not supposed to present any new views nor to be worthy of such a dignity. To say anything in the way of criticism concerning a book which students have rejoiced in up to a fifth edition is equally difficult, and to find fault with a compilation which has been added to by an active teacher during years of experience is to seek for those little flaws which are present everywhere in every work, and singularly absent in this. The only just criticism which we can make is in regard to the tables, which give with mathematical exactitude the chemical constituents of certain secretions or parts. Practically, the student is never expected to burden himself with such figures, and a compend is supposed to deal only with what he must know. The book before us teems with interesting facts, and we shall shortly expect to see a sixth edition appear on the publishers' shelves.

STUDENT'S AID SERIES. Vol. I. 12mo., pp. 200. New York: G. P. Putnam's Sons, 1889.

THIS is the first part of a series bearing the marks of this well-known American house, although the authors are residents of England. The volume is divided into three parts, all of them on diagnosis. Parts I. and III. are by J. Milner Fothergill, while Part II. is by Thorowgood. The latter considers diagnosis from its physical standpoint, while Fothergill writes on semeiology, and "what to ask" when searching among the symptoms for the signs of disease. Both these articles can be read in Fothergill's *Handbook of Treatment*, but they are undoubtedly valuable enough to make the possessor of this little book a fortunate purchaser. The type is very small, and the ink is unevenly distributed; a fault common in books printed in England, but which are sent over to take an American imprint.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, October 9, 1889.

THE VICE-PRESIDENT, JOHN B. ROBERTS, M.D., IN THE CHAIR.

DR. LAWRENCE WOLFF read a paper on

THE CHEMISTRY OF THE FUNCTIONAL DISORDERS OF THE STOMACH.

DR. FREDERICK P. HENRY read a paper on

THE DIAGNOSIS AND TREATMENT OF FUNCTIONAL DISEASES OF THE STOMACH.

(See THE MEDICAL NEWS, October 26, 1889, p. 449.)

DR. H. A. HARE: I wish simply to suggest a possible explanation of the results of one investigator referred to by Dr. Henry, who found a large quantity of hydro-

chloric acid in the stomachs of persons who had been fasting. Dr. Beaumont and others have found that any foreign body introduced into the stomach will cause a secretion of gastric fluid. I do not see why such an outpouring of fluid might not be produced by the introduction of the rubber tube.

DR. J. P. CROZER GRIFFITH: I wish simply to bear testimony to the value of the tests for hydrochloric acid presented to us this evening, and to say that if the method devised by Dr. Wolff proves one by which the clinician can make a quantitative analysis rapidly and easily, I think much will have been gained. Perhaps many hearing Dr. Wolff speak, and knowing how conversant he is with chemical procedures, may think these manipulations are beyond our skill. Speaking as a clinician who has no special knowledge of chemistry, I can say that I have used these tests for several years, and with great satisfaction. Methyl-violet has proved reliable and delicate, as has also Congo paper. Probably I have failed to obtain the proper variety of tropæolin, though two different kinds have been used, for success has attended none of the trials I have made of it. With Günzburg's test I have no experience. The principal difficulty which we encounter in this country lies in securing the consent of the patients to the withdrawal of the contents of the stomach.

As is well known, attention was first directed to the subject by the investigations of Riegel and others, with reference to the mutual relation of hydrochloric acid and carcinoma of the stomach; the claim having been made that in this disease free hydrochloric acid is always absent, and the peptic strength of the gastric juice diminished. Much strife has arisen over the matter, which has nothing to do with the subject under discussion tonight, except that these investigations led to the study of the secretion in functional disorders of the stomach. An interesting point in this connection which seems to have been undoubtedly proved is, that in the majority of cases of dyspepsia we are not dealing with a diminution of the gastric secretion of hydrochloric acid. It is poured out too soon, or in too great quantities. We are, therefore, working on a wrong basis if in every case of dyspepsia we straightway administer pepsin and hydrochloric acid. In many cases an affection which starts as a functional disturbance may end as an organic disease. There is no question that too much hydrochloric acid will produce gastric ulcer. Gastrectasia is due also to an excessive secretion of the acid, which, being secreted before the normal time for it to appear, interferes with the digestion of the starches. These consequently remain too long in the stomach, accumulate there, and by at last interfering with its motor power, produce the dilatation.

DR. JAMES TYSON: I used the tests which have been described by Dr. Wolff in a patient suffering with cancer of the stomach, with the results described. In this case it seemed that there was a deficiency in the hydrochloric acid of the gastric juice. My experience with tropæolin was similar to that of Dr. Griffith; perhaps for the same reason.

DR. S. SOLIS-COHEN: In the limited experience which I have been able to obtain from a few patients, I have been unable to confirm the clinical value and the diagnostic value of these tests. It may be through some fault of my own. With the phloroglucin-vanillin test and Congo red there was no difficulty in demonstrating the presence of hydrochloric acid. With all due respect to the eminent observers who have recorded their researches in this matter, I am unable to see that we are much advanced in diagnosis, of either functional or organic disease of the stomach, by these tests. As has been suggested, the very presence of the tube may interfere with secretion. Cases have come under my observation where the too frequent or improper use of the tube has rather aggravated the condition. I would not, however, decry lavage as a therapeutic agent. I use it constantly, with good results.

I have been much interested in the remarks in regard to the connection between lithæmia and nervous dyspepsia, and am satisfied that many of these cases are intimately connected with the uric acid diathesis. There is a vicious circle: the dyspepsia, the neurasthenia, and the uric acid in the blood. Which is the first, and which the last, is difficult to determine. I have found that the uric acid element was the weakest part, and treatment directed under the supposition that we were dealing with a case of lithæmia produced results quicker than any other.

I have thought that much of the pain complained of some time after meals was due more to faulty intestinal digestion than to gastric disturbance, and with the use of pancreatin, properly guarded, I have relieved the pain. Hoffmann's anodyne is also useful in these cases, not only from its anodyne effect, but from its effect upon the pancreatic and intestinal secretions. These remarks are simply supplementary to those of Dr. Henry, and are not intended to take issue with what he said.

DR. ALBERT P. BRUBAKER: There is one symptom of impaired motility not alluded to by clinicians which may be of importance in the diagnosis of gastric disorders, and which is connected with the process of deglutition. According to the current works on physiology, after the food passes from the mouth into the pharynx it is grasped by the constrictor muscles, and by a rapid peristaltic action forced through the œsophagus into the stomach. The experiments of Kronecker and Meltzer have shown that deglutition is not due to a peristaltic action, but that after the food passes the isthmus of the fauces it is thrown by the action of the mylo-hyoid muscles through the œsophagus to the cardiac orifice, which is normally closed. If auscultation is made over the xiphoid process at the beginning of an act of deglutition, a sound is heard five or six seconds later, which is due to the squeezing of the bolus through the cardiac orifice, and which is denominated the "squeeze sound." Now, if there be a relaxation of the cardiac orifice, there is heard immediately after a swallow of water a different sound, which is denominated the "squirt sound," and which is due to the propulsion of the water directly from the pharynx into the stomach. The squirt sound is heard in cases of relaxed cardia with a tendency to eructations and vomiting.

DR. HARE: I happen to know something of the investigations to which Dr. Brubaker refers, as I was Kronecker's student immediately after Meltzer. Dr. Brubaker has left out an important point—namely, that if, after swallowing the food or water, the subject immediately makes a second swallow, the portion previously swallowed will at once be precipitated into the stomach. If, however, the subject refrains from making the second swallow, the six seconds will elapse. The patient must

be cautioned to resist this tendency to swallow the second time.

DR. WOLFF: If Dr. Hare's suggestion were correct in regard to the effect of the tube, the gastric secretion should always be hyperacid. The fact is, that it is often anacid and often subacid. I have made with Dr. Davis, at the Philadelphia Hospital, some examinations of the gastric secretion of normal infants, and in all the cases that we have examined in the predental stage, there has been entire absence of hydrochloric acid. In the gastric catarrhs we find a subacid condition whether the tube is used or not.

After exhausting other measures, and after enlightening the patient in regard to the use of the tube, I generally succeed in gaining his consent, and after it has been used a few times it can be introduced without difficulty. I had one case which would vomit as soon as the pharynx was touched, but by persistent effort he got so that he would swallow the tube himself and wash his stomach out every morning. He was admitted to the hospital in a run-down condition, weighing eighty-nine pounds, and unable to leave his bed from emaciation in consequence of pyloric stenosis. He was discharged, weighing one hundred and fifteen pounds, after two months' treatment. I presented him to the Atlantic County Medical Society a short time ago, well and hearty, weighing one hundred and twenty-six pounds. Lavage is, of course, not indicated in every stomach case, but in the severe cases, where there is not only functional, but also organic, trouble, the mechanical treatment is of the greatest benefit.

DR. HARE: Dr. Wolff has misunderstood my remark with reference to the irritation of the tube. Dr. Henry referred to the investigations made to determine by the passage of the tube, whether gastric juice was or was not secreted during fasting, without reference to acidity or hyperacidity. I pointed out that the introduction of the tube would cause a flow of gastric juice.

DR. HENRY: The irritation caused by the introduction of a soft-rubber tube into the stomach is very slight, and its stay in that viscus not long enough to produce the amount of secretion removed from it in the fasting condition. This varies from one or two to four or five cubic centimetres. In regard to the observations of Beaumont, I do not think the quality of the secretion which he obtained by irritating the gastric mucosa was ever accurately determined. It was probably nothing more than a feebly acid mucus.

It is a most significant fact that no mention has been made of pepsin this evening. From the lavish manner in which it has been and is still prescribed, one might suppose that the absence of this enzyme is the root of every gastric ailment, whereas investigations prove that it is almost never absent from the gastric secretions. The amount necessary for healthy digestion is very minute. Bourget, whom I have already quoted more than once, has shown that one-tenth milligramme of pepsin is enough to suggest well-marked digestive power.

Dr. Cohen complains of want of success with these methods, and of the difficulty of applying them. I confess that the difficulty is great. Dr. Wolff seems to have been unusually fortunate in persuading his patients to submit to them. There can, however, be no doubt of the great value of these researches. The discovery of the hitherto unrecognized condition of hypersecretion is ample reward for all the labor expended in their pursuit.

Reference has been made to the swallowing sound, the *Schluckgeräusch* of the Germans. It is fully described in Part First of Ewald's work on *Diseases of Digestion*, but he attaches little or no diagnostic importance to it.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, October 7, 1889.

J. EWING MEARS, M.D., IN THE CHAIR.

DR. THOMAS G. MORTON read a paper upon

THE TREATMENT OF CLUB-FOOT; THE REMOVAL OF THE ASTRAGALUS IN EQUINO-VARUS.

DR. MORTON said that the results of treatment in many cases of congenital varus and equino-varus have been very unsatisfactory.

In no other department of surgery do we find so great a difference of opinion in regard to treatment, while the various kinds of apparatus which have been recommended for correcting the deformities are simply legion.

Congenital club-foot, which results from intra-uterine paralysis, may be mild or severe. More or less atrophy can always be found, and even under the most favorable surroundings is but partially recovered from; nerve supply to the limb is impaired, groups of muscles are affected, and, as in infantile paralysis, the stronger group overcomes the weaker and deformity follows.

Not only is the club-foot of less size than the foot of the normal side, but a comparison of the lengths of the limbs shows a general impairment of development, and with marked and permanent atrophy. This condition is more observable as the patient advances in life.

It seems reasonable to assume that the amount of deformity is in accordance with the period of intra-uterine life at which the palsy occurred. Paralysis coming on early in fœtal life is likely to give rise to the more severe forms of foot-deformity, as the tarsal bones, when in process of development, are then more readily distorted by muscular action; when palsy occurs toward the close of gestation, the tarsus is fully developed, and there is less opportunity for displacement.

There are cases of club-foot which readily yield to stretching, manipulation, and apparatus, or later on, possibly tenotomy, but the tarsal bones are in nowise involved in the deformity; such cases follow the palsy which occurs late in fœtal life.

There are others where the tarsus is found distorted at birth, with which, by immediate treatment and subsequent tenotomy, excellent results can be obtained, and the bones can generally be forced into proper position.

Without treatment, or by neglect after tenotomy, these cases, if the distortion is anterior to the astragalus, may require tenotomy, or tarsectomy, with or without open incision.

In some cases, after the open incision, a considerable gap is made when the foot is placed in the proper position, and in the subsequent healing of the wound we have a predisposition to the recurrence of varus; to avoid this, Dr. Morton turns upon the open wound surface a flap of integument, which may be taken from the dorsum or side of the foot.

Another class of cases are those where the nerve

lesion has probably occurred early in intra-uterine life, involving the entire tarsus; the astragalus is often found rotated and displaced forward, thus acting as a wedge, and preventing flexion and extension of the foot. Here tarsectomy only partially corrects the deformity; the same can be said of the open incision. In such cases, the removal of the astragalus must be considered, and if this bone is excised, the anterior tarsus need not be disturbed.

DR. MORTON exhibited several recent cases and photographs of astragalus excision, tarsectomy, open incision, cuboid and tarsus excision.

He was well aware that objections might be made to such radical operation as excision in young children. In the cases presented, the operation had been, however, for recurring varus, cases which are always difficult to deal with. He was equally confident, also, that in most cases of marked astragalus displacement, only a radical operation such as excision would give a satisfactory result. The operation is without danger, while the advantage of promptly correcting the deformity and avoiding the use of braces, will the sooner permit a development of the feeble limb.

DR. MORTON showed the following case: A boy aged fourteen, admitted to the Orthopedic Hospital, July 12, 1889. He had been operated upon for club-foot when nine months old by general tenotomy, and had used braces for several years.

Left foot: congenital equino-varus with great outward displacement and rotation of astragalus—its fibular articular process presenting subcutaneously in the central plane of the leg. Considerable atrophy. Right foot normal; three-quarters of an inch longer than the left.

On July 13th, the astragalus was excised through an incision extending in a curvilinear direction, from half an inch above the external malleolus to the base of the metatarsal bone of the third toe. The bone had to be split with cutting pliers before the calcaneo-astragaloid ligament could be divided; otherwise the operation was easy. Catgut drain and permanent antiseptic dressing. A right-angle tin splint was used.

August 11. Dressed for first time; foot in excellent position and condition; wound healed, save a very superficial ulcer.

18th. Wound entirely cicatrized.

28th. Brace was applied, and he was able to walk on the foot; no tenderness, and good ankle motion.

The next case shown, a boy aged three years, was admitted to the Orthopedic Hospital, August 21, 1889.

Right foot: congenital equino-varus, operated upon in infancy and tendons divided, but foot greatly deformed at present.

Left foot: also operated on previously, but in much worse condition, the astragalus being rotated through nearly half a circle, with its tibial articulating surface subcutaneous.

August 22. Left astragalus removed entire, without difficulty, through an incision extending in a curvilinear direction from just above the external malleolus to the base of the metatarsal bone of the third toe. Catgut drainage, permanent dressing, and right-angle tin splint. Open incision with extensive division of tendons in the right foot.

September 3. Feet dressed; right foot wound closed; left, slight superficial wound.

October 5. Left foot in excellent position. Right foot, some disposition to recurrence of varus; excision of astragalus is advised.

This third case was also a boy, aged two and a half years, who was admitted to the Orthopedic Hospital on September 26, 1889, with severe left equino-varus, the astragalus markedly rotated, and the tibial articulating surface subcutaneous; a curved incision was made from the external malleolus forward, and the astragalus removed. The wound was dressed in the usual manner, with gut drain, permanent dressing, and right-angle tin splint. There was excellent position of the foot in this case.

DR. JOHN ASHHURST, JR., said that he came to the meeting principally for the sake of seeing these cases, as he had heard Dr. Morton speak of his success with removal of the astragalus. He understood that in certain cases of relapsed club-foot, where tendons have been divided, but the after-treatment not properly carried out, it would be desirable to operate in this manner. In young patients who have not been previously operated upon he had met with no cases that could not be cured by simple tenotomy and division of the plantar fascia, with proper mechanical after-treatment. He, however, had considerable trouble with relapsed cases, and would be disposed to adopt this operation in such cases hereafter.

DR. DE FOREST WILLARD said that in the cases referred to by Dr. Ashhurst, and in large children or adults where we have hard, intractable feet with distorted bones, where the tarsal units have become wedge-shaped, where almost all the bones and tissues have become fixed, he thought that the excision of any bone which might be necessary to bring the foot into proper position was not only justifiable, but desirable. In the younger cases, however, especially under three years of age, he had never found feet which could not be brought into position with strong force after free division. He divides everything in the way, tendon, fascia, or ligament, and applies extreme force, which never produces sloughs or does any harm. Although he had torn ligaments and even a section from a bone, yet it had been nothing more than a simple fracture.

The results in these cases were, he thought, better than after the removal of a bone or a portion of the tarsus. If the astragalus is removed, we must have either anchylosis, or the calcaneum must form a new articulation with the tibia and fibula, which must be a painful process. In one of the cases shown to-night, that of the boy, the foot seemed more tender than would be found after the foot had been put in position by force.

He thought that removal of the astragalus was better than the removal of a wedge, for, in the latter case, there is usually anchylosis with stiff and rigid locomotion. In the majority of uncomplicated cases under the age of fourteen years, he believed that we are able, with manual and instrumental force, to carry the foot into position after free division. After this age it becomes exceedingly difficult and often impossible, and in many of these cases removal of the astragalus is a desirable operation, as it saves time and gives a better foot.

DR. O. H. ALLIS had not had sufficient experience with removal of the astragalus to speak of the ultimate results, but could confirm what had been said in regard to the immediate results. In a boy fourteen years of age, he worked for a year to bring the foot into good position,

but did not succeed until finally he removed the astragalus. He found that although the child had a shapely foot and did not need to wear an apparatus, yet there was no ankle motion, and the patients of Dr. Morton could not yet bring the feet to a right angle. What the condition will be six months or a year hence could not be foretold.

Dr. Morton, in closing the discussion, said that of course the operation for the removal of the astragulus is not for deformity of the anterior tarsus, but for those cases where the astragulus forms a wedge and prevents the foot from being brought into proper position. He had always been in favor of the forcible correction of club-foot when practicable, and years ago devised an instrument by which great force could be so applied. His experience was that we have had more relapses of club-foot and more unsatisfactory results than we are perhaps willing to admit. In the boy shown to-night, he did not believe that it would have been possible to bring the foot into a right-angle position without the removal of the astragalus. In regard to the boy's movement, it must be remembered that he has a more or less paralyzed atrophied limb which is much shorter than the other. A certain amount of awkward character in his walk is irremediable. He thought that the quicker we can put a distorted foot into the proper position so that the patient can plant the sole on the ground and dispense with apparatus, the better result we shall have.

Dr. J. M. Barton presented a patient showing

BONY UNION OF FRACTURED PATELLA, AFTER WIRING THE FRAGMENTS; PERFECT MOTION OF THE FOOT.

He had expected a case of fractured patella treated by the modified Malgaigne's hook, to have been presented here to-night by one of the Fellows. He had brought this patient to show the results of wiring the fragments. The patient broke her patella by muscular contraction about five months ago. Dr. Barton wired the fragments with a heavy silver wire a few days later; the wire remained in position for six weeks when it was removed. She had no symptoms except a slightly elevated temperature (from 99½° to 100°) for the first two weeks, and he feared that a low grade of inflammation was present in the joint, which might result in anchylosis, but his fears proved groundless. The limb was kept at rest in plaster for two weeks after the wire was removed, and she was then permitted to use it. The patient was shown, and it could be seen that she had now full use of the leg, walking without any limp. It was readily flexed past a right angle. The patella was as movable as its fellow of the opposite side. And as there were no inflammatory deposits around it, and its outline was well defined, there was no difficulty in deciding that firm bony union had occurred.

At the time of the operation the usual distinct veil of tissue, about one-eighth of an inch thick, was found lying over each fractured surface.

Dr. John B. Roberts said that he was inclined to think that many of these cases of supposed bony union are nothing more than exceedingly close ligamentous union. He had placed in the Mütter museum a specimen of what was supposed to be bony union after the use of the modified Malgaigne's hooks by Dr. Levis. When the specimen was fresh a little motion could be discovered between the two fragments; now when the specimen is dry, no motion can be detected. Wiring of the fragments seems to be a little more serious operation than the use of Malgaigne's hooks.

Dr. DeForest Willard said the only case of bony union after fracture of the patella that he had been able to verify, occurred in an old woman who broke the patella by direct violence. He saw her within five minutes after the accident, before there was any effusion. There was free motion between the fragments, but there had been no separation, and the fragments were at once secured with adhesive plaster and a posterior splint applied. The dressing was kept in place eight weeks. Two years later he verified the occurrence of bony union by sawing the patella. There was never any swelling or inflammation of the joint, and no pain.

Dr. Barton thought the operation by wiring was not called for in cases like that described by Dr. Willard, where the fracture is due to direct violence. In cases where the fracture is due to muscular action the tissues over the patella separate after the fracture and fall between the fragments, preventing bony union. It is this tissue that causes the ligamentous union and which stretches so much afterward. Macewen found this veil of tissue in all of his cases, and Dr. Barton's experience had been the same. In one of his cases the double layer of membrane was fully three-eighths of an inch thick. When the fragments are brought in contact with each other and wired it seems impossible for bony union not to occur. As regards the risks of the operation, Macewen has had no difficulty whatever, and in the case coming under his own observation there had been no symptoms calling for alarm. It is probable that in this case the high temperature was due to something else than the wiring.

Dr. Roberts presented the following

SIMPLE THOUGH PERFECT METHOD OF RENDERING INSTRUMENTS AND DRESSINGS ASEPTIC:

All have experienced difficulty in getting instruments and dressings absolutely aseptic, and he had always felt that unless his instruments and dressings were prepared by himself or a tried assistant, there was a probability that they were not germ-free. In order to sterilize dressings and instruments, he had made by a tinsmith an ordinary laboratory sterilizer with double walls, under which he places one or two Bunsen burners. The instruments are always kept in a tightly covered copper box which can be placed in the oven. If he gets the instruments in the box sterile by heat, he can carry it around for a week or more, as there is no tendency for dust to get into it. The handles of the knives must, of course, be of steel, or, if of wood, must be riveted to the blades. The box is placed in the oven and the temperature run up to 130° C. This is shown by the thermometer passing through the top of the open. He usually allows the instruments to remain in the sterilizer about two hours, though the temperature is not at 130° all of that time.

We know that moist heat is a better sterilizer than dry heat, but the objection is that subsequently one has to dry the instruments and thus run the risk of contamination. The instruments might be placed in the dry-oven after being in the steam, but this would complicate matters. If the temperature of his oven runs above 130° C. or 145°. C., the steel instruments become oxi-

dized, some becoming blue, some yellow, and some quite brown. Nickel instruments, however, are not affected at this temperature. He keeps the thermometer bulb about the middle of the oven, where he had found that the temperature is about ten degrees lower than at the bottom, so that if the thermometer indicates a temperature of 120° to 125° C., it was certain that it was about 130° to 135° C. at the bottom shelf This temperature will scarcely scorch the dressings, but it does not do to go higher than this. All germs except that of anthrax are destroyed at a temperature lower than 130° C., and the bacillus anthracis is destroyed at this temperature. The staphylococci and the streptococci are destroyed at a lower temperature.

DR. J. EWING MEARS presented the following case of

RADICAL CURE OF HERNIA:

One year ago he presented to the Academy a patient on whom he had performed the operation for the radical cure of hernia. The operation was done in June, 1888, sixteen months ago. He again presented the patient at the expiration of this time in order that the Fellows might examine him and determine the result of the operation, in which there was no sign of a return of the hernia, although the man has been steadily working in a woollen mill where he is obliged to lift heavy bales. This was a case of entero-epiplocele. He opened the sac, divided the stricture, returned the gut, excised the omentum, returned the stump to the abdomen, then tied the neck of the sac with a double ligature and cut between. The proximal portion was twisted and secured in the internal ring with a long pin. The distal portion of the sac was sutured and allowed to remain, as it was found that the hernia was congenital, and by this plan a tunica vaginalis was formed

He also reported this evening another case of entero-epiplocele on which he had operated three weeks ago. In this case the operation was performed in the same manner as in the one above reported, except that the distal portion of the sac was removed. It was an inguinal hernia of some years' duration in a woman. The omentum had become so much changed that it was difficult to recognize, and the sac was one-quarter of an inch in thickness. The omentum was ligatured in sections and removed, the stump being returned to the abdomen. The patient came into the hospital after prolonged taxis had been employed.

Adjourned.

CORRESPONDENCE.

RHUS TOXICODENDRON.

To the Editor of THE MEDICAL NEWS,

SIR: There appeared in the issue of this journal for April 20th a short communication from me upon the use of rhus toxicodendron in rheumatic affections, in which I mentioned the beneficial effects obtained in sciatica, lumbago, muscular and joint affections, and in varicose veins. In that letter I inadvertently omitted giving information in regard to the dose of the drug or the special preparation that I had used, and in consequence of this omission a number of gentlemen have written for information upon these points. The preparation I have referred to further on in this memorandum; but here I wish particularly to speak of the dose. My observations thus far have been confined to the exhibition of the drug in doses not exceeding one-half drop of the tincture made from the fresh leaves according to the formula of the *Pharmacopœia*, and for convenience I have this prepared in the form of a solution with dilute alcohol, in the strength of one part of the drug to ten parts of the solution, so that five drops of the solution contain one-half drop of the tincture. This is to be taken three times daily.

Since that time I have published accounts from different observers (*Therapeutic Gazette*, October, 1889), and the following note from Dr. Everett is offered with a view of confirming the statements I advanced last April:

Dr. J. O. Everett, of Edington, Illinois, under date of August 21, 1889, writes: "I have taken the rhus four times a day for two months. First the tincture you sent me; then the fluid extract. . . . . It has helped me, but I am not yet entirely well. I have had sciatica nine months; have taken nearly every thing we give, with but little, if any effect, until I began with the rhus. I shall continue taking it for some time. I have given it in two other cases of sciatica, in which it worked splendidly. One case took it only four days, the other one week, and so far they have had no return of the disease. I gave it to seven cases of muscular rheumatism, in each of which it acted very satisfactorily, and a case of lumbago and one of torticollis were each quickly relieved.

Again, under date of September 29, 1889, he writes, asking me to send him some of the fresh tincture, as he is unable to procure it. He says: "Out of several lots I have used I have been disappointed in its effect:" and adds, "I am pleased to say that I am feeling much better. It has now been over one month since I have felt anything of my old trouble, sciatica."

Referring to my correspondence with Dr. Everett, I wish to say that on the receipt of his communication in the latter part of August, I wrote him to the effect that I was inclined to the opinion that the preparation he had been using was faulty, and accordingly I forwarded to his address a supply of what the importers, Messrs. Parke, Davis & Co., call the *German tincture*, which, I believe, is prepared according to the formula of the *United States Pharmacopœia* for the making of tinctures of fresh herbs—the maximum dose that I have used being one-half drop three times daily. My impression was thus confirmed that the tincture of the fresh plant was far superior to any and all other preparations, because as soon as he began taking this product his sciatica was relieved. Another evidence that this is the true interpretation may be inferred from the fact that he says in his first communication nothing afforded any relief until he began taking the tincture that I first sent him, along with the directions for its use. Whether this is assuming too much I submit to the judgment of the reader, and should like to have the matter tested by other observers besides myself, as I have shown that it is a drug of no small importance, and also that it can be used with safety.

JOHN AULDE, M.D.

4719 FRANKFORD AVENUE, PHILADELPHIA.

ANN ARBOR, MICHIGAN.

(From our Special Correspondent.)

To the Editor of THE MEDICAL NEWS,

SIR: Notwithstanding the great changes in the Faculty of Medicine in the University of Michigan, and the attempt which was made by one of the retiring instructors to induce the old students to go elsewhere to complete their studies, the department has more students than it had last year.

The fearful mortality which has followed the operation of ovariotomy in our hospital for the past two years promises not to be repeated this year. Prof. Nancrede has operated upon two very difficult cases, before the class, and both are recovering nicely.

The Regents have purchased twelve acres of land, and will begin immediately the erection of a new hospital, for which $75,000 have been appropriated. The site is a commanding one, overlooking the river, and the patients will not be compelled to complain of lack of air or of unsanitary surroundings.

The chemical laboratory, which already contains more than three hundred work tables, is being treated to an extensive addition. All the laboratories are filled to the utmost. Freshmen students are required to spend the afternoons of three months each in the anatomical, histological, and chemical laboratories. During the junior year, afternoons are employed in the laboratories of physiology, physiological chemistry, pathology, and hygiene. The afternoons of the senior year are devoted to hospital work. Many of the students approve of the proposed four years' course.

NEWS ITEMS.

The Johns Hopkins Hospital Bulletin.—The Trustees of the Johns Hopkins Hospital have authorized the issue of a publication to be known as the *Hospital Bulletin*. It will contain announcements of courses of lectures, programmes of clinical and pathological study, details of hospital and dispensary practice, abstracts of papers and other proceedings of the Medical Society of the Hospital, reports of lectures and all other matters of general interest in connection with the work of the Hospital. Nine numbers will be issued annually. The first number will appear in November, 1889. The subscription price will be one dollar per year, and subscriptions may be sent to the Publication Agency of the Johns Hopkins University, Baltimore, Md.

A Professorship Endowed.—It is stated that Peter Graff, of Worthington, has announced the gift of $25,000 out of the estate of his son, Charles H. Graff, M.D., who died recently in Duluth, Minn., to endow a professorship in Pennsylvania College at Gettysburg, to be known as "The Dr. Charles H. Graff Professorship of Hygiene and Physical Culture." Dr. George D. Staley, of Lebanon, formerly of Harrisburg, has been chosen to fill the Chair.

Reception to Dr. Rihl.—On Tuesday evening, October 29th, at the Colonnade Hotel, a reception and banquet were tendered to Dr. Henry W. Rihl, upon his return from Europe, by members of the Northern Medical Association and other professional friends. The following gentlemen were present: Drs. Hulshizer, Fischer, Pepper, Da Costa, Mitchell, Longaker, McBride, Nightingale, J. L. Rihl, Q. P. Kellar, Shriner, McDowell, Dieterich, Hornor, Gibb, Collins, Hess, J. S. Walker, Knorr, Vogler, Bochroch, Bissey, Ott, Strittmatter, Maylau, Oliver, Strobel, Rohle, Stern, Teller, Bobb, Beates, Horn, Gaus, Steinbach, Taylor, Updegrove, Hohnes, Deaner, Mills, J. B. Walker, Love, Roberts.

The Southern Surgical and Gynecological Association holds its session at Nashville, Tenn., November 12, 13, and 14, 1889, and has issued a preliminary programme. The meeting promises to be a large and successful one. About forty papers by eminent members of the Southern profession are already on the list.

Johnstown Health Bulletin.—In issuing this, its last bulletin, in reference to the health of Johnstown and the Conemaugh Valley, as affected by the great flood, the State Board of Health has its most serious obligation yet to perform—that of urging upon the people in the most emphatic manner the necessity and the duty of becoming themselves the protectors of the public health. If the success which has attended the efforts of the Board to prevent the occurrence of a pestilence such as has invariably followed like disasters in the past, has impressed upon their minds this lesson: that accumulations of decomposing animal and vegetable matter near human habitations are always dangerous and never to be tolerated, and that in thickly settled regions the only way to avoid such accumulations is by the creation of specially constituted authorities charged with the duty of their prevention and removal, clothed with full power and provided with sufficient means to enforce their own regulations—the direct and immediate benefits which its presence here has conferred will be trifling compared with the far-reaching good which will have been thus indirectly accomplished. If, on the other hand, the assistance rendered by the State has unfortunately been to lessen the self-reliance of the citizens, leading them to look outside for the performance of a function of self-government which belongs rightly to themselves alone, then the greatest work ever undertaken by a State Board of Health will have been prosecuted in this valley with results which will be far from an unmixed good. If the simple precautions which the Board has been exercising in the matters of sanitary inspection, disinfection, and the removal of garbage are at once dropped, the Board will not hold itself responsible for the consequences. The municipal authorities of all the boroughs lying along the Conemaugh and Stony Creek rivers should unite in constituting a Board of Health, to which should be confided the protection of the health of the entire district. The organization of this Board should be on the plan authorized by the Legislature for cities of the third class. It should consist of five of the most intelligent and reliable citizens, appointed without reference to locality or political preference, whose term of service should be limited only by their failure to perform properly the duties of the position. Such a Board, adopting the model ordinance of the State Board of Health as its code, and faithfully executing its provisions, would speedily become a pattern for all sanitary organizations throughout the Commonwealth.

The Board feels that it may well congratulate the citi-

zens on the standard of health which has been maintained during the trying period in the face of so many adverse influences. Their cheerful acquiescence in the decisions of the Board, which must often have appeared to them onerous, and their brave and resolute temper, have had a considerable share in conducing to this result.

BENJAMIN LEE, M.D.,
Secretary State Board of Health
of the Commonwealth of Pennsylvania

JOHNSTOWN, Oct. 12, 1889

Nashville Prison Congress.—The Annual Congress of the National Prison Association of the United States will convene in the Senate Chamber of the Capitol at Nashville, Tennessee, at 10 A. M., Saturday, November 16th, and will continue its sessions until the evening of Wednesday, November 20th.

The objects of this Association, as defined in its constitution, are: (1) The amelioration of the laws in relation to public offences and offenders, and of the mode of procedure by which such laws are enforced; (2) The improvement of the penal, correctional, and reformatory institutions throughout the country, and the government, management, and discipline thereof, including the appointment of boards of control and other officers; (3) The care of providing suitable and remunerative employment for discharged prisoners, especially such as may or shall have given evidence of a reformation of life.

THE thirteenth annual session of the American Academy of Medicine will meet at Leland's Hotel, Chicago, Ill, on Wednesday and Thursday, November 13 and 14, 1889.

THE Vienna *Weekly News* gives the following additional information regarding the Anglo-American Vienna Medical Association, to the initial movements of which attention was called last week. Such an organization would be a great aid if established in Berlin, Leipzig, and similar continental cities. A meeting of British and American physicians was held at No. 12 Landesgerichts Strasse, to consider the question of establishing an association for the purpose of furnishing all needed information to English-speaking medical men coming to study in Vienna. A large proportion of those now in the city were present. After a lengthy discussion, it was resolved to start such an association, under the title of "The Anglo-American Vienna Medical Association." A committee of management was appointed, with five members, representing different branches of medical study. *Their chief duty will be to supply information to new-comers, on their arrival, as to matriculation, medical courses, lodgings, etc.*, and, when necessary, to call meetings of the Association. The committee, on the occurrence of vacancies in their number, through members leaving Vienna, will fill these up as soon as possible. The office of the Association will be at No. 12 Landesgerichts Strasse, a few minutes' walk from the General Hospital. It was agreed that membership should be open to any British or American physician or medical student, on payment of an entrance fee of one gulden. The application to the authorities, necessary according to Austrian law, for permission to establish such a society has been made, and the committee expect that toward the end of October the Association will be in working order. Meanwhile, *letters of inquiry addressed to the President or Secretary will at once receive attention.*

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 29 TO NOVEMBER 4, 1889.

By direction of the Secretary of War, so much of Par. 2, S. O. 241, October 16, 1889, from this office, as relates to Anthony Heger, Lieutenant-Colonel and Surgeon, is amended to read as follows:

ANTHONY HEGER, *Lieutenant-Colonel and Surgeon.*—Is relieved from further duty in the Division of the Atlantic, and will report at once to the Major-General commanding the Army, for duty in this city.—Par. 5, *S. O. 252, Headquarters of the Army, A. G. O.*, October 29, 1889.

By direction of the Secretary of War, Par. 3, S. O. 241, October 16, 1889, from this office, is so amended as to grant ROBERT M. O'REILLY, *Major and Surgeon*, leave of absence for six months, with permission to leave the United States, to take effect November 1, 1889.—Par. 6, *S. O. 252, A. G. O., Washington, D. C.*, October 29, 1889.

TAYLOR, MORSE K., *Major and Surgeon* (retired).—Died, October 20, 1889, at San Antonio, Texas.

War Department, Washington, October 30, 1889. By direction of the President, WILLIAM H. FORWOOD, *Major and Surgeon*, is detailed as a member of the Army Retiring Board at St. Paul, Minnesota, convened by War Department Order dated January 12, 1889, published in S. O. No. 10, January 12, from Headquarters of the Army, vice Edgar A. Mearns, Captain and Assistant Surgeon, hereby relieved.—Par. 12, *S. O. 254, A. G. O.*, October 31, 1889.

By direction of the Secretary of War, WILLIAM C. GORGAS, *Captain and Assistant Surgeon*, is relieved from temporary field duty in the Department of the Missouri, and will join his proper station (Fort Barrancas, Florida).—Par. 2, *S. O. 251, A. G. O.*, October 28, 1889.

Appointments in the Medical Department, U. S. Army, as Assistant Surgeons, to rank from October 29, 1889: *First Lieutenant* CHARLES WILLCOX, *First Lieutenant* HARLAN E. MCVAY, and *First Lieutenant* E. B. FRICK.

By direction of the President, the Army Retiring Board convoked at Vancouver Barracks, Washington Territory, by War Department Order dated December 15, 1888, published in S. O. No. 292, December 15, 1888, from Headquarters of the Army, is dissolved.—Par. 1, *S. O. 250, A. G. O., Washington*, October 26, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING NOVEMBER 2, 1889.

NASH, F. S., *Passed Assistant Surgeon.*—Detached from duty in the Bureau of Medicine and Surgery, and ordered to the "Petrel," November 14, 1889.

BOGERT, E. S., *Medical Inspector.*—Ordered to examination preliminary to promotion to Medical Director.

NORTON, O. D., *Assistant Surgeon.*—Ordered to examination preliminary to promotion to Passed Assistant Surgeon.

KITE, I W., *Assistant Surgeon.*—Ordered to examination preliminary to promotion to Passed Assistant Surgeon.

STONE, E. P., *Assistant Surgeon.*—Ordered to examination preliminary to promotion to Passed Assistant Surgeon.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

INSULAR SCLEROSIS OF THE BRAIN.

A Clinical Lecture
Delivered at the Rush Medical College, Chicago, Ill.

BY HENRY M. LYMAN, M.D.,
PROFESSOR OF PHYSIOLOGY AND DISEASES OF THE NERVOUS SYSTEM.

GENTLEMEN: This man, who was before the Clinic on a previous occasion, is thirty-four years of age, a canvasser by occupation, and says that in November last he had a "stroke," and since has been unable to walk well. He has had no previous illness so far as we are able to ascertain. The attack came on while he was sitting in a chair at home, though he states that he had a peculiar nervous feeling shortly before. For fifteen minutes after the stroke he could not speak and had a cramp in both hands, but did not fall or lose consciousness. At the end of fifteen minutes he was able to speak a little. The trouble has been growing worse. The reflexes are normal, heart sounds normal, vision good, but the right arm is getting weaker, and in it he has numb feelings which last for half an hour at a time.

After questioning a little further, we learn that he has been engaged in the canvassing business for several years, and in the course of that time he suffered a good deal from exposure to the sun; and that he has taken a glass of beer with his supper for the last ten years. He has had no venereal disease, but suffered with rheumatism before this stroke.

It is important to establish these facts in order to ascertain if there is a predisposition toward constitutional diseases. In the case of patients suffering from syphilis, there is a predisposition to syphilitic disease involving the arteries of the brain, so that in such patients rupture of a bloodvessel is common. Rheumatism frequently predisposes to cerebral difficulties in the way I indicated when speaking of chorea on a former occasion. As a consequence of endocarditis, vegetations form upon the edges of the valves of the heart; minute fragments may be broken off and washed into the circulation, and we may have obstruction to the bloodvessels in a certain territory of the brain, which produces the symptoms of a stroke. A favorite locality for this plugging of the vessels is the Sylvian artery, which lies in the fissure of Sylvius and which gives off branches right and left to that portion of the brain cortex forming the *motor zone*. Now, when we get a plugging of the vessels and an arrest of the circulation, there is enfeeblement of all the functions of that part of the brain.

This patient tells us that it was the right side that was weakened, therefore, as the left motor zone is in direct communication with the right side of the body, it was upon the left side that the disease occurred. The fact that he did not lose consciousness at the time of the attack indicates that the lesion is not very extensive. We have not as yet made any investigation as to whether it was a rupture or a plugging of the artery. The effects, so far as the functions of the brain are concerned, are similar. If there be rupture of one of the twigs connected with the Sylvian artery, there will be an escape of blood and compression of the brain substance in that neighborhood. If there is a plugging of the artery, the blood-supply is shut off, and the final result of this stoppage is also arrested functional activity.

It is a singular fact that when the left side of the brain in the region of the Sylvian artery is thus affected, the power of speech is interfered with. When, on the other hand, the right side of the brain is affected, there is no loss of speech, but paralysis of the limbs. I will not stop to tell you how this loss of speech may be produced by lesions of the brain, but there are other portions of the brain which may be affected in such a way as to destroy the power of speech.

We will ask the patient to hold a glass of water with his hand, and you notice that he cannot do so steadily; yet there is not so much agitation of the hand as there is sometimes in the case of tumors of the brain. The left hand is much steadier than the right.

I will now ask him to write the words, "Rush Medical College." The reason I ask him to write an unfamiliar sentence is, that if I were to give him a familiar one he would write it more or less automatically. You will observe that there is an irregular, angular character to all the strokes of the pencil, that instead of being regular and well formed, they are of characteristic inequality. You will often see this tremor in old age, for many persons, as they advance in years, suffer from atrophy of the brain, which causes tremulous hands, so that the lines or characters which they make with pen or pencil are characterized by the same irregularity and inequality which we observe in this patient.

The use of narcotic poisons, such as tobacco, will produce it, and sometimes excessive venery. Loss of sleep, which produces great exhaustion of the brain, especially in persons advancing in years, will often be followed by the appearance of tremor; but the most serious cause of it is disease of the brain substance itself, either a sclerosis in disseminated patches or injury to the brain substance, here and there, consequent upon disease of the cerebral bloodvessels. I think that this is the case here.

When sclerotic disease invades the brain, there is, furthermore, a tendency to the manifestation of occasional paroxysms of paresis, partial loss of consciousness, and perhaps epileptiform attacks, which are multiple in their development. Sometimes the patient becomes completely paralyzed and comatose, but in two or three days' time recovers the power of locomotion and is able to walk again; speech and consciousness reappear, but the diseased condition returns after a time. Such a condition is not infrequent in cases of chronic inflammation of the cortex, which constitutes the foundation of paretic dementia; and you see it, moreover, in the case of chronic dis-

ease of the bloodvessels, as we have here. When there is this tendency to chronic sclerosis and to arterio-sclerosis, not only do we have this tremor, but there is also disturbance of speech when the patient has recovered. There is an irregular utterance, and instead of speaking out smoothly with a continuous flow of sounds, the words are uttered in a broken manner. Let me direct your attention to the articulation of this patient. It is with apparent difficulty that he utters the word *institution*. In asking him where he resides, you notice that he replies, "Eight-een Ev-ans Cou-rt," instead of speaking out clearly, "Eighteen Evans Court." He utters each syllable with a special effort in an unnatural and artificial way. This is consequent upon the lack of equable and continuous flow of energy from the brain. In order to make this intelligible, you must think of the efforts that are evolved from the healthy brain in the movement of the muscles during articulation, the disordered brain preventing that easy and continuous flow of sounds or words necessary for fluent speech. In this case we have a conspicuous illustration of the fact. There was a sclerotic disease going on in the brain before it was recognized, on the occurrence of one of the paroxysms of which I have spoken. These paroxysms are liable to occur from time to time during the course of the disease. The patient now shows the consequences of a confirmed and fully developed disease in the brain and its bloodvessels. There is only partial paralysis of the muscles on the right side, the difference being more conspicuous in the hands than in the legs.

Let us try the condition of the reflexes. There is spastic rigidity of the muscles on the right side; they are not under the control of the will. The degeneration in the motor zone of the brain reaches down to the pyramidal tract of the lateral column of the cord, and the muscles are at times thrown into a state of rigid contraction. Here there is constant rigidity kept up by the irritation in the lateral columns of the spinal cord.

You notice, too, that when he puts his tongue out it is impossible for him to do so without trembling. The tongue varies its position in consequence of his inability to control the action of the muscles that are concerned in the disorder.

The patient says that the paralysis is not increasing as time goes on, but that his hands become more unsteady, which is due to the fact that the sclerotic process continues to spread in the brain, and constantly involves larger areas.

If this trouble had been plugging of an artery, there would have been a preëxisting inflammation in the heart, with valvular lesions, which, on auscultation, we find is not the case; consequently this is one of those cases in which the disease originated in the brain and had been going on for a considerable length of time before attention was directed to it.

The treatment in such a case is not very encouraging. The disease depends upon a sclerotic process that is permanent, and which is liable to extend, rather than diminish. Still we should not neglect the patient. We should give him the best opportunities and treatment that are accessible; and in those cases of long-continued chronic changes in the brain substance, where we cannot hope for complete restoration, we sometimes see marked improvement from the use of mercury in small doses. My favorite prescription for such cases is the biniodide of mercury, given in doses of about the twenty-fifth of a grain three times a day. This may be given for months without any danger of salivation or injury to the patient, and frequently with considerable improvement in the general condition. The iodide of potassium does not seem to be as efficient as the biniodide of mercury given in this long-continued and patient manner. After all, it is doubtful whether you will ever see such a case cured.

CONGENITAL DISLOCATIONS OF THE HIP.[1]

BY CHARLES SETH EVANS, B.S., M.D.

As time has gone by, certain facts of a clinical and general nature have been tolerably well established in regard to congenital dislocations of the hip. These are:

1. The malformation most commonly affects each hip, in the proportion of three or four to one.

2. It is much more frequent in the female than the male sex.

3. The most usual form of dislocation is upward and backward on the dorsum ilii, though other dislocations do occur, such as directly upward, upward and forward upon the pubes, or into the sacro-sciatic notch.

4. The affection is distinctly hereditary.

5. Many cases are associated with other deformities, such as congenital dislocations of other joints, but more especially with malformations due to a lack of development, or a failure of one of the body cavities to close—such as spina bifida, ectopia vesicæ, and meningo-encephalocele.

6. The deformity is first noticed when the child begins to walk.

The clinical history of a case of congenital dislocation of the hip, briefly stated, is generally as follows: The child, after a normal birth, seems perfectly well, and nothing is noticed until it makes its first attempts at walking; this it does rather later than other children. The limping gait, in the rare unilateral dislocations, due to the shortening of the affected extremity, or the waddling movements, like a duck, in the double dislocations, call attention to the hip-joints.

The waddling gait is caused by the body, which is, as Volkmann points out, swung between the femurs like an old-fashioned stage coach on its leather springs, being alternately thrown from side to side so as to place its weight upon the limb which is not to be moved in making the next step.

As the patient increases in age the gait grows worse up to, if not after, puberty. The condition, as a rule, is not painful.

The deformity is quite characteristic. The patients

[1] Read before the Southwestern Ohio Medical Society, Cincinnati, October 9, 1889.

have a peculiar squatty figure, the body appearing longer than normal, while the legs seem shorter and more puny. The body looks as if it had fallen down between the thighs until the umbilicus is on a level with the iliac crest. A marked lordosis and a corresponding prominence of the belly are present. The pelvis is much more oblique than normal; the hips are raised, while in the neighborhood of the posterior superior spinous processes of the iliac bones. the ends of the femurs may be seen as rounded prominences. The gluteal folds are not obliterated, but raised upward and outward. In a recumbent position many of these changes are modified: The lordosis and projecting belly disappear more or less completely, according to the age of the patient, and the prominence of the great trochanters grows less.

If moderate traction is made upon the legs, certain further changes may, or may not, occur, for in a not inconsiderable number of cases the legs can be drawn down until the heads of the femurs occupy, more or less approximately, positions opposite to those of the acetabuli, when, of course, the deformity ceases to be manifested. In other cases the femurs are fixed in their abnormal positions and traction produces no effect.

An examination of the hip region shows that the rounded prominences are due to the great trochanters, and, at times, reveals the femur heads lying in the vicinity.

On constructing the Roser-Nélaton line the trochanters are found to lie more or less above it. Motion, active or passive, is generally free and painless, and when limited, it is most apt to be in the directions of abduction and rotation.

As a rule, two of the cardinal symptoms of a traumatic luxation are absent: adduction and internal rotation.

The deformity is a progressive one. The gait becomes more and more striking, and is always more noticeable in walking than in running or dancing. The disproportion between the body and legs increases as the child uses its limbs, for it is only in extremely rare cases that a strong nearthrosis is formed.

Pathology.—Here two very distinct and separate classes of cases must be considered:

A. Those which have walked.

B. Those which have never walked.

The pathological changes may be classified thus:

1. Changes in the position of the femur head.
2. Changes in the component parts of the joint.
3. Changes in the tissues in abnormal relation with the head of the femur.
4. Changes in the muscles inserted round the hip-joint.

We shall first consider the pathological changes in the class of cases which *have walked*, more especially the *changes in the position of the head of the femur*.

As I have already stated, in the vast majority of cases of this class, the head of the femur is found dislocated upon the dorsum ilii, and resting either upon the gluteus minimus or upon the iliac bone itself.

The *changes in the component parts of the joint* consist in those occurring in *the capsule*, which is usually entire, but may be wanting opposite the head of the femur, under which circumstance its absence is best explained as due to an atrophy from pressure. The capsule is elongated, stretching around the cotyloid cavity to envelop the head in its abnormal position.[1] It is much thickened and very fibrinous, especially in that part representing the Y-ligament,[2] and is quite frequently attached to the fascia of the gluteal muscles,[3] and not infrequently has an hour-glass form,[4] rendering an apposition of the head of the femur and the acetabulum impossible.[5] More or less movement of the head of the bone within the capsule is the rule.

The synovial surface of the capsule is usually polished and of normal appearance, while attachments to the more or less imperfect round ligament are common, as are also attachments to the acetabular ring, over which the capsule is stretched, as well as to the head and neck of the femur.

The synovia varies in amount, in some cases being normal, in others excessive, although one would expect an enlarged capsular cavity and more synovia than in a normal joint.

The condition of the *ligamentum teres* varies extremely. In some cases it is found not only elongated, which, if the ligament exists in its entirety, must be the case, but also thickened, ribbon-like, and on the stretch, pointing to the fact that it had played an important *rôle* in carrying the weight of the body.[6] Or, again, the ligament, though entire, is more or less attached to the capsule.[7] In opposition to this condition the round ligament has been found entirely wanting,[8] or may be represented by a band no thicker than a thread, which is often incomplete or of abnormal origin, arising by two heads from the acetabulum or from the cotyloid ligament.[9]

The neck is usually shorter than normal, and has a direction more horizontal to the axis of the femur.

[9] Adams, of Dublin.

The head, in the reported dissections, varies from normal to entire absence, its place being then taken by a smooth and flattened place upon the trochanters.

The *acetabulum* has never been found normal, but in no case entirely absent. Certain changes are the most constant—such as:

Smaller than normal, and perhaps too small to receive the head of the corresponding femur.

The normal round and semispherical form may be changed into a flattened oval.

Hypertrophy of the acetabular fat, or "glands of Havers," which is a very common condition.

The cartilaginous cotyloid rim is often wanting.

As has been mentioned, the capsule is at times, though rarely, perforated by the head of the femur, and abnormal attachments of the capsule to the fasciæ are common. The head is not infrequently found buried in the gluteus minimus. As a rule, very few or no signs of inflammatory reaction or the formation of a new joint are present.

The *muscles around the hip-joint* are affected in two ways: First, by the alteration in position of the points of insertion—hence the course of the Gemelli and obturator inferior around the neck of the femur, and the contracture of the gluteal muscles; second, atrophy and pallor, induced as an effect of non-use or of pressure made by the displaced head of the femur.

In *incomplete dislocations* the above-mentioned changes in and around the hip-joint are modified by the position of the head upon the rim of the acetabulum. Certainly the majority of these changes are due to simple mechanical causes, and no one should hope that a theory, however ingenious, built upon such changes, and having for its object the explanation of the nature and cause of the congenital dislocations of the hip, could command the serious attention of any one possessed of a mind in the slightest degree logical.

We shall next consider those cases which have never walked.

Here the number of authentic dissections is indeed few—fewer than the theories which have been advanced for their explanation. And of these few, quite a number are cases in which the dislocation of the hips was but one of a number of malformations.

Mr. Mercer Adams[1] reports the dissection of a double dislocation in a fœtus, otherwise much deformed: The acetabulum was irregular, but well formed. The head of the femur lay upon the dorsum ilii, where it had formed for itself a new cartilaginous acetabulum. The axis of the neck of the femur was nearly horizontal, the capsule lax, and ligamentum teres longer, thicker, and stronger than is common in fœtal life. The thigh and gluteal muscles were much atrophied and contracted. Adams believed the cause of the luxations to be contracture of the muscles. It is worthy of note that in this *fœtus* a new cartilaginous acetabulum should have been formed when a nearthrosis is so rare even in cases which have walked.

Parise is quoted by Adams as reporting the case of a child ten weeks old, in which the ligamentum teres was elongated and on the stretch.

Dollinger[1] dissected a fœtus with failure of union of the symphysis pubis and ectopia vesicæ, and found that the acetabulum was so small and altered that the femur head could not be replaced.

Grawitz[2] reports the following seven cases:

CASE I.—Male fœtus of eight months' gestation, much deformed. Pelvis small, thin, and delicate. Double dislocation of the hips. Acetabuli correspond in size to those of a five-months' fœtus, and are irregularly oval. The Y-shaped cartilage of the acetabulum is decidedly larger than normal, at the expense of the three pelvic bones, which have been retarded in their ossification. The anatomical evidence of this delayed bone formation is found in the microscopical examination of sections from the Y-cartilage. The area of proliferation of the cartilage cells is much narrower than normal, and the formation of these cells into columns is but poorly represented. Head of femur smaller than normal, yet much too large for the intended acetabulum. The shoulder-joints are in about the same condition; both are subluxated, and in both the glenoid cavities are very small.

CASE II.—Pelvic bones are thin and delicate, but about normal in size. Double dislocation of the hips, upward and backward. Acetabuli present; in size, those of a fœtus several months younger. Again the anatomical evidence of delayed ossification of the pelvic bones is found in the Y-shaped cartilage; slight proliferation of the cells, and failure to form columns. Head of the femur also delayed in its development, yet too large for the acetabulum. Child born at term; died twenty-one days later, of spina bifida.

CASE III.—Delay of ossification and the same microscopical changes as above, were found both in acetabulum and in femur head. Head too large for the socket. Changes most marked in the acetabulum.

CASES IV. AND V.—Double dislocations. Femurs cannot be replaced in the acetabuli. Heads about normal. Y-shaped cartilages of the acetabuli show not only the lack of proliferation of the cells, but also a degeneration of the same, as indicated by their spindle form.

The two following cases, though they belong here, are mainly interesting in the question of etiology:

CASE VI.—Much-deformed infant, with both acetabuli small. Right femur is luxated upward and backward; left femur in its proper place. On the right side ossification of the acetabulum and growth of the same were delayed, and changes in the cartilage were discernible with the microscope. The head of the femur is too large for its acetabulum. On the left side the microscopical examination shows that both the socket and the head have been delayed in ossification, though they still fit one another.

CASE VII.—Much-deformed infant. Left hip normal. Right hip dislocated upward and backward. Microscopical examination of the left side gave the normal picture of growth of bone from cartilage. On the right side, the

[1] Loc. cit.

[1] Virchow's Archiv. [2] Arch. path. Anat., vol. lxxiv.

acetabulum small, and the main change found in the ordination of the cells of the Y-shaped cartilage, and especially in that part of the same which is made up from the pubic and ischiatic bones, and not, as in the other cases, in the part supplied by the ileum.

The etiology is, perhaps, the most interesting chapter in the whole subject, and has been only too assiduously studied, if one may judge from the number, variety, and variance of the theories which have now and again been advanced to make plain the why and wherefore of this affection.

Certain etiological factors are shared by dislocation of the hips with other congenital malformations. It is hereditary, and it occurs most frequently in the female sex. With these two settled, others have been added *ad libitum*—of which may be mentioned: injuries and fright during gestation; accidents during childbirth; diseases of the hip-joint *in utero;* an inherent defect of the germ; and, finally, rheumatism, that all-potent disease, as if, says Dollinger, the fœtus had caught cold in its bath of liquor amnii.

A short review of the theories which from time to time have been suggested, is necessary.

Hypocrates and the older writers were of the opinion that these luxations were due to injuries; that is, to force, either acting suddenly, as in blows, or slowly, in the form of a preternatural smallness of the uterus.

By some it was supposed that the luxation of the femurs occurred in breech presentations from traction, or the use of the blunt hook. These occur, but are traumatic luxations, and not congenital in the true sense.

Dupuytren and others considered the congenital hip dislocations to be due to an inherent weakness or disturbance of the germ, an aberration of the "autotrophy," or power of self-development inherent in the fœtus.

Other theories are: Defective development of the acetabulum, advanced by Breschet, and advocated by Cruveilhier, Sayer, Dollinger, and Grawitz.

Morbus coxarius, advocated by Morell, L'Avallée, and Guérin. A very rare disease in fœtal life.

Hydrarthrosis, to prove which, as the true cause, Parise's paper was written.

Hypertrophy of the "Haversian glands," which is a *post hoc ergo propter hoc* argument.

Muscular contraction was advocated by Adams, Guérin, Melicher, and Carnochan.

The theory of *nervous influence* was advanced by Carnochan, who says that "the luxations result from some active morbid muscular contraction; this contraction is to be traced to a morbid condition of the central ganglionic mass of the cord."

To these theories two more must be added, not because they have especial claims for veracity, but rather because of those who have advanced them.

Hueter believed that in the development of the luxated hips, the head of the femur and the acetabulum were not developed opposite one another; forgetting that embryologically they both are formed by a splitting of one piece of cartilage.

Roser thinks that an extreme adduction of the thighs in the fœtus *in utero* will explain the luxation, and also why the female sex is the one usually affected; the male genitals, according to his idea, being too sensitive to pressure to allow of their development with the thighs, in their position of adduction, pressing upon the genital region.

Of these theories perhaps only one is really worthy of serious consideration, for it alone rests upon a basis of proven anatomical facts. The theory referred to is that of a mal-development of the acetabulum, advanced by Breschet, and put upon a scientific footing by Grawitz. The latter reminds us that the Y-shaped cartilage of the acetabulum rarely represents the epiphyseal line of the pelvic bones which meet and conjointly form the acetabulum; that the growth and development of the acetabulum and pelvic bones are dependent upon certain formative changes in this cartilage, as is the growth of every other bone dependent upon the changes in its epiphyseal cartilage.

Grawitz examined five cases of congenital dislocation of both femora in children who had not walked, and found that the acetabuli did not correspond in development to the age of the child, and also certain changes in the acetabular Y-shaped cartilage; changes which have not been elsewhere noticed, and which pointed indisputably to a lack of formative development in this structure. The heads of the femora were by no means always found in a normal and healthy condition, but they were larger than the corresponding acetabuli, and their cartilages showed much less sign of disturbed proliferation. And to combat what would probably have been the first and greatest objection urged against his theory—that he had confounded cause and effect, *i. e.*, that the changes in the Y-shaped acetabular cartilage were only secondary, and caused by the absence of the head of the femur from the acetabulum—Grawitz reports two other cases, in one of which the right femur was luxated, but the left in place. Both acetabuli were small for the age of the infant, and both presented the signs of delayed ossification; but on the right side the head of the femur was too large for its socket, while on the left, the head and socket fitted together perfectly. On microscopical examination of these two heads, the cause for the small size of the left was found in the marked evidence of change in its cartilage, while on the right side these changes were much less pronounced. The other case is one of single, unilateral luxation, in which the usual signs of delayed proliferation of the cartilage cells and ossification were

found in the luxated hip, while on the normal side the usual picture of proliferation of the cartilage cells and ossification was found.

In none of the twelve joints examined by Grawitz was there any sign of an arthritis or other joint disease.

Grawitz believes to have shown by these seven cases that in congenital luxation of the hip the cause is to be found in a diminished activity of formation in the Y-shaped cartilage of the acetabulum, while the head of the corresponding femur is not at all, or not proportionately affected. And also that when the diminished formative activity affects both acetabulum and head in the same degree, no dislocation occurs. In no case is the congenital dislocation referable to a synostosis of the Y-shaped acetabular cartilage.

As a similar condition, Dollinger refers to the early synchondrosis of the spheno-occipital cartilage producing what has been termed prognathismus; it is also hereditary, and so much so that it is almost a type in certain races.

PROGNOSIS.—Prognosis as to life is good; as to bringing the process to a standstill, is dubious; as to *restitutio ad integrem* is bad. These conclusions, which are borne out by clinical experience, may also be deduced from a consideration of anatomico-pathological conditions.

TREATMENT.—Treatment may be divided into two classes—mechanical and operative.

Mechanical treatment is instituted with two ends in view. The first, and the one which has the more scientific basis and more hope of success, is by means of extension, fixation, support, or the removal of the weight of the body from the capsule in the act of walking, to deprive this affection, in young people, of its progressive character.

The second is, by mechanical means to draw down the head into the old acetabulum, and by keeping it there to produce a cure with *restitutio ad integrem*. But, it would appear, the cause of the dislocation is that the acetabulum is too small for the femur head, hence this treatment is based upon a false premise, and the final results show that the false premise leads to an equally false conclusion.

Operative treatment, with the view of making a movable joint at or near the site of the old acetabulum, has not, as yet, been reported as successful, though it should by no means be placed among the impossibilities. Operative treatment to produce anchylosis in unilateral, or indeed in bilateral dislocations of high degree, is justifiable, and at times the only treatment.

THE National Academy of Science has been in session in this city the past week.

OSTEO-SARCOMA OF THE SPINE, WITH REPORTS OF CASES.[1]

BY FRANK BILLINGS, M.D.,
OF CHICAGO,
PROFESSOR OF PHYSICAL DIAGNOSIS AND CLINICAL MEDICINE IN THE CHICAGO MEDICAL COLLEGE.

THE purpose of this paper is to present a report of cases of osteo-sarcoma of the spinal column. This location of the disease is rare enough to make the cases unique, and is my only excuse for presenting them. It is not necessary to describe the well-known histological characteristics of sarcomata in general; suffice it to say, that all known histological types of sarcoma may partake of the osteoid type (Joh. Müller, Rindfleisch), and that the osteo-sarcoma may undergo cystic, mucoid, cheesy, and fatty degenerative changes, as in the other sarcomata. The osteoid form, too, is prone, like other forms, to extend to other tissues and organs by metastasis; of these secondary growths more will be said later.

Though osteo-sarcoma occurs usually during early adult and middle life, it is not entirely unknown in advanced age, in childhood, or even congenitally.

Two varieties are recognized by most writers: (1) the *central*, or *myelogenes*, so called because it takes its origin from the medullary canal or diploë; and (2) the *peripheral* or *subperiosteal*. As the cases to be reported include only the peripheral form, the former will not be considered.

The peripheral, subperiosteal, or osteo-chondroma of Virchow is more malignant than the central variety, and is formed of granulation tissue with young bone-cells (Billroth), or of the latter mixed with very large spindle-cells. The presence of bone seems not to alter the natural tendencies of sarcomata to unlimited growth and to recur locally, and, by metastasis, in distant organs and tissues. Of spinal osteo-sarcomata, owing to their rarity, but little is to be found in pathological literature. As trauma seems often to be the starting-point of osteo-sarcomata, the protection afforded the spinal column by a thick pad of muscle, and by the intervertebral cartilages, may explain their rarity in this situation.

Spinal osteo-sarcoma springs usually from the lumbar or lower dorsal vertebra. It may grow from the bodies of any part of the spinal column, and, like other sarcomata, grows with variable rapidity. The tumor is usually globular or ovoid, is generally encapsuled by the periosteum and surrounding connective tissue. If it occur on that part of the column which renders the tumor palpable, it is found hard and resistant to the touch, and usually immovable, because of inflammatory adhesions to the surrounding tissues or organs. One important characteristic is the early involvement of the lymphatic vessels and glands, especially those near the tumor.

[1] Read before the Chicago Medical Society, October 21, 1889.

The early involvement of the lymphatic glands in osteo-sarcoma of the spine, leads to the development of secondary growths in other organs, notably in the abdominal cavity and lungs, the secondary tumors always partaking of the characters of the primary.

The clinical course, in comparison with sarcoma elsewhere, is rapid, as might be supposed from the early involvement of the lymphatics and the rapid occurrence of metastatic growths in other important organs. As a rule, too, the tumor invades the bone at the point of origin, and the growth advances far enough to press upon the spinal cord; or a hemorrhage occurring into the spinal canal causes pressure paresis, or paralysis. Usually the indurated tumors develop more slowly than the softer forms, and the rapidity of growth and malignancy are in direct ratio to the softness of the tumor, which is explained by the fact that the softer form is made up of round cells.

Though the symptoms must necessarily be peculiar to each case, pain in the spinal column at the seat of the growth, with neuralgia of the corresponding spinal nerves, is almost constant. The precursor of this pain is often a general backache, usually located in the lumbar region. The presence of sugar in the blood, as mentioned by Freund, is not of sufficient reliability to make it a safe diagnostic sign of sarcoma in the body; and of peptonuria the same may be said.

The histories and clinical course of my cases are as follows:

CASE I.—Mr. M., aged forty-nine, Swede, married, and stockman by occupation, has lived in America for twenty-five years. Family history free from hereditary taint of any kind. Three brothers and one sister living and in good health. The patient's health has been good until the present illness commenced. Habits vicious in early life, when he had gonorrhœa and a venereal sore, which, however, was not followed by constitutional symptoms. He has used alcohol to excess at times, and has suffered from alcoholic gastritis, with consequent dyspepsia and vomiting.

During the summer of 1888 the patient's general condition of health deteriorated; his appetite became poor, and everything taken into his stomach caused discomfort. Severe, constant, lumbar backache, worse at night, and aggravated by exercise, became a prominent symptom. His trouble was ascribed to drinking the alkaline water of the West.

In September of 1888 he came to his home in Chicago and consulted several physicians, each giving a diagnosis different from the others. His spleen was said to be enlarged, and consequently chronic malaria, chronic dyspepsia, incipient leucocythæmia, etc., were diagnosticated.

December 3, 1888, I took charge of the patient. He was then confined to his bed, but able to sit up. He was slightly emaciated and had a cachectic appearance. His face had a peculiar dusky, red hue, and on the skin of his body and extremities were peculiar brown pigmented spots, from the size of a pea to a silver quarter. The spots were most numerous over his back. One supra-clavicular lymphatic gland of the right side was enlarged to the size of an almond. In the left hypochondrium a tumor, the size of an infant's head, could be felt. The tumor moved vertically with respiration, was ovoid in form, of medium resistance to touch, and only slightly painful on strong pressure. No murmur could be heard. The absence of a defined border and notch seemed to exclude the spleen. The liver, lungs, and heart appeared normal. The blood showed no increase of white blood-corpuscles, though an occasional very large leucocyte could be found. The urine was scanty, of high color, but contained nothing abnormal. The patient complained chiefly of severe aching pain in the lumbar region of the spine, which was always worse at night. The diagnosis was made of probable sarcoma of the spinal column.

I saw the patient frequently until his death, which occurred on January 19, 1889. During that interval the tumor grew rapidly, finally extending forward to the median line, and downward to a line drawn from the umbilicus to the crest of the ilium. The patient daily became more emaciated and cachectic, and the pain in the back could only be controlled by opium.

Ten days before his death the patient complained of numbness in his feet and legs, and on the day following the appearance of this symptom he suddenly became paraplegic. Absolute paralysis and loss of sensation were present below the second lumbar vertebra. Retention of urine and constipation made the case much more difficult to take care of from this time.

The paralysis and anæsthesia gradually extended upward until weakened respiration and cardiac asthenia combined to produce œdema of the lungs and death.

A post-mortem examination was made twenty-four hours after death, and the diagnosis confirmed. A primary, large round cell osteo-sarcoma was found involving the first and second lumbar vertebræ. The body of the first vertebra was softened and broken down by the sarcomatous tissue. A large blood-clot occupying the root of the tumor, extended into the spinal canal, firmly compressing the cord. Secondary tumors were found in the lymphatic glands on the left side of the spinal column, from the last lumbar vertebra upward to the root of the left lung, and also in the bronchial and mesenteric glands. Calcareous deposits were present in both primary and secondary tumors. The spleen, liver, and lungs were free.

CASE II.—Mr. G., German Jew, aged forty-eight, married, merchant. Family history excellent; no history of hereditary disease. The patient's previous health had been excellent, and he had always been sober and industrious, and never afflicted with venereal disease. He had used alcoholic beverages in moderation.

In December, 1888, his health began to fail,

though he presented no well-defined symptoms. His appetite became poor, he gradually lost flesh, and soon developed a slight cough with muco-purulent expectoration. Four or five moderate attacks of hæmoptysis occurred during the first four weeks. His disease was diagnosticated consumption by a homœopathist.

On January 30, 1889, he became the patient of Dr. H. Milbacher, of Aurora, to whom I am indebted for a complete history of the case and notes of the post-mortem examination.

On taking charge of the case Dr. Milbacher found the patient complaining of cough with muco-purulent sputa, of sleeplessness, weakness, loss of appetite, indigestion with flatulence, constipation, constant, aching pain in the dorsal and lumbar spine, and lancinating and shooting pain along the course of the intercostal and lumbar nerves of the right side.

A careful examination revealed slight emaciation and moderate anæmia. The temperature and pulse were normal. There was evidence of partial consolidation, in areas, of the left lung, with some pleuritic effusion on the same side. There was tenderness on pressure on the right dorsal and lumbar nerves near the spine. The sputa contained no tubercle bacilli. Urine was diminished in quantity, and contained an abundance of urates, but nothing abnormal. During February there was continued emaciation, anorexia, indigestion, constipation, and cough, with an increase of the morbid process in the left lung. There was also developed marked paresis of the right thigh, with loss of sensibility in the area supplied by the external cutaneous nerve. Several small subcutaneous tumors developed over the abdomen, and one small tumor between the inferior angle of the scapula and the vertebral column on the right side. The tumors were slightly tender on pressure and movable. No tubercle bacilli could be found on repeated examinations of the sputa.

On March 3, 1889, I was called in consultation. The patient was then confined to his bed, and was emaciated, pale, and cachectic in appearance. He complained of aching pain in the dorso-lumbar region, with sharp pains radiating over the lower right chest, right lumbar region, and right thigh. His appetite was poor and his digestion imperfect.

On examination there were found several subcutaneous, irregular, doughy tumors over the abdomen, the smallest the size of a filbert, the largest two or three inches in length, and irregular in outline. Under the posterior border of the right scapula, extending toward the vertebral column, was found a similar subcutaneous mobile mass about the size of a lemon. The tumor fluctuated, and on aspiration yielded blood. There were slight paresis and partial loss of sensation in the right lower extremity. The right chest presented nothing abnormal except the tumor mentioned. The left chest was somewhat less mobile than the right, and there was diminished and absent vocal fremitus, in irregular areas in the mammary and scapular regions. There was relative dulness on percussion over the whole left lung, with marked dulness over the scapular region, and in irregular regions over the anterior surface. There was also evidence of some fluid in the left pleural cavity. The sputa contained no tubercle bacilli. The urine was normal, and the blood showed only an occasional very large leucocyte.

The cachexia, superficial tumors, slight paresis, and irregular distribution of the signs over the chest, led us to make a diagnosis of osteo-sarcoma of the spine, with secondary growths in the left lung, pleura, and skin. The prognosis, consequently, was death, with probably preceding paraparesis or paraplegia. Dr. F. S. Johnson saw the case subsequently and concurred in the diagnosis.

The patient rapidly declined, with increasing paresis ending in paralysis of the lower right extremity, increase in size of the subcutaneous tumors, and increase of the pleuritic exudate of the left side. The heart's action was weak, with pulse of 110 to 120; temperature usually normal. Death occurred on March 27, 1889, in an advanced stage of asthenia, from heart failure and œdema of the right lung, both induced by a rapid increase of the pleuritic effusion on the left side.

An autopsy made twenty-four hours after death revealed the following condition:

The visceral and parietal pleura of the left side were transformed into a firm white mass, from one-half to one inch in thickness, with a nodulated surface firmly adherent to the sternum, the ribs, pericardium, and diaphragm. The left lung, compressed to one-half its normal size, occupied the upper portion of the chest cavity, and was covered by the thickened, diseased pleura. Within the lung was a large, round, whitish tumor, with a soft colloid central spot. The compressed lung formed a thin capsule for the tumor. The lower portion of the chest cavity was filled with five or six litres of watery, straw-colored serum.

There were two spinal tumors. One, as large as a fist, was attached to the body of the eighth dorsal vertebra, and could be traced into the intervertebral openings of the spinal canal. It covered the anterior surface of the neck of the seventh, eighth, and ninth ribs, being attached firmly to their periosteal covering. There was partial destruction of the body of the eighth rib by pressure, the tumor extending through the opening in the rib to form the subcutaneous dorsal tumor. On section the growth was found to contain blood, partly liquid and partly coagulated. The second spinal tumor, about the size of an orange, grew from the second and third lumbar vertebræ, and was covered by the somewhat atrophied right psoas muscle. There was destruction of a portion of the vertebræ to which it was attached, and an invasion of the spinal canal. The lymphatic glands of the mesentery and omentum were involved. There was one large gland, the size of an orange, in the great omentum just below the transverse colon. Other tumors were found in the kidneys and the pancreas. A microscopical examination revealed a round-celled sarcoma.

CASE III.—Mr. S., aged thirty-seven, salesman, single, American. His family history was free from hereditary taint. The patient had always been temperate in the use of alcoholic beverages, and denied having had venereal disease.

During the last two weeks of May, 1889, the patient, while assisting his family in packing the household goods preparatory to moving, was suddenly seized with severe pain in the right inguinal region, and continued to suffer with sharp pain in that locality, accompanied, he said, with fever. He was decidedly jaundiced. His physician pronounced his case typhlitis. The patient made a quick recovery from the acute attack, and on June 10th arrived in Chicago. When I called to see him he was pretty well nourished and not markedly pale. He walked in a slightly stooping posture, because of inability to extend completely his right thigh without pain. On examination the thoracic viscera, the liver, and spleen presented no abnormal signs The urine was normal. On a level with the umbilicus, in the course of the ascending colon, could be felt an irregular, slightly movable, and tender mass. This was dull on percussion and easily isolated from the liver and the right kidney.

He was given a large enema of soap and water, which moved his bowels thoroughly, but the tumor did not diminish in size. The patient was then obliged to leave town, and I did not see him again until July 4th, when the tumor had increased greatly in size, was hard, and gave a feeling of fluctuation The patient was told that it was probably a cyst. He desired Drs. E. C. Dudley and D. A. K. Steele in consultation, and on July 17th those gentlemen examined him, and advised an exploratory abdominal section. At the patient's request, he was tranferred to Dr. Dudley's care at St. Luke's Hospital, and on July 30th Dr. Dudley made an exploratory incision into the tumor, after an unsuccessful attempt at aspiration. The tumor was found to be a solid mass, firmly attached to the right sacro-iliac synchondrosis, and pushing the peritoneum and ascending colon forward; all being blended and united to the anterior abdominal wall by inflammatory adhesions. The mesenteric glands were enlarged and calcified as far as the finger could explore. The tissue of tumor examined microscopically revealed spindle-cell sarcoma. The patient rapidly recovered from the exploratory wounds, and on August 20th left the hospital for his home in Benton Harbor, Michigan.

September 23d, when he returned to Chicago, the tumor had increased in size, and there was slightly increased emaciation and pallor. There was also a good deal of distress due to flatus. On the 26th, a small abscess formed in the cicatrix of the incision into the tumor, and on opening it, half an ounce of dark blood and pus escaped.

October 1st the patient again returned to Benton Harbor, and his father states, in a letter of recent date, that the wound is still discharging a bloody pus and that the tumor is slowly increasing in size. The hard form of this tumor will make the case of longer duration than the others reported.

235 State Street.

Bromidia.—At Kansas City, Mo., judgment has been given in the sum of $500 each against seven local druggists for counterfeiting the trademark of the above preparation.

GUNSHOT WOUNDS.

With the Reports of Four Cases.

By THOMAS H. MANLEY, M.D.,
of New York.

In these days of antiseptics and a new technique in the management of wounds it is important that surgeons should report their cases in detail and impartially to the profession.

It is especially imperative to examine into the treatment with the most discriminating care; for one should have the various methods of treatment well fixed in mind, and be prepared for every emergency, before he would assume to deal boldly and confidently with serious gunshot wounds.

It is well, too, that we take a glance at the recent studies on the subject, divesting ourselves for the time of any undue enthusiasm or prejudice. We must look squarely in the face the claims of modern surgery, and determine, if possible, whether the advantages accruing from antiseptics in civil practice are correspondingly great in war; or whether, in certain regions of the body, their application is useless, or harmful.

The relative value of antiseptics to the military surgeon cannot yet be estimated; but their advantages and disadvantages, in wounds resulting from the explosion of firearms and in penetrating wounds, can be determined in civil practice.

A great impetus was given to abdominal surgery through the memorable essay of Sims, presented to the New York Academy of Medicine, in the autumn of 1881. In this the author boldly, and with marvellous energy and convincing argument, advocated abdominal section for almost every lesion involving the peritoneal cavity, whether from disease or traumatism, acute or chronic. There can be no denying that this lucid and skilful exposition of the possible future of the treatment of lesions in the abdominal region had much to do with the extended application of exploratory laparotomy, and opened a new era in surgery.

Many surgeons, especially in America, promptly manifested their acquiescence with the views of Sims, by commencing the treatment of penetrating wounds of the belly by laparotomy. Senn conducted a series of investigations on the abdomens of dogs, and demonstrated that the intestines of these animals would endure almost any amount of mutilation, and make a good recovery.

With the predictions of Sims, and the long, interesting, and successful series of investigations of Dr. Senn, together with the supposed efficacy of antiseptics in preventing infection, it certainly seemed that the treatment of abdominal wounds had attained perfection.

At first, on this side of the Atlantic, we were quite confounded with the brilliancy and originality

of Senn's experiments—supposing that they originated in this country; and we were credulous enough to presume that the deductions reached in these canine investigations would apply to the human being.

Did we think for a moment that Sims's essay was simply the views, theories, and speculations of one known only in his profession as a gynecologist, and whose experience as a general surgeon was so slight as to give but little weight or value to his assertions in this domain of his profession?

And, finally, when we examined the experimental work of the Chicago surgeon—exclusively of the apposition of the gut by lateral approximation, and ballooning the bowel with gas—we find that the whole of this line of intestinal surgery is very old; the only difference being that the older surgeons did their work on man, while Dr. Senn's was confined exclusively to dogs. Messrs. Reybert, Jely, Joubert, Boutard and Amussat, distinguished French surgeons, in the early part of the present century, had separately and severally done resection of the bowel, with enterorrhaphy.[1] They invaginated the bowel, as a means of establishing continuity, after division or exsection. They used the plate, or *tablet*, as they designated it, for lateral apposition of the serous surfaces of the bowel, guided by the same principles in using it on man, as was Senn on animals.

In our haste to put into practice the latest methods, we neglected to institute a comparison between the brute—in which, regardless of antiseptics or drainage, we may eviscerate the bowel by the yard without bad symptoms following—and the human being, whose organs in the abdomen are structurally and functionally unlike the dog's; and on whom we are seldom called to operate, except where shock is marked, and blood has been lost. Finally, the most successful surgeons have altogether abandoned antiseptics in abdominal operations.

Dr. L. A. Stimson,[2] in a paper of great literary, statistical, and scientific value, collected together the various cases of gunshot wounds of the abdomen occurring in New York during the past eight years, and presented figures of startling significance to those of us who had hoped that modern science had robbed penetrating wounds of the abdomen of their former terrible mortality. His figures showed that, as far as could be learned, the mortality following operative interference in penetrating gunshot wounds of the abdomen was greater than when the older and more conservative plan of expectant treatment was in vogue.

My cases, herein reported, embrace lesions of various regions of the body; but the most recent case being pertinent to the discussion of penetrating wounds, I will narrate it first:

CASE I.—J. B., aged forty-four, married, shopkeeper, of spare habit, who had previously enjoyed good health, was admitted into the Harlem Hospital, September 13, 1889. When found by the Ambulance Surgeon, Dr. Walter H. Dade, he was lying on his back, almost pulseless; the extremities being cold and the features of a ghastly, ashy white. This was about forty-five minutes after the injury. Restoratives were freely given, and he was hurried off to the hospital.

On admission he was still greatly prostrated, though had rallied somewhat from shock. His pulse was 135 per minute and feeble. His lips, nose, and ears were of a waxy white, and cold. He was vomiting blood freely, and complained of pain in the epigastrium.

On examination, it was found that he had accidentally shot himself with a 36-calibre Smith & Wesson revolver, the ball entering about two inches to the left of the median line and three inches from the navel, passing through the seventh intercostal space anteriorly; then taking a course upward and fracturing the seventh rib, two inches from the corresponding spinous process to the right.

Though probing was not attempted, it was evident that the lung had been torn through, as immediately over the seat of fracture there was considerable bulging of the integument with an extensive margin of emphysema into the loose connective tissue.

This wound was inflicted one hour after he had eaten a full meal, and it is probable that the stomach was distended when the ball entered.

If this were the case, it must have caused great destruction, for on inspecting the relations of the organs and tissues in the cadaver, or carefully considering the anatomical situations of the various structures, it was seen that if the ball passed directly upward and backward, in a straight line, the pleural cavity was perforated; afterward the thin, edge of the liver, and the stomach, the missile crushing through the crus of the diaphragm, opening the pleura and lung again, posteriorly, to be arrested only in its transit by the rib, which it shattered.

It seemed positive from the subjective and objective symptoms that three important organs and two cavities were perforated, viz , the liver, stomach, and lung, with both the pleural and peritoneal cavities. He undoubtedly was suffering greatly from loss of blood when admitted, as proved by his exsanguinated condition and the protracted shock. The emphysema and hæmatemesis were strong evidences of lung and stomach lesions.

It was not deemed advisable to jeopardize his life further by any kind of operation. He was given cracked ice, and laudanum unsparingly for the purpose of tranquillizing the mind and relieving pain. The bullet wound was antiseptically dressed, and a firm binder applied around the thorax. During the first night he had considerable pain in the abdomen and chest, but in the morning felt better. Stimulants and light nourishment were then freely given.

[1] Operative Surgery and Surgical Anatomy. By C. Bernard et Ch. Huette (De Montargis), Paris.

[2] N. Y. Med. Journal, Oct. 25, 1889.

The remainder of his history is uneventful. He made a good recovery. Ten days after his admission, the swelling having subsided, the ball was felt under the skin posteriorly, and removed. He left the hospital on Oct. 2d, entirely restored to health, though he was yet somewhat weak.

CASE II.—D. J., aged thirty-three, policeman, was shot on the morning of July 2d, the ball entering the body about three inches to the right of the sixth chondro-sternal articulation. No wound of exit could be found. The bullet was discharged from a 36-calibre revolver—the man's own weapon—and was fired while the muzzle was in close contact with the skin, as the latter was considerably burned and blackened by powder.

The wound was not probed. He was suffering considerably from agitation of mind when admitted, though it was clearly evident that he had lost but little blood. It was quite clear that the missile had not entered the thorax, for if it had, and taken a horizontal line backward, it must needs have penetrated both the peritoneal and pleural cavities, and done terrible havoc with the convex surface of the liver, which mounts upward nearly to the nipple-line on this side; and, moreover, the spongy, vascular tissue of the lung would have given rise to free hemorrhage had it been perforated.

The ball undoubtedly struck a strong, flexible rib, which deflected it in a direction where but little harm was done. We could find no trace of the missile, for, though of considerable size, if it were lodged in the body, there was no swelling, soreness, or pain which gave the slightest clew to its whereabouts. I am inclined to believe that it did not enter at all, but that after its velocity was broken by the resistance of the rib, it rebounded and fell to the ground.

This man left the hospital one week after admission, in good condition, though with some soreness over the seat of injury.

CASE III.—S. L., aged twenty-four; bartender. On Monday, June 12, 1889, while in an altercation, he was shot. He was brought to the Harlem Hospital immediately after being wounded, by the ambulance. On admission, it was found that the ball had struck exactly in the centre of the chin—at the symphysis mentis—and at its point of impact had detached a small, shell-like piece of bone. The fellow suffered none from shock, and was out in a week.

Not the slightest trace of the ball could be found. There was no evidence of its having lodged anywhere in the body. The day after admission, he had some deep-seated pain in the region of the cervical plexus, but this could be accounted for by the violent struggle with his assailant before the shot was fired, and in which he may have strained the muscles of the shoulder.

As in the preceding cases, I am inclined to believe that the ball rebounded and came out as it entered.

Baron Larrey[1] mentions several such cases, in his experience, as does also Guthrie.[2]

[1] Chirurgie Militaire, vol. ii. p. 217, 4th ed.

[2] The Surgery of the War of the Peninsula, vol. i. p. 374.

CASE IV.—J. H., aged thirty-one, was shot on October 13th. As he saw his antagonist draw his pistol, the patient threw up his arm as a shield. As a result, his head was saved, but he received the ball in the dorsal aspect of the right forearm, about midway between the wrist and elbow.

When I saw him the following day, there was considerable infiltration into the connective tissue, accompanied by swelling and discoloration. The skin was of a dark yellow color, mottled, and of a decidedly ominous aspect. I made a free incision into the parts, with a view of relieving the turgescence of the vessels and exploring for the ball. Careful probing in every direction failed to reveal the bullet.

The following day he felt so much better, and the circulation was so much improved, that he asked to go home, saying that he was well able to pay for professional service. I am informed that he is doing well.

I am aware that in the brief summary presented each report has neither been full nor possessed of much value, but the cases taken collectively teach important lessons:

1st. That we have yet no accurate method for locating missiles when lodged in the body.

2d. That with the expectant, or rather the conservative plan of treatment, many serious traumas of the great cavities may terminate favorably.

3d. That *opium* must be given with a free hand until shock is past and pain is subdued.

4th. It seems probable that under certain circumstances a bullet may, after coming in contact with a firm, strong, resisting body, rebound and not lodge in the tissues; hence the uselessness, and sometimes the danger, of free probing in this class of injuries.

TORTICOLLIS GREATLY IMPROVED BY TOXIC DOSES OF GELSEMIUM AFTER FAILURE OF MYOTOMY.

BY CHARLES B. WILLIAMS, M.D.,
CLINICAL ASSISTANT IN THE PHILADELPHIA POLYCLINIC.

THE case here reported is that of a man aged twenty-four, who was admitted to the Polyclinic Hospital Oct. 24, 1888. His family history was good. His previous history negative, excepting that he has had several slight attacks of torticollis, and a number of falls upon the shoulders and neck, and has suffered from rheumatism. In the autumn of 1886 he noticed a jerking of his head and neck to the left side, associated at times with severe pains. This continued and gradually grew worse for a year, when he began to have also twitchings of the left arm and leg. He soon lost entire control of the left foot and could not stand properly. After three months of medical treatment he began to have more control of his leg. When he first came under observation he described the muscular twitching as being more like a tremor. While the patient was sitting quietly no spasm was noticed, but on attempting to walk, use his arms, or move his head, a cramp or spasm oc-

curred in the muscles of the neck, and his head was turned to the left. The chin and face did not turn *upward*, as would be the case if the right *sterno-cleido-mastoid* muscle was affected, but rather horizontally and outward; hence it was believed to be the splenius capitis muscle of the left side that was affected. Any voluntary muscular action would cause the spasm. On Nov. 2, 1888, a myotomy was performed by Dr. John B. Roberts upon the muscle that was supposed to be the source of the torticollis, but with no beneficial results. Dr. Roberts furnished the following description of the operation:

"On account of the peculiar twist of the head, which seemed to imply that the splenius capitis was at fault, I determined to divide the left splenius capitis instead of the right sterno-mastoid. Accordingly, on Nov. 2d I exposed the muscle, and proceded to do a partial myotomy, dividing the belly of the muscle throughout its entire thickness, but leaving a band of fibres upon each edge intact, hoping in this manner to weaken without destroying muscular action. This was done because it was not absolutely certain that I was cutting the muscle which produced the spasm, and, in order that I might at any time during the after-treatment bring the fibres together, if the torticollis was not improved, I introduced a wire suture through the cut edges, crossing the ends and bringing them out through the skin, thus causing a loop underneath the skin, so that traction on the ends would draw the muscular bellies together. For a day or two some improvement was perceptible, which caused me to withdraw the suture and allow the fibres to remain retracted. The head and neck for some time was kept in position by a plaster-of-Paris bandage, and it was believed that something was gained by the operation. Within two weeks, however, the spasm returned. I then made a subcutaneous division of the splenius muscle with so much freedom that I believed I had divided all its fibres. The results were again unsatisfactory. There was temporary improvement, but it soon became evident that the condition was practically no better. Any violent motion, such as walking or the use of his arms, at once brought on a spasm, in which his head was twisted to the left, with considerable pain in the back of the neck and in the shoulder of the left side. Rigid muscles could also be felt in the splenius region."

Electricity was also used without benefit. He was next placed upon the fluid extract of gelsemium in ordinary doses, but without relief. Dr. S. Weir Mitchell then suggested hyper-physiological doses of the drug.

On Dec. 29, 1888, the patient was admitted to St. Agnes Hospital in an unchanged condition. He was placed upon full doses of the tincture of gelsemium without the production of any physiological effect. He was then placed upon full doses of Wyeth's fluid extract of gelsemium, the dose being gradually increased so that by Feb. 1, 1889, he was taking twenty-three drops three times a day.

The physiological action of the gelsemium was now manifested by dilatation of the pupils, languor, some headache, and flushing of the face, with slight attacks of giddiness; the patient describing his sensations as though a band were tied around the forehead. On Feb. 4, 1889, he was taking ten grains of the salicylate of sodium, and five of iodide of potassium three times daily, with eighteen drops of extract of gelsemium four times daily. On March 15, 1889, the administration of other drugs was discontinued and the gelsemium increased to twenty-four drops four times daily, with the same effects as above noted. The patient, who was intelligent, was allowed to regulate the dose of gelsemium according to its physiological effects, being instructed to take the largest possible dose. The patient, much improved in his condition—in fact, almost entirely free from pain and spasm, was discharged from the hospital March 26, 1889, and subsequently returned to work.

A letter from him, dated June 9, 1889, stated that at that time he was still improving, and was taking ten to fifteen drops of the gelsemium five times daily. He had found that twelve drops of a preparation of gelsemium from Allegheny City were stronger than thirty drops of that obtained in Philadelphia, showing how great is the difference in the relative strength of preparations of powerful drugs as prepared by different chemists.

The commencing dose of gelsemium should never be greater than two to three minims, as alarming symptoms have been caused by larger doses. It seems remarkable that this patient could take such enormous doses apparently with no ill effect.

A somewhat similar case of torticollis was treated by Dr. C. K. Mills and Dr. Roberts at the Polyclinic a few months previous to the admission of this patient. In their patient, however, the spasm appeared to be chiefly of the sterno-mastoid, though it affected a number of the posterior cervical muscles. The characteristic uplifting of the chin showed contraction to be of the opposite sterno-mastoid. This patient, in order to keep his head from being turned violently to the right, constantly kept between his teeth the knotted end of a handkerchief, and with the other end in his left hand was able to oppose the spasm. The habitual position of his shoulders and back seemed to indicate that numerous muscles were affected by the spasm. His head and shoulders were constantly bent forward in addition to the constant clonic spasm produced by the sterno-mastoid.

Dr. Roberts in this case excised about one inch of the spinal accessory nerve, making the incision posterior to the left sterno-mastoid muscle. The nerve was recognized with absolute certainty by means of the electric current. No benefit followed this operation. The patient has not returned for treatment, though efforts have been made to find him in order to test the virtues of gelsemium.

HOSPITAL NOTES.

LATERAL CURVATURE OF THE SPINE—HIP DISEASE.

Abstract of a Clinical Lecture Delivered at the Children's Hospital, Philadelphia.

By JOHN ASHHURST, Jr., M.D.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

Professor Ashhurst showed the class a case of marked lateral curvature of the spine, which was made evident by following downward the line of the spinous processes, and explained that the bodies of the vertebræ were rotated to a greater extent than appeared externally. In the present patient the spinous processes of the dorsal region curved to the right, and on the same side was to be seen a sharp projection caused by the tuberosities and angles of the ribs. In this affection two curves are always found, the one compensatory to the other, the primary curve usually being the lower, though the upper is more distinct.

The predisposing cause of lateral curvature is relaxation of the ligaments, and the exciting cause some malformation of the body, or some vicious habit of standing or sitting. For example, if one limb is shorter than the other, the pelvis will be tilted upward on one side and a curve produced in the spine. The military position of "standing at ease," with one foot forward, has the same tendency. Another cause is sitting at too high a desk, which necessitates the elevation of one shoulder.

Lateral curvature is frequently met with in young girls, but in the majority, as they advance to womanhood, it disappears or becomes too slight to be noticed. Often the first sign is observed by the mother, who will say that the child's shoulder is "growing out." On examination it is found that the scapula does project, and that there is already some deviation of the spinous processes, the principal curve usually being above and toward the right side.

Treatment in the earlier stages can usually be satisfactorily conducted by the correction of improper positions and by gymnastic exercises. When a girl is found with the scapula projecting, and some pain in the part, she should be directed to lie flat on her back for an hour each day. Desks should be made of the proper height, and children should be trained to sit before them without elevating a shoulder. If, as is not infrequently the case, children fall into the habit of "standing at ease," with one foot advanced, the habit should be broken. Patients should be made to sleep upon a firm mattress, with a single pillow under the head, but not under the shoulders. Useful gymnastic exercises are those which cause the arms to be elevated, such as swinging from a horizontal ladder, or the use of pulley weights.

When, however, the disease is further advanced an apparatus is advisable, which, for most cases, should have a pelvic support and means for reinforcing the weakened spine. In very bad cases a plaster jacket gives better support than a brace, and has been used in the case before the class.

Professor Ashhurst then showed a case of antero-posterior curvature, or Pott's disease, in which the deformity was angular and without any lateral curvature. Pott's disease is a more serious affection than lateral curvature, as it involves the bones of the vertebral column instead of the soft structures. Usually more than one vertebra is diseased, causing a projection of several spinous processes, as was well shown in this patient.

There are certain distinctive risks and dangers in lateral curvature, of which contraction of the chest and consequent interference with respiration are the most important. Such a condition seriously complicates pneumonia or pleurisy. In its milder forms, however, lateral curvature is not a grave disease, but merely a deformity.

HIP DISEASE.

Professor Ashhurst then brought before the class a case of hip disease in the third stage, with abscess, in which he proposed to perform excision of the joint. An incision was made in the line of the muscular fibres above, curving around the back of the trochanter, and continuing below in the direction of the muscle. Such an incision exposes the joint thoroughly without unnecessary disturbance of the tissues. On passing the fingers into the wound, it was found that not only the head of the femur but the acetabulum was involved. The head of the bone was then turned out of its cavity, sawn off, and the end rounded with bone forceps, this step being of importance, as cases are recorded in which a spiculum of bone has penetrated the femoral artery or vein. During the manipulations an abscess in front opened into the wound, which necessitated thorough washing out of the cavity. A counter-opening was made in the anterior wall of the abscess, and a drainage-tube inserted through the wound. The wound was then sutured and dressed in the usual manner.

Professor Ashhurst said that excisions of the hip were less satisfactory than any other of the large excisions; not that, among children, many died from the operation, but satisfactory cicatrization was less likely to be obtained. Whether this is due to the presence of tuberculosis, or whether it is merely due to the difficulty of securing proper drainage, cannot be positively determined. Professor Ashhurst believed that tubercles were often, though not invariably, present.

CLINICAL MEMORANDA.

GYNECOLOGICAL.

Mania following Gynecological Operations.—I wish to supplement the cases of mania following gynecological operations, reported by Dr. T. Gaillard Thomas to the New York Academy of Medicine, as published in The Medical News, April 13, 1889, with two cases that have occurred in my practice.

Case I.—Mrs. E., aged thirty-five, was operated upon by Dr. J. H. Etheridge, in the Presbyterian Hospital, Chicago, in November, 1888, for salpingitis and cystic ovaries. Both tubes and ovaries were removed. The patient was much reduced, and was a typical case of hystero-neurosis, there being scarcely any organ or part of her system but which, during the previous six months, had suffered from derangement of function or sensation. She had been extremely melancholy, and, since her recovery, says that those six months are nearly a blank to her, only occasional incidents being remembered, and

those generally in an exaggerated or ridiculous manner. On the third day after the operation acute melancholia set in, and she was wildly delirious for seven days. On the twelfth day she became calm and rational; said she felt better and would get well. There has been no mental aberration since; neurotic disturbances, such as pain in back, knees and heels, have troubled her to some extent, but have been greatly benefited by galvanism. She is being gradually restored to health.

CASE II.—Miss H., aged twenty-four. Family history shows a taint of insanity, a brother having been treated in an asylum, and her father died an inebriate. She had cerebral meningitis at seven, and a second attack at thirteen. Puberty occurred at fourteen. Becoming frightened at the first menstrual flow, from ignorance of its nature, she ran to a creek near by and sat in the ice-cold water, washing herself until the flow ceased. Pain and severe suffering occurred at each succeeding menstruation. During the succeeding ten years she was treated by several physicians. She suffered much from acute pain in both ovarian regions, nausea, headache, and frequent attacks of metro-peritonitis. She became impatient, irritable and restless, and life became a burden to her; had attacks of acute melancholy, and was an inmate of the Mt. Pleasant, Iowa, Asylum for eight months. She was sent home as being "improved."

When consulted in February last, I found her to be fairly nourished. She still had acute pain, nausea, and headache at each menstrual period, with frequent attacks of melancholia, irritability, and religious fervor; bowels very constipated, and appetite capricious, besides many minor symptoms. There was vaginal hyperæsthesia; the broad ligaments on either side were thickened and exquisitely sensitive. In view of her mental condition, and the length of time she had been affected, there was but little hope that a removal of the uterine appendages would accomplish more than to relieve the periodical distress incident to menstruation. She eagerly requested an immediate operation, willing to take any risk that promised her immunity from her sufferings. I removed both tubes and ovaries, a few days later. There were adhesions, which made it difficult to bring the ovaries up out of the pelvis. Both were cystic; in one all, and in the other nearly all normal ovarian stroma had been destroyed. The tubes were enlarged and thickened. On the ninth day violent delirium of a melancholy type set in, and she died on the twelfth day, comatose. An autopsy showed the abdominal and pelvic cavities to be clean and odorless. The ends of the ligated stumps were wholly free from suppuration. Complete union had occurred throughout the abdominal incision.

In opening the calvarium, the skull was found to be extremely thick and hard. At no point along the line of section was it less than three-eighths, and in many places it was fully one-half an inch in thickness. The dura mater was very vascular, and so intimately adherent to the skull that great violence was necessary to strip it off, and it plainly showed the results of old inflammations. The surface of the brain was much congested, as was also the choroid plexus. The brain was well formed, the convolutions well marked, and the sulci remarkably deep. The cerebral substance was apparently normal.

E. H. KING, M.D.

WEST LIBERTY, IOWA.

MEDICAL.

Lozenges of Pyrethrum and Pilocarpine for Relief of Dryness of the Throat and Mouth.—I have used with much satisfaction for the relief of the uncomfortable sensations of heat and dryness which characterize many acute and chronic affections of the mucous membrane of the mouth and throat, a lozenge made according to the following formula:

Fluid extract of pyrethrum .	2–3 minims.
Pilocarpine hydrochlorate .	$\frac{1}{32}$ grain.
Pure extract of licorice .	2 grains.
Powdered acacia . . .	2 "
Glycerin	1 minim.
Sugar, enough to make .	20 grains.

The lozenge is allowed to dissolve in the mouth, and one is used every two, three, or four hours, as may be indicated. Should more frequent use be necessary the quantity of pilocarpine should be reduced. The addition of two grains of ammonium chloride will often be beneficial in subacute inflammatory conditions of the mucous lining of the respiratory tract; while in more chronic affections, two or three minims of the oleoresin of cubebs will serve a good purpose. The lozenge has a pleasant pungency, and its effect in keeping the parts well moistened is quite marked.

Speakers and singers have told me that the use of a lozenge just before lecture or performance has made it possible to do work comfortably which otherwise would have caused much pain and fatigue. It is possible that a little extract of coca might be advantageously added for special occasions of this nature.

The lozenges are skilfully prepared by Mr. Frank S. Morgan, of this city, and are dispensed by him under the name of *trochisci pyrethri et pilocarpinæ*.

SOLOMON SOLIS-COHEN.

TOXICOLOGICAL.

Tyrotoxicon Poisoning.—On May 29, 1889, about 9.30 A.M., I was called in great haste to see Mrs. R., of this city, who, her husband said, had been taken suddenly and violently ill. While on our way to the house Mr. R. complained of feeling very weak, nauseated, and dizzy, and had a choking sensation. Within fifteen minutes I was at the bedside of his wife. I found her suffering great pain in the region of the stomach, and a severe headache, with dryness of the throat, extremely weak and nervous, with some delirium and convulsive movements of the limbs. Her pulse was 124, weak, and irregular; temperature 99.5°; her pupils fully dilated. Upon inquiry I obtained the following history: Mr. and Mrs. R. were perfectly well previous to breakfast. They ate breakfast at 7.30 A.M., which consisted of milk-toast, coffee, and milk. Before the meal was finished Mrs. R. complained of severe headache, roaring in her ears, and dizziness. Convulsive movements of the limbs soon began, accompanied by a choking sensation; she grew weak so rapidly that she required assistance in reaching her bed. In five or ten minutes she became delirious, and in less than half an hour was totally unconscious, in which condition she remained ten or fifteen minutes, during which time there was an involuntary discharge of urine. The convulsive movements of her limbs con-

tinued until consciousness was restored, and more or less for half an hour following, and the choking sensation still longer; the headache grew worse, and the patient complained of severe pain in the region of the heart. "I feel as if my heart was being crushed between two solid bodies," she said. I administered an emetic dose of sulphate of zinc, which produced free emesis. The convulsive movements stopped immediately, but pain in the head and heart continued until they were relieved by nitrite of amyl. She remained weak during the day; the next morning was able to walk, but owing to extreme weakness, any exertion produced marked palpitation of the heart. At the end of seven days she had completely recovered.

Mr. R., who ate none of the toast, but drank of the milk in his coffee, felt no ill effects until some twenty or thirty minutes after his wife was taken sick, when dizziness compelled him to lie down; he became faint, but did not lose consciousness. His wife's serious condition aroused him, and he came for me, a half mile distant. On the way he experienced a choking sensation, pain in the chest, and headache. He afterward remarked: "I should have considered myself a sick man if my wife had not been so much worse." The milk used had been delivered the day previous about 9 A.M.; received in a tin pail with close-fitting tin cover, and placed at once in the cellar-way, near the cellar-stairs, and close by an open window. Part of the milk was used for milk-toast and part for coffee. That part used for the toast was heated to near the boiling-point, thickened with cornstarch, poured over the toasted bread, and eaten while hot. The milk used freely in the coffee was not heated. Suspecting tyrotoxicon poisoning, I procured the unused portion of the milk for analysis. Mr. Novy, instructor in hygiene and physiological chemistry in the University of Michigan, made a thorough analysis, and found tyrotoxicon present in large quantities.

John Martin, Ph.M., M.D.
University of Michigan.

MEDICAL PROGRESS.

Treatment of Gonorrhœal Orchitis.—Dr. Castel, in *L'Union Médicale*, October 10, 1889, draws attention to the value of internal medication combined with compression and refrigeration, in the treatment of gonorrhœal orchitis. Salicylate of soda, first recommended by Edward Henderson, he has found of use in alleviating the pain and hastening resolution. Observations in the Hospital du Midi prove that after the administration of this drug the majority of the patients found greater relief in twenty-four hours than after other methods of treatment. The duration of the disease was diminished, the painful symptoms disappearing and swelling being reduced in a short time. Six grammes of the salicylate of sodium were given daily. Anemone pulsatilla has lately been highly recommended, and given in the following mixture Dr. Castel considers it about equal in value to the salicylate:

℞.—Simple syrup . . . 120 grammes.
Tincture of pulsatilla . . 30 drops.

A half teaspoonful every two hours. Both drugs have a decided and rapid action upon the seat of pain and cause almost immediate cure.

To obtain compression, Dr. Castel uses Langlebert or Horand suspensory bandages, which are composed of a thick pad of cotton, a piece of rubber cloth pierced for the passage of the penis, and a bandage. The wadding is applied directly to the scrotum. The rubber cloth is placed over it to keep the diseased parts moist, and the bandage supports all and compresses the diseased organs. The effect of a well-applied dressing gives immediate relief, and patients are not obliged to stay in bed, but can walk with ease. The constantly increasing moisture necessitates the renewing of the dressing every four or five days.

Refrigeration is a rapid and decidedly efficacious treatment for the pain of orchitis, particularly in the few cases where the testicle itself is inflamed. In cases where the epididymis and the cord only are affected, as is usual, the good effect of cold is denied by many. Refrigeration is usually obtained by applying ice-bladders to the inflamed parts, and the applications should be methodically continued until all signs of inflammation disappear, or troublesome relapses may occur. An excellent method of obtaining the effects of cold is to apply, for a few moments daily, a simple pad of wadding cooled by a jet of chloride of methyl. This causes the dartos to contract and the skin to become cool and pale. To avoid cutaneous lesions, persistent erythema and vesication, any one of which would prevent the continuation of the treatment, the application should be removed in a few seconds.

Treatment of Barber's Itch.—Dr. Rosenthal orders the diseased skin to be closely shaven, and the following ointment well rubbed in twice daily:

℞.—Acid. tannic. . . . . gr. xlv.
Sulphur præcip. . . . ℥jss.
Zinci oxid. } . . āā ℥jv.
Amyl . }
Vaseline . . . . ℥j.—M.

A month's treatment with this is usually sufficient to cure the disease.

Dilatation of the Stomach in Syphilis.—In the recent International Congress of Dermatology and Syphilography Dr. Jullien, of Paris, stated that he had observed a number of instances in which dilatation of the stomach developed in tertiary syphilis, and believed that it was in many instances the cause of nervous symptoms which were usually attributed directly to syphilis. Large doses of the iodide of potassium were, he thought, not infrequently the cause of the dilatation.

Treatment of Appendicitis.—Dr. Senn thus summarizes his opinions on the operative treatment of appendicitis:

1. All cases of catarrhal and ulcerative appendicitis should be treated by laparotomy and excision of the appendix as soon as the lesion can be recognized.

2. Excision of the appendix, in cases of simple, uncomplicated appendicitis, is one of the easiest and safest of all intra-abdominal operations.

3. Excision of the appendix in cases of appendicitis before perforation has occurred, is both a curative and prophylactic measure.

4. The most constant and reliable symptoms indicating the existence of appendicitis are recurring pains and circumscribed tenderness in the region of the appendix.

5. All operations on the appendix should be done through a straight incision parallel to and directly over the cæcum.

6. The stump, after excision of the appendix, should be carefully disinfected, treated with iodoform, and covered with peritoneum by suturing the serous surface of the cæcum on each side over it with a number of Lembert stitches.

7. The abdominal incision should be closed by two rows of sutures, the first embracing the peritoneum, and the second the remaining structures of the margins of the wound.

8. Drainage in such cases is unnecessary, and should be dispensed with.—*Journal of the American Medical Association*, November 2, 1889.

Version in Contracted Pelves.—Nagel has recently studied this subject, and compared version with forceps delivery in cases of contracted pelvis. His conclusions are, that version is usually preferable. The most common varieties of contraction are, the symmetrically contracted (justo-minor), the flat pelvis, and the flat rachitic pelvis; and the author believes that podalic version is equally indicated in these three forms. He considers the measurement of the diagonal conjugate of little practical value, and measures the true conjugate only. The shortest true conjugate in his cases measured three and one-eighth inches. His record is 60 versions in contracted pelves, without a maternal death; 61 children were delivered, 46 of whom lived. Version should be performed early; mortality and morbidity increase with the duration of labor. The obstetrician must not delay until the os is fully dilated, but should perform version as soon as the hand can be introduced and the breech brought into the cervix, when uterine contractions generally dilate the os sufficiently to permit birth. So long as the membranes have not ruptured the case should be left to nature; but in transverse positions, when the membranes rupture, version should be performed at once, and extraction follow as soon as the os is sufficiently dilated. Nagel considers the use of the forceps after version unjustifiable. He performed version in all grades of pelvic contractions, as it affords the fœtus a chance for life, and perforation of the after-coming head has been no more difficult than when the head presents.

In delivering such cases, Nagel relies chiefly upon external pressure upon the head through the abdominal walls. Traction should not be made upon the trunk until flexion is well established. At the moment when the head emerges undue haste is to be avoided, as children may survive after a delay of five or ten minutes.—*Dublin Journal of Medical Science.*

Tongue-tie.—Dr. Tassius, of Berlin, protests against the indiscriminate cutting of the frænum linguæ for tongue-tie, and considers that this tiny and admirably constructed organ is a correct regulator of the various movements of the tongue, and that, if the same be too hastily interfered with, the more delicate movements may be forever destroyed—a momentous fact for those destined to become public singers. He advises his medical brethren, therefore, to proceed very cautiously, and not to operate at too early an age, as much improvement may result from the advancement of general development. Only in those cases in which the frænum is so abnormally large and tendinous as to cause a fissure in the tip of the tongue may the incision be made at once, but it should be calculated almost mathematically what proportion the depth of incision should bear to the fissure. The author deprecates, therefore, the use of scissors, as not to be depended on, and advocates the employment of a small knife, the incision to be made obliquely from below upward. Where the frænum is of fleshy character, and it is, consequently, certain that the child will never gain distinction in singing or elocution—there is, according to Dr. Tassius, no cause at all for immediate interference, unless the deformity causes a real impediment. It is far better to leave such cases—at any rate, for some time—entirely to the *vis medicatrix naturæ*.—*Weekly Medical Review*, October 26, 1889.

Digitalis in Aortic Regurgitation.—Dr. Graham Steell says, in the *Practitioner*, that it has long been a disputed point whether digitalis is contra-indicated in cases of aortic incompetence or not. The chief reason assigned for the rejection of its use is the prolongation of the diastole, which the drug is known to induce. Considering the question from the practical standpoint, he unhesitatingly affirms his belief, as the result of his clinical experience, that aortic incompetence offers no contra-indication to treatment by digitalis.

Local Treatment of Syphilis.—M. Hallopeau believes that local antiseptics should be systematically used in all accessible manifestations of syphilis, as each of these manifestations should be considered a centre of reinfection. This fact is evidenced by those syphilides which first appear as a papular or an initial tubercle, and around which lesions, appear, after variable periods of time, other papulæ of which each in its turn becomes a new centre of infection. Local treatment in these cases is a powerful aid to the general treatment, and should, therefore, be employed. If a profound and energetic effect is desired, recourse must be had to the caustics, of which the acid nitrate of mercury and powdered corrosive sublimate are the most used. It is well known that acid nitrate of mercury is a powerful remedy in the case of syphilides of the mucous membrane. Specific vegetations, which have resisted many months of general treatment, disappear after one or two cauterizations.

It is the same with lingual patches and ulcerations. The fear of the pain that the application causes has often prevented its being used; but cocaine makes, to-day, the use of it almost painless. The cauterization of the mucous syphilides by nitrate of silver, which is only moderately efficacious, should be abandoned, and universally replaced by cauterization with the acid nitrate of mercury. Powdered corrosive sublimate exercises a caustic action which should be closely watched, for it should be limited exactly to the part which one wishes to reach. It can be used as a means of aborting very recent chancres if unaccompanied by adenopathies indicating the generalization of the disease; and though the attempts made in this direction have been so far unfruitful, they are few in number, and should be repeated.

The continuous application of sublimate solution of a strength varying from 1–500 to 1–2000 is of the greatest service; the diseased parts are covered with compresses impregnated with the solution, then with oiled silk; this forms a sort of permanent local bath. Not painful, and

of easy use, it constitutes one of the surest means of rapidly improving specific ulcerations. The same solutions are useful against the buccal manifestations of the disease. Ointments containing calomel and corrosive sublimate are much used; they should not be too concentrated. Excellent results have been obtained with the ointment of salicylate of mercury containing from one to twenty per cent. A valuable means of causing a rapid and energetic action on a localized manifestation is the subcutaneous injection of a mercurial preparation, but small doses only should be used. Syphilides of the respiratory organs can often be effectually combated by inhalations of vapor obtained by letting a pinch of cinnabar fall upon a red-hot shovel.

Iodoform, besides being an antisyphilitic, is, at the same time, an antiseptic, and, on this account, of great service in the treatment of fetid syphilides which develop on the vulva, anus, or the extremities. Iodoform should not be used on large surfaces where there is danger of absorption and toxic symptoms. It should be applied either in powder, as an ointment with vaseline, as a solution in ether, or, finally, in the form of gauze or Unna plasters. In the words of M. Diday: "Local treatment is always useful, it is often necessary, sometimes indispensable."—*L'Union Médicale*, October 8, 1889.

Naphthalin Injections in Cold Abscess and Chronic Adenitis.—In place of iodoform, as in injection in chronic abscesses and adenitis, Dr. Henri Lasserre advises naphthalin solution. The naphthalin is harmless, strongly antiseptic, and can be dissolved in water containing a small amount of alcohol. The following is the formula used:

℞.—Naphthalin . . . . . ʒiss.
Alcohol . . . . . f ʒjss.
Aquæ . . . . . f ʒiijss.—M.

The water should be added hot, and the whole filtered before using. Previous to the operation the bottle containing the solution should be placed in a warm-water bath, and the syringe in a warm antiseptic solution, else the naphthalin will be deposited in the canula. The pus should be evacuated, and the cavity slowly distended with the solution.—*Wiener medizinische Presse*, October 13, 1889.

Fish Poisoning.—In connection with an editorial on Fish Poisoning, in a previous issue of The Medical News, it may be of interest to note some further suggestions of Mr. Lawrence-Hamilton, as to the preservation of fish. The foundation of his advice is, cleaning and bleeding fish the moment they are taken from the water, and keeping them frozen from that time until consumed. To accomplish the latter, he advises that dry-air refrigerator steamers should be constantly on the fishing grounds to receive the fish and transport them to market. The temperature of the refrigerators should be considerably below the freezing point. In addition, the fish should be packed in peat moss, to keep them separate from each other.

[However wise the latter precautions may be, we fear they are too Utopian for us to hope that they will ever be adopted, though the gutting and bleeding of fish when caught is a simple matter, and should be insisted upon.—Editor.]

Salol has been found very effective in the treatment of slight burns, being applied as an ointment, containing three per cent. of salol, lanolin forming the base.

As an agent for preserving the teeth and gums, salol, from its antiseptic properties, has special claims on our attention. Salol has demonstrated its great usefulness as a toothwash, particularly for decayed teeth. A general formula for such a wash is: Salol, gr. xx; Tinct. cochinell, ♏ vij; ol. menth. pip., ♏ iij; attar of rose, ♏ iij; sp. vini rect. dil. ad ℈ iv.—M. Dissolve the salol in rectified spirit together with the essential oils, and then add sufficient water. Such a mouthwash leaves a very refreshing taste, the odor of salol resembling the fragrant smell of oil of wintergreen.—*The Pharmaceutical Journal of New South Wales*, September 16, 1889.

Menthol in Phthisis.—Dr. Bramwell uses, apparently with good results in some cases, the intra-laryngeal injection of oily solution of menthol for phthisis. After the method of Jamieson, he employs a ten per cent. solution in olive oil, of which about twenty drops are injected by introducing the curved nozzle of a syringe between the vocal cords. Three or four injections are made at each sitting, and repeated daily. Dr. Bramwell believes the method is of advantage in certain cases, but how wide its range of usefulness may be, he has not decided.—*Studies in Clinical Medicine.*

Hydrastis Canadensis in Uterine Hemorrhage.—Where hemorrhage complicates fibroid uterine tumors hydrastis seems to exercise a favorable effect. The fluid extract may be given in the dose of sixty to eighty drops a day in doses of twenty drops each. The tincture of the strength of twenty per cent. may be used, or a decoction of the strength of sixty per cent. A useful formula is as follows:

Fluid extract of hydrastis
Malaga wine
Syrup
} āā 2½ drachms.

A teaspoonful in coffee every two hours.—*Lyon Médicale*, October 13, 1889.

Naphthalin in Enteric Fever.—Dr. C. Sehrwald has made some bacteriological experiments in Prof. Rossbach's laboratory, from which he draws the following conclusions: 1. Naphthalin at the temperature of the room retards but slightly the development of the bacilli of putrefaction, of feces and of typhoid. 2. Naphthalin, finely powdered or in solution has its disinfecting power increased. 3. In a temperature of 98° the effect of naphthalin is much more powerful than at lower temperatures, which makes it highly probable that it is chiefly in its gaseous state that it destroys the germs. 4. Gaseous naphthalin has more effect on aërobic than on anaërobic bacilli, and more on germs cultivated in a solid medium than on those cultivated in liquid. 5. The conditions for the full effect of naphthalin are much more favorable in the intestines than in the test-glass. 6. Naphthalin added to feces decreases their germs by about one-half, but, administered internally, it first decreases them one-third or even one-quarter; after this, however, the number rises again almost to its original figure. 7. Against the bacilli of typhoid stools naphthalin is still more effective, and decreases the number of germs even to one-tenth. 8. The administration of

naphthalin should be commenced at the very beginning of typhoid fever. 9. As calomel affects some of the fecal bacilli, while others are more readily destroyed by naphthalin, it is best to give, whenever possible, both drugs.—*Lancet*, September 28, 1889.

Prevention of Pitting after Variola.—In the *Revue Médico-Pharmaceutique* for September 30, 1889, SCHWIMMER gives his treatment for the prevention of the pitting of smallpox.

The method consists in a mixture of carbolic acid and thymol applied to the skin in the parts most exposed. The formula consists in the following:

Carbolic acid . . .	60 to 75 grains.
Olive oil	1½ ounces.
Powdered prepared chalk	2½ "

If an emollient salve is desired the following may be used:

Carbolated oil . . .	1 drachm.
Olive oil	1 ounce.
Pure starch . . .	1 "
Thymol	1 drachm.
Linseed oil	1 ounce.
Powdered prepared chalk .	2½ ounces.

Schwimmer asserts that he has tried this application in no less than six hundred cases of smallpox with good results, as it prevents deep suppuration, acts as a protective, and hastens the development of the lesions.

Ointment for Acne.—

Naphthol	2½ drachms.
Precipitated sulphur . .	1½ ounces.
Black soap, Vaseline . . .	āā 5 drachms.

This is to be applied to the skin every half hour or hour, and on the following day desquamation begins and lasts for eight days.

If the inflammation is very severe a local application of oil is to be made. Lewin cauterizes the pustules with nitrate of silver.—*L'Union Médicale*, October 12, 1889.

Solution for Chronic Coryza.—*L'Union Médicale* for October 17, 1889, gives the following formula of Morell Mackenzie for chronic coryza:

Bicarbonate of soda, Biborate of soda, Chlorate of soda .	āā ¾ grain.
White sugar . . .	15 grains.

Dissolve in warm water. The solution is to be heated to 98.5° F., placed in the palm of the hand and drawn up into the nostrils in such a manner that it traverses the nasal cavities back to the pharynx. Better still, the solution may be injected into the nose by means of a syringe.

Antipyrin in Whooping-cough.—DUBOUSQUET-LABORDERIE (*L'Union Médicale* for October 10, 1889) recommends the following for whooping-cough:

Antipyrin	5 to 15 grains.
Syrup	6 drachms.
Vichy water . . .	3 ounces.

A dessertspoonful of this may be given after meals to infants of one or two years. Dubousquet-Laborderie prescribes as much as fifteen grains of antipyrin to very young children without unpleasant results, and even gradually augments the dose. Sometimes as much as from fifteen to sixty grains are given to well-grown children and adults. After the ingestion of the drug a little soup or milk may be taken.

Collyria to Prevent Hernia of the Iris.—

Eserine	⅛ grain.
Distilled water . . .	2½ drachms.

This collyria is useful in staphyloma of infants, and is to be used whenever there is danger of perforation of the cornea. After paracentesis of the eyeball for glaucoma it is also useful.—*L'Union Médicale*, Oct. 1, 1889.

Carbolic Acid in Furuncles.—The treatment of boils by the parenchymatous injection of carbolic acid solution is strongly advocated by DR. LEU, who has used the method on a large number of cases and with most excellent results. He plunges the hypodermatic needle obliquely into the centre of the swelling, and injects from one-half to one syringeful of a two or three per cent. solution, the size of the boil governing the amount used. Four injections are, according to Dr. Leu, usually sufficient rapidly to bring about resolution.—*Prager medicinische Wochenschrift*, October 16, 1889.

Empyema in Children.—In a paper read before the American Pediatric Society DR. FRANCIS HUBER advocated early operation in cases of empyema in children. Immediately before operating the exploring syringe should be inserted as a crucial test to establish the presence of pus, at the point where the incision is to be made. Pus being detected, the soft structures should be divided, layer by layer, to the extent of one and a half to two and a half inches, the index finger feeling the various tissues as they are divided. The pleura having been opened and the pus allowed to escape more or less slowly, according to the condition of the patient, the pulse being carefully watched, the largest size drainage-tube is inserted and the cavity irrigated with hot water or (1-10,000) bichloride solution. An antiseptic dressing is now applied, and changed when saturated or the temperature becomes elevated. In performing irrigation the greatest caution should be observed that a gentle stream only is employed; that the fluid be at a proper temperature, and its free escape not interfered with. It has been his practice to employ a siphon irrigator, improvised from Whitall, Tatum & Co.'s siphon nasal douche, the nozzle being replaced by a piece of glass tubing, and the vessel holding the antiseptic solution being held about one and a half to two feet above the level of the wound. The drainage-tube is secured by employing a piece of rubber bandage one and a half inches square, with a central perforation, through which the tube split longitudinally for about an inch is passed. The divided ends are then turned down and fastened to the square of rubber (acting as a shield) with small safety-pins or wire sutures, or the split portion of the tube is turned down and transfixed with a large safety-pin, no shield being used.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 16, 1889.

THE TREATMENT OF CHRONIC GONORRHŒA.

THERE is probably no subject in medicine upon which more time and thought have been spent than that of the management of chronic urethritis. With the discovery of Neisser's gonococcus as the cause of gonorrhœa, and the introduction of antiseptics into its therapeutics, there seemed to the enthusiast little doubt that at last a way had been found to shorten the duration and to limit the effects of acute urethritis, and that chronic urethritis would be less often the sequel than in pre-antiseptic days. Unfortunately this hope has not been by any means entirely realized. There are so many conditions which tend to perpetuate a urethritis, or to reëstablish it when recovery is close at hand, that it is dangerous to put our faith in any one line of treatment. In dealing with chronic urethritis the treatment that is most apt to lead to success is that which is based upon a careful, thorough examination of the diseased urethra in question. Whatever may be the pathological condition present, whether stricture, granular state of the mucous membrane, or what not, the plan of treatment adopted must be directed intelligently to it.

In the *Münchener medicinische Wochenschrift* for October 1st, is an interesting paper by DR. WILHELM FLEINER, of Heidelberg, entitled "Contributions to the Therapeutics of Gonorrhœa." After a concise review of the pathology of acute urethritis—Neisser's coccus of course occupying the prominent position—Fleiner makes particular mention of the formation of granulation tissue in the deeper layers of the mucosa, and the subsequent atrophy leading to its alteration into cicatricial tissue, and the narrowing of the urethral calibre thereby. Giving to Unna proper credit for having suggested the combination of medication with the mechanical treatment of chronic urethritis, the writer gives his entire support to the method. Unna used sounds covered with a mixture composed of nitrate of silver (1 per cent.), balsam of Peru, yellow wax, and cacao butter. In order, of course, that the medicinal agent introduced into the urethra may be effective, its vehicle must be such as to permit its intimate contact with the surface of the mucous membrane. Casper and others have claimed that lanolin fulfils this requirement, and substitute it for cacao butter and wax in Unna's formula. They claim that lanolin will take up 50 per cent. of its weight of water, and, consequently, that when the ointment comes in contact with the moist surface of the urethra, a thorough application of the active ingredient is insured. Fleiner shows that the small amount of ointment rubbed upon the sound could take up but a very insignificant quantity of moisture from the mucous membrane, so disposing of the claim made for the superiority of lanolin on that ground. A further objection that he makes to it is that the lanolin mixture does not melt readily in the urethra, and that but an infinitesimal amount of the remedy is left in contact with the diseased area.

Fleiner uses cacao butter with a small proportion of yellow wax as the basis of his mixture. Nitrate of silver is the stimulating agent he prefers. His formula is as follows:

℞.—Argenti nit.	. . . .	1 part.
Ceræ flav.	. . . .	2 parts.
Ol. theobrom.	. . . .	17 " —M.

He employs ordinary steel sounds, sizes 18 to 28. The appropriate instrument being selected, it is heated and the ointment rubbed upon its surface, or such parts of its surface as may be desired. The preparations for this method of treatment are, therefore, of the simplest possible kind. The object aimed at is the combined effect of dilatation of the urethra with stimulation of unhealthy parts of its mucous membrane. Fleiner's results are quite flattering. In forty-one cases twenty-eight were cured and eleven improved. As to the number of sittings required,

from four to six are generally necessary; on two occasions recovery followed upon one application, and in eight cases there were over ten sittings.

Nitrate of silver has always occupied an acknowledged high position in the list of remedies for chronic urethritis, but experience shows that there are many urethræ to which it is wholly unsuited, and for these Fleiner recommends that either tannin, thallin, or bismuth, be substituted in the application used.

The value of antiseptic or astringent solutions employed for irrigating the urethra, in addition to the above described measures, is not lost sight of by the writer. His claim for the results of treatment by combined dilatation and medication is most modest, and the statement is candidly made that there are some cases which will resist every kind of treatment.

It cannot be said in favor of Dr. Fleiner's method that it is in any way novel, and, in fairness to him, it must be stated that he makes no such claim. The practice of dilatation of the urethra up to its full capacity is a familiar method of treating chronic urethritis, and, as for local medication, the means for carrying it out and the agents used by different authorities are numerous. It is interesting, however, to meet with an account of such good results derived from the judicious modifications of methods already well known, although frequently far from satisfactory.

MISERABILE DICTU.

At the present time, when the power of evil legislation seems to have the upper hand, and the endeavors of the regular profession to obtain a State Medical Examining Board, have been thwarted in the State of Pennsylvania by certain opponents of professional high standing, the following abstract from the *Brooklyn Medical Journal* may carry to the public a sufficient idea of the frightful dangers which they allow to exist under the present law. It is very easy for a man, as brutally ignorant as some of these men seem to have been, to mistake the symptoms resulting from one of their poisonous doses for evidences of disease, and in this way to fail absolutely to attempt to remedy the evil which their criminal negligence has brought about.

The Virginia Board of Medical Examiners received the following answers to questions put to graduates of medical colleges, who, under the Virginia law, applied for licences to practise medicine in that State:

Describe the larynx. *Ans.* The larynx is composed of cartilage. The œsophagus passes through the larynx.

What is the function of the liver? *Ans.* Do not know.

Give tests for arsenic. *Ans.* Sulphuretted hydrogen is one. Don't know rest.

Give test for mercury. *Ans.* Do not remember.

Give dose of tartar emetic. *Ans.* Ten grains.

Give dose of sulphate of atropia. *Ans.* Hypodermatically ten grains; by mouth sixty grains.

Give dose of corrosive sublimate. *Ans.* One grain.

How would you treat placenta prævia? *Ans.* I don't know what it is.

Give dose of powdered cantharides. *Ans.* Forty grains.

What is the source of iodine? *Ans.* It is dug out of the earth in blocks like iron.

Describe dengue or break-bone fever. *Ans.* By four applicants: A fever that comes on soon after the bones are broken. By one applicant: The patient should be cautioned against moving, for fear the bones should break.

Describe the peritoneum. *Ans.* It is a serous membrane lining the belly and extending into the chest, covering the heart and lungs.

Anatomical ignorance is bad enough, but the ignorance of doses of powerful drugs is terrible in its results.

It is hardly necessary for us to point out that the doses of atropine here given are sufficient in the one case to poison over twenty men, and in the other instance to kill, perhaps, over one hundred adults. The proper punishment for the man who would order forty grains of cantharides would be the administration of the drug in consecutive divided doses, lest the one should kill him too soon.

For every candidate applying for the right to practise medicine in the State of Virginia, where the people are intelligent enough to protect themselves, fifty similar and worse dealers in human lives enter this and other States, where no examination frightens them away; and it is worthy of remark that the candidates in Virginia were not only ignorant of medicine, but were ignorant enough of their own mental state to dare the terrors of an examination. The provision of a State Medical Examining Board is not a measure to be engineered through the legislature by the medical profession. It possesses far less importance to us than to the laity, for

one doctor can generally grasp the calibre of another and protect himself. It is the people who suffer in silence, instead of protesting against such fearful homicidal practitioners. To-day the writer of this editorial read of a case where ergot was given in the early part of the second stage of labor, and yesterday he heard of a woman killed by a great, burly brute who was ignorant of the most simple form of obstetrical procedure. Yet with the perversity of human nature, the apothecary who dispenses poisons must be examined, and the man who orders the poison prescription goes unendorsed. Two means of remedying this crying evil are possible. The first, is to prevent the entrance of the money-grasping ignoramus into the sacred guardianship of life, home, and family. The other, is for the laity to inform themselves of the standing of surrounding medical schools, and refuse to recognize the degree of an institution turning out unqualified men or of one of which they know nothing. When the people become educated well enough to know when their wives, children, and those dearest to them are killed because of the employment of a miserable charlatan, then, and not till then, apparently, will an effort be made to prevent this "yearly sacrifice."

REVIEWS.

Student's Aid Series. III. Medicine. By C. E. Armand Semple, M.D. New York: G. P. Putnam's Sons, 1889.

This handbook is intended as an aid to students preparing for examination in medicine. The various diseases of special organs are briefly described with their pathology, symptomatology, and treatment.

The chief object of such manuals is to enable the student to classify and arrange his knowledge. In order the better to accomplish this all but the essential facts should be eliminated, leaving to more extensive works the discussion of abstruse questions. Absolute accuracy is, of course, one of the most essential requirements.

The author has in many instances departed from the region of known facts, without, however, following to their conclusions the theories advanced. The purpose of the book would have been much better attained had the known facts or the more plausible theories alone been given.

As to accuracy, the book is far from satisfactory. Had the author occasionally made a statement that either could not be verified, or would not have seriously misled those for whose aid the book is intended, the brevity required in a work of this character might have excused it. When such misleading statements, as are to be found throughout this book, are made, it is impossible to regard it as one that could be safely recommended to the student.

From numerous equally erroneous statements, the following examples are selected:

It is stated by the author that pleurisy is usually single, but that the disease may *extend* and constitute double pleurisy. The pulse of aortic regurgitation is characterized as dicrotous. Instead of accepting the undue prolongation of the diastole and consequently longer period for regurgitation produced by digitalis as a reason for its failure to benefit cases of aortic insufficiency, the author states that in this affection the drug may do harm by driving the ventricle into a state of contraction from which it may never become relaxed. Medullary *sarcoma* is given as a variety of carcinoma of the liver. Tincture of iodine is said to give a *brown* staining to tissues that have undergone amyloid change. Albuminous urine is said to be absent in pyelitis. "Sarcinæ is a name applied to a variety of vomiting." Idiopathic enteritis is classed as a rare disease. In describing colica pictonum, the hands are said to be generally first affected, giving from the context the impression that wrist-drop was the first symptom of lead colic. The following sentence is peculiar, "The organ (spleen) should be percussed whilst the patient is lying or standing on his right side." In regard to the treatment of laryngismus stridulus, the first statement made is, that the gums must be lanced and a warm bath used, leading the student to suppose that he should lance the gums in all cases, whether dentition were in progress or not, there being nothing in the text that could remove such an impression. Among the remote causes of apoplexy, the author gives first place to "a peculiar configuration of the body." In describing *delirium tremens*, there are given as causes: Excessive use of opium, mental exhaustion, intense study, prolonged anxiety, all causes of debility, physical and mental shock.

Some of these examples appear to express what could not have been the opinion held by the author. Nevertheless the statements are made, and the student would be unable to put any different construction upon the text.

Taken altogether, the book cannot be considered one that would be either a safe guide or a satisfactory aid to the candidate for examination.

SOCIETY PROCEEDINGS.

TRI-STATE MEDICAL ASSOCIATION OF TENNESSEE, GEORGIA, AND ALABAMA.

In pursuance to a call made during the past summer, a number of physicians from Georgia, Alabama, and Tennessee, met in Chattanooga, Tennessee, October 15 and 16, 1889, and organized themselves into a Tri-State Medical Association, to meet once a year. Having adopted a Constitution and By-laws, the association was duly organized with the following officers: *President*, J. B. Cowan, M.D., Tullahoma, Tennessee. *Vice-Presidents*, Andrew Boyd, M.D., Scottsboro, Alabama; James B. Edge, M.D., Dencork, Georgia; S. B. Barber, M.D., Tracy, Tennessee. *Secretary*, Frank Trester Smith, M.D., Chattanooga. *Treasurer*, S. B. Wert, M.D., Chattanooga.

Dr. W. L. Gahogan read a paper on

THE PHYSIOLOGY OF THE HEART AND ITS VALVES,

containing an accurate description of the minute anat-

omy, the innervation, action, and sounds of the heart, normal and pathological.

DR. G. W. DRAKE, in discussion, said the question, What makes the heart beat? has not yet been satisfactorily answered, and called attention to the importance of recognizing the difference in the nervous mechanism of the lower and higher orders of animals.

DR. JAMES E. REEVES, of Chattanooga, read a paper on

THE IMPORTANCE OF THE MICROSCOPE IN THE PRACTICE OF MEDICINE,

which was discussed by Drs. W. C. Tacones, G. A. Baxter, and J. B. Cowan, who emphasized the importance of microscopical investigations at the bedside. The paper was carefully written and well received.

DR. J. E. PURDON, of Cullman, Georgia, reported

A CASE OF FRACTURE OF THE SKULL IN AN OLD MAN, WITH RECOVERY.

The man was sixty-five years old. The interest in the case laid in the fact of recovery at such an age and from such an extensive fracture. The opening of the removed bone was three inches or more square, and located over the third frontal convolution. There was complete loss of memory of names followed by partial recovery.

The paper was freely discussed by various members. In this line, Dr. G. A. Baxter mentioned a case of anomalous distribution of the anterior branch of the middle meningeal artery, which was wounded while trephining for compression caused by blood-clot. The hemorrhage was controlled by pressure, the plug of bone being inserted. In a few days, union of bone took place, and complete recovery resulted.

Meeting then adjourned until 8 P. M.

At the night session, letters were read from Drs. Robert Battey, of Rome, Georgia, and F. W. McRae, of Atlanta, Georgia, expressing their regret at not being present.

DR. ANDREW BOYD, of Scottsboro, Alabama, presented a paper on

CROUPOUS PNEUMONIA,

in which he briefly reviewed and discussed the etiology, holding that the disease is due to a specific germ, and citing cases to prove his position. He thinks the diagnosis can only be made from physical signs, and that the rusty sputum and herpes labialis are pathognomonic. The disease runs a definite course in from seven to fourteen days. He mentioned four varieties of treatment: depletory, sedative, stimulating, and mercurial, and reasoning from analogy he concluded that the best plan is to keep down the fever and stimulate the heart.

This paper was discussed by Drs. Reeves, P. D. Sims, E. T. Camp, J. E. Purdon, and C. W. Cooper. Dr. Drake called attention to the importance of keeping in mind fibroid phthisis as a sequela of croupous pneumonia.

DR. MAX THORNER, of Cincinnati, Ohio, presented a paper on

IMAGINARY BODIES IN THE THROAT.

These were divided into three classes: 1. Cases where some object had been removed from the throat, but the sensation of the body remained. 2. Cases where the sensation was due to some pathological lesion of the throat. 3. Where neither of the above existed, but where the sensation was due to a reflex, or produced by some remote ailment, as *e. g.*, indigestion, or a pure neurosis. The treatment varies according to the state; some can be persuaded that there is no foreign body present; in others innocent deception is necessary. Pathological conditions, as enlarged tonsils or uvula, varicose veins on back of tongue, hypertrophied papillæ, or lymph nodules should be removed. The paper was discussed by Drs. W. C. Steele, N. C. Cooper, and Frank Trester Smith.

SECOND DAY.

The President appointed the following chairmen: On *State Medicine*, P. D. Sims, Chattanooga; *Meteorology*, E. T. Camp, Gadsden, Alabama; *Psychical Research*, J. E. Purdon, Cullman, Alabama; *Pathological and Practical Microscopy*, J. E. Reeves, Chattanooga; *Otology*, R. D. Boyd, Chattanooga; *Ophthalmology*, N. C. Steele, Chattanooga; *Obstetrics*, W. T. Blackford, Graysville, Georgia; *Gynecology*, R. J. Trippe, Chattanooga; *Surgery*, G. A. Baxter, Chattanooga; *Practice*, G. W. Drake, Chattanooga; *Laryngology*, Max Thorner, Cincinnati; *Experimental Physiology*, W. L. Gahogan, Chattanooga; *Materia Medica and New Remedies*, Junius F. Lynch, Chattanooga.

DR. J. A. LONG, of Long's Mills, Tennessee, read a paper on

TYPHOID FEVER.

He reported 505 cases with a death-rate of 2 per cent. The main treatment was turpentine in drop doses every hour; whether it acts as a stimulant, retards ulceration, or acts as a disinfectant he did not pretend to say.

DR. J. E. REEVES criticised the paper, questioning the statement that the death-rate did not exceed 2 per cent., and thought that all Dr. Long's cases were not genuine typhoid fever.

DR. DRAKE remarked that the paper contained the most complete pen-picture of the disease which had ever been presented to his mind; aside from some confusion in regard to infection and etiology, it merited high commendation. Much interest attaches to the paper as being the result of the observation of over 500 cases in a practice confined to one locality. Dr. Long gave his observations on his own cases without reference to text-books or experience of others. Turpentine, quinine, alcohol, milk, and home-made beef tea are the medicines and foods Dr. Drake has used in his practice.

AFTERNOON SESSION, SECOND DAY.

DR. W. C. TOWNES read a paper on

HYPNOTISM AND SUGGESTIBILITY.

DR. J. E. PURDON, of Cullman, Alabama, presented a paper on

THE SPHYGMOGRAPH AS A NEW AGENT IN PSYCHICAL RESEARCH.

Dr. Purdon claimed to have discovered the fact that psychical influence of one nervous system upon another at a distance, unconnected by any of the ordinary physiological bonds, could be demonstrated by the aid of the syhygmograph; that he had identified, in many instances, forced relationship of the pulse tracings from the fact that certain neurotic subjects had departed from their usual trace-forms to conform to those of individuals with

a more dominant nervous system. Dr. Purdon further argued that this was a first step toward the proof of psychical connection between the higher centres of different brains, which the progress of modern psychology obliges us to acknowledge. In the face of the now well-established fact of psychical communication, mind-reading, sympathetic sensibility, etc., Dr. Purdon argued against the fundamental principles of materialism by falling back upon the possibilities of the infra-conscious intelligence, and by regarding mind and matter as but different aspects of the one underlying reality.

DR. DRAKE said we had hitherto been taught that nerve impulses are confined to the individual in whose organism are contained the cerebro-spinal and ganglionic nervous systems. In Dr. Purdon's paper the startling thought was presented that nerve impulses (or nerve fluid) may escape from the body of one individual, and like electricity, passing through the intervening media, penetrate the body of another individual. When impulses from the cardiac centres of one person may pass to those of another, or to the nerves leading from them, and so control the pulse as to cause the sphygmographic tracings of the individuals to be identical, when impulses, as instanced in the cases cited, passed through prison walls and affected individuals in separate cells, this fluid must be more subtle than electricity.

As to hypnotism and suggestibility, presented by Dr. Townes, the brain centres are kept awake by impulses which flow in through the five senses, and also by thoughts and ideas from the mind. Impulses may be conducted by nerves to any or all of the brain centres, or subconscious impulses may originate in these centres. To become expert in the practice of hypnotism, it is necessary to resort to the methods of temporarily suspending or retarding the action of the brain centres. If one learns to control a normal action in the subject, by the same means he may be enabled to modify an abnormal action which is producing some functional disturbance. The method of suggestion is a species of faith-cure, and depends, in a great measure, upon the credence of the patient in the promises of the physician. Suggestibility, as Dr. Drake understood it, is a susceptibility to certain psychical influences, and may be increased by the hypnotic state.

DR. COOPER HOLTZCLAU presented a paper entitled,

REPORT OF TWO CASES OF LAPAROTOMY, WITH A SPECIMEN.

CASE I.—Female, married; aged twenty. History of pelvic cellulitis for two or three years previously, and ascites, which was tapped several times. Uterus adherent; tumor size of hen's egg, situated to the right of Douglas's pouch and rectum; pain on touch and defecation. Diagnosis, ovarian cyst. At the operation the ovaries and tubes were found adherent. The patient recovered, and is in good health.

CASE II.—Female, unmarried. In January, 1888, patient noticed a small tumor in right iliac region, which grew so large that she appeared as though at the full term of pregnancy. She also suffered from dyspnœa and irregular menstruation. Xiphoid cartilage dislocated and painful. Heart sounds rapid and weak. Diagnosis, parovarian cyst. At the operation on October 1, 1889, a large sac of fluid and colloid matter, containing two gallons, was removed. The pedicle was short. Patient was dismissed on the fifteenth day well.

DR. JUNIUS F. LYNCH reported the following case of laparotomy: Patient, aged thirty-five, an invalid for several years. Diagnosis, pyosalpinx. The sac ruptured in trying to remove it, and the contents emptied into the abdominal cavity. Some hours after the operation tympany became marked and the patient was given Epsom salts and enemata of turpentine and assafœtida, but the gas continued to accumulate. Dr. Lynch advised further operative procedure, but fortunately at this time, the fifth day, there was a copious evacuation of the bowels, and no further distention. Operation performed under strict antiseptic precautions, and patient recovered without further bad symptoms.

DR. TRIPPE reported other cases of laparotomy for cystic tumors and stab wounds.

The night session was chiefly occupied by a general discussion on the subject of hypnotism.

The meeting was highly successful in point of numbers and the amount of work done. The number of papers was not large, but the discussions were full and free.

The Association meets in Chattanooga, Tennessee, October, 1890.

GYNECOLOGICAL SOCIETY OF CHICAGO.

Stated Meeting, June 21, 1889.

THE PRESIDENT, CHARLES T. PARKES, M.D., IN THE CHAIR.

DR. W. W. JAGGARD presented a photograph of a

CASE OF FŒTAL APLASIA,

and read an account furnished by Dr. Mansfield, in whose practice the case occurred.

The confinement in which the monster was delivered was one of twin pregnancy at about the seventh month. The mother was a multipara.

On dissection, all the tissues were found very œdematous. The feet were clubbed, and had but two toes each, great and second. The weight was ten pounds. The external genitals were female, normal. No anus was present. The right side of the abdomen and right side of the thorax were occupied by a vesicular tumor, which on dissection proved to be of spinal origin, the pedicle arising from the seventh cervical and first thoracic vertebræ. The sac was continuous with the membrane of the cord, and filled with cerebro-spinal fluid. The right arm was united to the side of the abdomen. The radius and ulna were the only bones present. The left arm was adherent to the thorax as far as the elbow. Hand clubbed, with rudimentary thumb and two rudimentary fingers. Both superior maxillæ and palate were cleft. The trachea, thymus, thyroid, lungs, œsophagus, stomach, spleen, pancreas, and liver were all absent. The umbilical vein entered the right auricle directly. The entire length of intestine was twelve inches, and at its blind end were two small, kidney-shaped, glandular organs that weighed five grains each. The kidneys were very large, one and three-quarters inches by one and one-quarter inches by three-quarters of an inch. Ureters as large as goose quills, and emptied with the intestine into a cloaca that occupied the normal position of the vagina. No trace of uterus or ovaries. Mesentery and peritoneum studded

with little bodies like miliary tubercles. On opening the skull, the membranes were found firmly united, and to them was attached a thin layer of brain substance. Cavity filled with cerebro-spinal fluid. Basal ganglia represented by about thirty grains of brain matter. No olfactory or optic nerves. Spinal cord in cervical region about one-quarter inch in diameter, and pinkish in color.

Dr. Jaggard said that the specimen, while rare, was by no means unique. It possessed many of the characters common to the acardiaci—it was the product of twin or multiple pregnancy, the placenta is single, the twin is perfectly formed and is of the same sex. On account of the presence of the rudimentary heart, however, this monster could not be referred to any one of the three types that are commonly described—amorphous, acormous, and acephalous, but appeared to represent a transition-form between the common acardiac acephali and the acranii.

THE PRESIDENT then reported the following cases of

HYSTERECTOMY, AND AN OPERATION FOR TUBAL PREGNANCY.

The first was a case of vaginal hysterectomy done some six weeks previously for persistent hemorrhage. All the usual methods had been resorted to for the purpose of controlling the hemorrhages, such as curetting the uterus, various applications, repair of the cervix, etc., without producing any effect on the bleeding or on the size of the uterus, which was considerably larger than normal. Finally, he advised her, since she had passed the forty-fifth year of her life, and was really losing her life with the hemorrhages, to submit to an operation for the removal of the uterus. A vaginal hysterectomy was performed, attended with many difficulties owing to the size of the uterus, which required much force to be delivered through the natural passage. After it was removed, the entire upper portion of the body of the uterus was found to be a mass of degenerated tissue. Microscopical examination showed it to be epitheliomatous.

The second was a case of abdominal hysterectomy for a very large tumor, which weighed about fourteen pounds immediately after removal. The case was of great interest, owing to the fact that examination of the tumor by himself and others left them doubtful whether it contained fluid or not, or whether it was a single cyst or a mass of cysts. Section through the abdominal wall showed a uterine tumor which had broken through the capsule at the upper end. It was particularly interesting, for the reason that for the first time in his experience an opening was torn into the small intestine, but none of the contents of the intestine escaped into the peritoneal cavity. The patient was in good condition till the fifth day, when she exhibited symptoms of obstruction of the bowel, and died.

A post-mortem examination was held, the incision being made in the line of the original incision. When the abdomen was opened, the distended intestines escaped. The tear was completely closed, and this portion of the intestine held gas as perfectly as the others; every suture was covered over, except at the knotted ends.

This was his fourth case of abdominal hysterectomy treated by the extra-peritoneal method, all of which had died.

The third case was one of tubal pregnancy, at about the third month, upon which he performed abdominal section. There had been quite a hemorrhage into the broad ligament. The tumor and the opening into the Fallopian tube were found without difficulty. He did not, however, find the fœtus. The tumor consisted of the remnants of the placenta and amniotic sac. All this was removed, the opening of the cavity closed, and the wound packed with iodoform gauze. The woman recovered.

The fourth case was also one of abdominal hysterectomy, or, rather, the sequel to that operation performed three years ago. Since the previous operation the patient had suffered from the fact that the lower end of the wound had not closed. Six months after the operation quite a quantity of pus was discharged, and six months ago she had a serious accumulation of pus, with septic fever. From this abscess one of the ligatures came out, two and a half years after the operation. The tumor was a large one, requiring a long incision, and the patient had quite a good-sized ventral hernia.

The recent operation was done for an opening through the remnant of the cervix, from which, by inserting a probe and turning it in the cavity of the cervix, he brought away a small amount of fecal matter. Evidently there had been adhesions between some portion of the bowel and the stump of the uterus, and sloughing and inflammation had gone on between the cavity of the bowel and the cavity of the cervix. The canal was short, so a conical incision was made through the remnant of the cervix, extending as high as possible, and the two surfaces sewed together to close the pocket and the cervical opening.

DR. E. C. DUDLEY reported

TWO CASES OF VAGINAL HYSTERECTOMY

similar to the cases reported by Dr. Parkes. The first operation was done January 9, 1889. The patient was fifty-eight years of age. The subjective symptoms were frequent and very profuse flowing, with intervals of free muco-purulent leucorrhœa, during the previous sixteen months.

Examinations of repeated scrapings from the endometrium failed to show anything except adenoma, but it was decided to remove the uterus on suspicion. Just before the removal, however, Professor Frank Johnson, after having examined a large number of slides, discovered unmistakable evidence of cancer. After the removal of the uterus, this cancer was microscopically proved to extend almost through the fundus uteri.

Although the patient had suffered for years from a ruptured and relaxed perineum, the perineum was divided to get more light and space for isolation of the broad ligaments. Immediate closure of the perineum thus divided resulted in perfect union. Four weeks later the patient had trouble in walking, from sagging of the pelvic floor, from cystocele, and from rectocele, and requested perineorrhaphy.

Upon examination, a small, soft, friable protuberance in the perineal scar caused Dr. Dudley to fear a return of the disease at that point. Consequently, after thorough disinfection of the vagina and external genitals, the growth was excised with a wide margin of healthy

tissue; the operation was completed as a perineorrhaphy. Upon examination of this little growth Dr. Johnson declared it to be a carcinoma.

The question arises, whether this was the result of metastasis, a transplantation, or an independent growth. It could hardly be metastatic, because the vessels do not run in that direction. If it were an independent growth, it is probable that the conditions which produced it would have been active in other parts before this time. More probably it was a transplantation during the operation. This speaks strongly for scrupulous care in the cleansing of all wounds after the removal of cancer.

The second hysterectomy was on March 22, 1889. Before the operation, the microscopic examination by Dr. Johnson, and the subjective symptoms, were essentially the same as in the previous case, except that the microscopic evidences from repeated scrapings showed nothing more than adenoma. The uterus was removed on suspicion.

The following is Dr. Johnson's report of the post-mortem examination:

"Cavity of body partly filled by a mass of outgrowing mucous membrane, consisting of long, slender villi.

"*Microscopical Examination.*—The villi covered with columnar epithelium.

"At the base of the new growth are found a few nests of cells not conforming to the gland type, but are irregularly shaped masses of polygonal epithelial cells packed closely together.

"In one specimen, a mass of lymph spaces in the uterine tissue at some distance from the bases of the villi, is seen packed with epithelial cells similar to those last mentioned.

"*Diagnosis.*—Villous adenoma, beginning carcinoma."

The patient recovered, and at the present time has no return of the disease,

Permanent hæmostasis and closure of the peritoneal wounds were secured by means of lock forceps.

OVARIOTOMY.

Dr. Parkes then read the notes of a post-mortem held on a patient presented to the Society in March, 1884. The case was one of ovariotomy complicated by miliary tuberculosis. From the time of the operation to her death there was a constant discharge from the old wound.

"The abdomen was flat, and on section the viscera appeared normal.

"Liver normal in size; slightly fatty (pale and mottled). Spleen, fully three times its normal size; very firm; amyloid. Right kidney nearly twice the normal size; capsule non-adherent; cortex twice the normal thickness; surface beneath the capsule is slightly paler than normal, and mottled. Microscopical examination was not made. Left kidney is represented by a large cyst, occupying the greater portion of the left half of the abdomen. Contents, cheesy, straw-colored fluid. The cyst wall formed by the capsule of kidney somewhat thickened, and in a few places thin remnants of kidney parenchyma are found upon the inner surface. The cyst is sacculated: the pouches seemingly correspond to the original calices of the pelvis. The left ureter is embedded in a mass of cicatricial tissue (site of old operation for suppurating dermoid cyst of the left ovary).

"*The Abscess.*—The external opening in the abdominal wall is in the median line about an inch below the umbilicus. The finger passes downward in the median line behind the pubic bones; from there downward and backward about two inches, also to the right, along the brim of the pelvis. Near the external opening is a communication with an inner sac, situated within the pelvis and projecting upward into the right iliac fossa. At the point of communication between the outer and inner sacs, the colon is adherent and opens into the abscess in such a way that the finger may be passed from the outer sac into either the colon or the inner sac. (The remainder of the head of the colon, the ilio-cæcal junction, and the vermiform appendix are normal.) The inner sac has thick walls. It is covered in front by peritoneum. The cavity is somewhat larger than a goose egg; the inner surface is irregular, in ridges and elevations, and is gangrenous. Beside the sac, no trace of ovary can be found on the right side. Left ovary absent; uterus small, atrophic; bladder contracted; alimentary canal, with exception of caput coli, normal."

Dr. Parkes referred to Kaltenbach's seven cases of vaginal hysterectomy for what he calls corpus carcinoma, or malignant adenoma, originating in the mucous membrane of the body of the uterus. Kaltenbach removed the uterus because all other methods of controlling hemorrhage had failed, and in all of these cases he found the same degeneration, commencing about the Fallopian tubes and spreading up over the fundus to join in the median line.

Dr. Dudley said that the question sometimes is, whether the uterus, or the ovaries and tubes, should be removed in a case of intractable uterine hemorrhage. If scrapings from the uterus prove to be adenoma under the microscope, and yet return promptly after removal, then he would fear carcinoma, present or prospective, and should be disposed to remove the uterus. If, on the other hand, it be not possible to get much out of the uterus by repeated curettings, the probability is against carcinoma as a cause of the hemorrhage, and the removal of the appendages would be preferable to removal of the uterus. The malignant tendency of adenoma—that is, its disposition to eventuate in cancer—is abundantly shown by the observations of Breisky, Schroeder, Winckel, and others.

Dr. Parkes said this latter fact was important to remember in all cases of enlargement of the body of the uterus.

Dr. Dudley believed that the enlargement of the uterus might be from myoma; in that case, the hemorrhage would be relieved by removal of the appendages. But if scrapings from the interior of the uterus show adenoma, be the uterus large or small, the patient may be losing valuable time until the uterus has been removed.

Dr. Parkes thought that pathologists required a full history of a case before making a diagnosis.

Dr. Holmes said that the recognition of typical carcinoma was easy enough; but if a surgeon removed a portion of tissue half the size of a pea, and presented it to a pathologist for examination, it was presumptuous to suppose that the pathologist could examine that minute fragment and decide by it whether the uterus contained carcinoma or not. A proper diagnosis depends as much upon the operator who removes the tissue as upon the pathologist.

DR. DUDLEY believed that the uterus need not be much increased in size to be carcinomatous. In the first of the two cases just reported, the uterus was not very much enlarged, but carcinoma was unmistakable.

DR. J. T. WATKINS presented an inaugural thesis, entitled

CONCENTRATED SOLUTION OF MAGNESIUM SULPHATE AS AN ENEMA, WITH SOME POINTS RELATIVE TO THE PHYSIOLOGY OF THE ABDOMINAL CIRCULATION.

After reviewing the literature, and reporting a number of cases in which the enemata had been used, he summarized its advantages as follows:

1. Its action is local.
2. It seldom fails, and produces copious stools.
3. The time of action is short.
4. The bulk is small, causing but very little, if any, discomfort to the patient.
5. It is as unirritating as a simple enema.

Its certainty of action has become so well recognized in the New York Woman's Hospital that it has been used in nearly all the operative cases, as the cathartic preparatory to operation, for the last six months.

It is best administered with the patient in Sims's position, the hips being elevated by a pillow; and when much tenderness exists, it should be given through a large rubber catheter passed well up into the bowel. The patient is to be instructed to allow the abdominal muscles to remain lax, and, if necessary, the nurse is to keep up pressure over the anus, to cause it to be retained for at least fifteen or twenty minutes. If the bowel should fail to expel the exuded liquid, a rectal tube should be inserted to allow its escape. Two ounces have been retained, without bad results; but Christison reports a case of death in a boy ten years old, where two ounces were taken by the mouth without being followed by purging. Where it is retained, the sphincter ani is likely to be strongly contracted, and great relief will follow forcible dilatation under an anæsthetic, which will also have a good effect upon the chronic constipation usually present.

The following is the formula he uses:

℞.—Magnesii sulph.	2 oz.	
Glycerine	1 "	
Aquæ . . . . q. s. ad	4 "	—M.

The solution is made more readily, and its power of diffusion increased, by the addition of glycerine. He has used three and four ounces of the salt, but does not see that it has any advantages over the smaller amount.

DR. J. H. HOLLISTER presented a paper entitled

NOTES ON ACUTE INVERSION OF THE UTERUS,

in which he said that the uterus, whether gravid or unimpregnated, may become partially or completely inverted as an obvious result of enlargement or *distention* of the organ. This may result either from the development of a fœtus or from the growth of a tumor in utero. In a uterus thus distended, he was convinced that inversion would not occur spontaneously—that is, from simple rhythmical contraction of its own muscular structure. It seemed more probable that *force* must be applied to the fundus to accomplish its inversion. This might occur independently of any manipulation by an attendant, by a simple gravitation of a pendulous tumor or by an adherent placenta, which may be partially discharged into the vagina, and, being adherent, drag a distended fundus after it. A more obvious, and, doubtless, more frequent, cause for such displacement is that of undue traction upon the umbilical cord while, as yet, there has been but partial detachment of the placenta. This last might be associated with undue pressure upon the fundus at its superior portion, applied by the hand upon the abdominal walls

The inversion commences by an infolding of the fundus more and more into the uterine cavity, the advancement of this involution to the cervix, then through the os into the vagina, and, when completed, the organ emerges through the vulva and hangs as a pendulous pyriform tumor.

The striking similarity which occurred in two cases which he had carefully examined, led to the conclusion that when the uterus is thus completely inverted the os is no longer discernible, but that in its place there is an inverted cervix, giving a band-like feeling and easily distended.

While the uterus remains in this state, there seem to be two important conditions present:

The first is the entire loss by the organ of the power of either rhythmical or tonic contraction. The function of sensation seems also arrested, for his patients were unconscious of pain from simple pressure or manipulation of the organ.

The second marked feature in each of his cases was this: after complete inversion, there was almost no hemorrhage from the uterine walls, and it was only after reduction had been nearly accomplished that hemorrhage became troublesome.

He believed it to be an exceedingly rare accident in labor.

The histories of the two cases under his personal observation were as follows:

CASE I.—Mrs. P., American, aged twenty-four years, well formed, spare in figure, in moderately good health, and of active habit; married one year. At her first confinement the patient was in labor ten hours, and gave birth to a healthy, well-formed babe weighing eight and one-half pounds. There was no unusual hemorrhage.

He was confident that he did not exert undue pressure upon the abdominal walls, nor did he detect *partial* involution. With some degree of traction upon the cord, still the placenta was not delivered. Holding the cord with moderate tension in his left hand, the vagina was explored with the right, and the placenta found partially protruding through the os. Gathering this more and more into his hand, and using considerable traction, it gradually descended, until suddenly it protruded in a large mass external to the vulva. In endeavoring to remove the placenta, it was found adherent to a tumor half as large as the infant's head, and pyriform in shape.

A portion of the placenta—apparently as large as the palm of the hand—adhered so firmly to the uterine wall that it required to be picked away, segment by segment, with some degree of force. During this process of separation there was almost *no* hemorrhage, showing that in this condition, by compression, the supply of blood to the uterus had been nearly cut off.

Dr. Shepherd, of Grand Rapids, was then called in, who drew the organ out as far as safety would permit, and by digital manipulation commenced the evolution of this

inverted organ. He was able to accomplish this, to a considerable extent, while the uterus was still external. Next, inserting the end of a round ebony rule an inch in diameter into the indented fundus, and still holding the cervix as securely in his left hand as possible, he gradually accomplished the reduction, and, as the fundus receded in the upward direction, carried it more rapidly upon the point of the instrument fully up to its normal situation. In a few moments the outline of the womb could be detected above the pubes; it again resumed moderately strong rhythmic contractions, and the patient made a good recovery without any untoward symptoms, and was afterward the mother of other children.

Case II.—Mrs. G., American, aged twenty-five years; housewife, moderately spare in habit; married, and first confinement. Dr. Hollister was called by Dr. J. H. Bates, of Chicago, to see this case in consultation, in 1888.

The confinement had been one of moderate severity, but not at all complicated.

Upon lifting the placenta from the vulva, Dr. Bates discovered the projecting pyriform tumor of an inverted uterus.

Involution was effected, as in the preceding case, but the uterus had not recovered its power of contraction, and pretty severe hemorrhage began. Friction over the abdomen failed to induce uterine contraction, and no outline could be discerned through the abdominal walls. In this emergency, a lump of ice twice as large as a hen's egg was wrapped in a handkerchief and carried into the uterus, when almost immediately rhythmical contractions began. Soon they were more and more established. The hand was gradually withdrawn, with the clots and ice, as the uterus closed down upon it. A few minutes later the uterus had accomplished normal involution. Its natural contour and position were evident by palpation above the pubes externally. The hemorrhage had nearly ceased; the hand was withdrawn with the ice nearly melted; the vagina cleansed of coagula: the crisis was passed, and, though the patient had lost considerable blood, she did not seem unduly exhausted, and the heart action was satisfactory.

He had been informed later by Dr. Bates that, though he had enjoined the utmost care as to over-exertion of any kind, when he made his visit on the fourth day after her confinement, at an unexpected hour, she was sitting at table with her family and serving the tea.

Dr Dudley asked if the placenta should be removed before reducing the inversion. The reason he asked the question was because contraction of the uterus while it is inverted is not favorable to replacement, and handling the uterus as much as one would need to, in detaching the placenta, might make it contract, and increase the difficulty of replacement; consequently it has been the practice of many to replace the uterus with the placenta still attached.

Dr. Parkes said that he would certainly expect, with a placenta as large as that body usually is, it would increase the difficulty of returning the uterus with the placenta in position.

Dr. Doering believed that if we use any traction at all on the cord in delivering the placenta, one hand should hold the uterus firmly, so that the slightest inversion could be detected.

Dr. Parkes said that in listening to this paper, and the criticisms that had been made upon it, it would be well to bear in mind the fact that the uterus may become extruded without any asssistance on the part of the physician, and cited such a case that had occurred in his own practice.

CORRESPONDENCE.

THE CAUSES OF CHLOROSIS.

To the Editor of The Medical News,

Sir: In the first part of my paper on the "Relations between Chlorosis, Pernicious Anæmia," etc., published in The Medical News of October 5th, I have somewhat misrepresented the views of Dr. William Hunter, of Cambridge, England. It is almost superfluous to say that this was done through inadvertence, as my admiration for his excellent work is freely expressed in the paper referred to. The misstatement to which I allude is, that Dr. Hunter attributes the defect in hæmogenesis in chlorosis "to a cadaveric poison which destroys the iron contained in the food we eat."

After consulting Dr. Hunter's papers in the *Practitioner* and *Lancet*, I find that he does not attribute the cause of chlorosis to any single hypothetical ptomaine, but to an "excess of decomposition-products in the intestine." Of course, the organic iron of the food—the hämatogen of Bunge—is not actually "destroyed" in chlorosis, but is practically so, for all nutritive purposes.

I make these corrections with pleasure, and do not think they weaken my argument in favor of the cognate characters of chlorosis and pernicious anæmia. According to Hunter, in chlorosis the organic iron of the food is destroyed in the intestinal tract by one or more products of decomposition; and, in pernicious anæmia, the organic iron of the red corpuscles, or these bodies themselves, is destroyed in the portal circulation by one or more products of decomposition. In both cases, products of decomposition are made responsible for the anæmia, thus, it seems to me, bringing chlorosis and pernicious anæmia into a relation more or less intimate.

I am, however, quite open to the conviction that pernicious anæmia is the result of excessive hæmolysis, and not, as I now hold, of defective hæmogenesis, and know of no one so likely to convert me as Dr. William Hunter.

Frederick P. Henry, M.D.

THE RADICAL CURE OF HAY-FEVER.[1]

To the Editor of The Medical News,

Sir: I am pleased to find that my communication on "The Radical Cure of Hay-fever with Chromic Acid" has attracted sufficient attention to raise a suspicion of an apparent weak spot in its argument. Ordinarily, conclusions founded on a single particular are properly regarded as unstable, not on account of inherent logical necessity, but on account of the difficulty of confining consideration to the net question at issue. Especially is this true in medicine, where the complexity of causes and effects is such that generally the only practicable method of reasoning is by the collection of a large number of kindred cases, the rejection of all evident irrelevancies, and

[1] This letter was received in time for the issue of November 9th, but was unavoidably delayed in publication.

the elimination of the non-obvious possibilities of confusion by the application of statistics. The result of all this is an approximate truth. But, given conditions which facilitate observation and eliminate confusing causes, a more accurate conclusion is reached without such circumlocution, and these are the conditions presented by the case in question. A sufferer from hay-fever in a severe form for twenty-two years undergoes, with plenty of hopefulness and patience, every form of medical and surgical treatment recommended by eminent specialists, and receives a modicum of "enduring benefit" disproportionate to the sufferings from the treatment, among which sufferings the pain produced by applications of "carbolic acid to nearly all parts of attainable nasal mucous membrane" was preëminent. The chromic acid treatment, on the other hand, in a few weeks causes the subsidence of the disease, during the period of its ordinarily maximum severity, with little pain and with no assistance from expectant attention. The patient and surroundings being the same, the confusing causes are cancelled, and the change in result stands coupled with the change in treatment by a canon of logic.

I much regret that the spirit of Dr. Robinson's letter should oblige me to disclaim any quest for priority, a motive none the less discreditable to a liberal profession because so common in it. The sole motive for the communication was to induce others to try a treatment which had succeeded on apparently rational grounds in a case where everything else had failed. Furthermore, the method was not vaunted as a panacea for the loosely related group of affections popularly known as hay-fever, but its range of usefulness was marked out with tolerable distinctness. The shade of dogmatism characterizing the article was chosen in order to lead competent observers to test for themselves a treatment which had been singularly successful, and I sincerely trust that I have not given the matter a coloring which will raise a causeless prejudice among specialists, or induce others unfamiliar with the intricacies of the nasal chambers to run risks which are best avoided by employing or carefully watching the patient's sensations. A. H. L.

NEWS ITEMS.

Obituary.—Dr. ISAAC E. TAYLOR died suddenly of pericarditis in New York City on October 30th, in his seventy-eighth year. He was very prominent thirty years ago in carrying out the medical reforms which took place in connection with the administration of several charitable institutions, chiefly Bellevue Hospital and those on Blackwell's Island. He was one of the earlier members of the New York Academy of Medicine and a member of the first Faculty of Medicine in Bellevue Hospital Medical College and Consultant to five general and special hospitals. In 1887 he was President of the New York State Medical Society. Dr. Taylor graduated from the University of Pennsylvania, in 1834.

A Fire during the French Surgical Congress.—During a meeting, held October 7th, in the amphitheatre of the Faculty of Medicine in Paris, a fire broke out which necessitated the immediate adjournment of the meeting. The damage wrought by the fire amounted to nearly $6000, and pictures, hangings, tapestry, and furniture were all considerably damaged.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 5 TO NOVEMBER 11, 1889.

By direction of the Secretary of War, ROBERT M. O'REILLY, *Major and Surgeon*, will, at the expiration of his present leave of absence, proceed to Fort Logan, Colorado, and report in person to the commanding officer of that post for duty.—Par. 6, *S. O. 256, A. G. O.*, November 2, 1889.

MERRILL, JAMES C., *Captain and Assistant Surgeon.*—Is relieved from duty at Frankford Arsenal, Pennsylvania, and ordered to duty at Fort Reno, Indian Territory.—Par. 6, *S. O. 256, A. G. O.*, November 2, 1889.

BLACK, CHARLES S., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Sidney, Nebraska, to take effect upon the expiration of his present leave of absence, and will report in person to the commanding officer Fort Du Chesne, Utah Territory.—Par. 6, *S. O. 256, A. G. O., Washington*, November 2, 1889.

JOHNSON, R. W., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, to take effect on or about November 10th proximo.—Par. 4, *S. O. 40, Department of Arizona, Los Angeles, California*, October 29, 1889.

By direction of the Secretary of War, leave of absence for two months, on account of sickness, with permission to leave the Division of the Missouri, is granted JUNIUS L. POWELL, *Captain and Assistant Surgeon.*—Par. 2, *S. O. 258, A. G. O., Washington*, November 5, 1889.

MACAULAY, C. N. B., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, to take effect about the 29th instant.—Par. 2, *S. O. 166, Department of the Missouri, Fort Leavenworth, Kansas*, November 8. 1889.

IVES, F. J., *First Lieutenant and Assistant Surgeon.*—Is granted two months' leave of absence.—Par. 3, *S. O. 256, A. G. O.*, November 2, 1889.

By direction of the Secretary of War, the following assignments of officers of the Medical Department (recently appointed) are ordered:

CHARLES WILLCOX, *First Lieutenant and Assistant Surgeon.*—Will report to the commanding officer at Fort Columbus, New York, for duty at that station.

HARLAN E. MCVAY, *First Lieutenant and Assistant Surgeon.*—Now at Fort Mackinac, Michigan, will report in person to the commanding officer of that post for duty.

EUCLID B. FRICK, *First Lieutenant and Assistant Surgeon.*—Will proceed from Philadelphia, Penna., to Fort Keogh, Montana, for duty at that station.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING NOVEMBER 9, 1889.

MACKIE, *Surgeon.*—Detached from the U. S. S. "Ossipee," and placed on waiting orders.

PICKERILL, GEORGE MCC., *Assistant Surgeon.*—Detached from the U. S. S. "Ossipee," and placed on waiting orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM OCTOBER 19 TO NOVEMBER 9, 1889.

PURVIANCE, GEORGE, *Surgeon.*—Granted leave of absence for twenty-one days, November 8, 1889.

AUSTIN, H. W., *Surgeon.*—To inspect unserviceable property at St. Louis Marine Hospital, November 4, 1889.

GASSAWAY, J. M., *Surgeon.*—Relieved from duty at New Orleans, La. To rejoin station at Cairo, Ill., October 23, 1889.

BANKS, C. E., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, October 28, 1889.

STONER, J. B., *Assistant Surgeon.*—Ordered to Vineyard Haven, Mass., for temporary duty, November 6, 1889.

CONDICT, A. W., *Assistant Surgeon.*—Ordered to Cairo, Ill., for temporary duty, November 4, 1889.

ton, D. C., for temporary duty, November 8, 1889.

GUITÉRAS, G. M., *Assistant Surgeon.*—Ordered to Washing-

GROENEVELT, J. F., *Assistant Surgeon.*—Ordered to New York, N. Y., for temporary duty, November 5, 1889.

ORIGINAL LECTURES.

CARTWRIGHT LECTURES.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, November 14, 1889.

BY JOHN S. BILLINGS, M.D.,
U. S. ARMY.

LECTURE I.

ON VITAL AND MEDICAL STATISTICS.[1]

I PROPOSE in these lectures to speak of vital and medical statistics, and of some of their relations to each other and to scientific and practical medicine and sanitation. The discussion will include such points as, character of the data required, methods of obtaining them by the census, by registration, and in other ways; relations of physicians to this kind of work, methods of compilation and forms of publication, the best existing sources of such data, and some of the more common fallacies in drawing conclusions from the data as ordinarily published.

These and other points will be considered in their practical applications to certain questions which I hope may be of interest to you, as, for example: Is the average longevity of man in civilized countries increasing? What data are required to judge practically of the relative healthfulness of different localities, or of the same locality at different times? What are the relations of certain forms of disease to race, to climate, to locality, to occupation? What is the relative tendency to increase of population in this country in the white and colored races? What is the statistical evidence with regard to improvement in practical therapeutics as derived from hospital data, from death-rates in obstetric practice, etc.?

Statistics, and discussion of statistical methods, are, as a rule, dry and uninteresting subjects, and it is with very considerable doubt and hesitation that such a topic has been selected for these lectures. I have no new discoveries to announce, and those who are practically familiar with statistical research will find some of my statements rather elementary; but the subject is not one which lies within the ordinary range of medical studies; the data are widely scattered in literature, and I hope at least to be able to remind you of some of the numerous points which you may have once known, but which may have been forgotten owing to the pressure of other studies and duties.

Circumstances have made it necessary for me to endeavor to ascertain the character and amount of the statistical data which have been published, and which are available for those who wish to make special studies of the relative frequency of certain diseases, deformities, or disabilities; of their causes and results, especially as to mortality; or of the relations which exist between disease and death, and such conditions as sex, age, race, soil, climate, occupation, etc., and in the course of this investigation it has seemed to me that many physicians are not as familiar with statistical methods and with existing sources of information relating to vital statistics as it is desirable that they should be to enable them to judge properly the value of the arguments and conclusions presented by those who make use of such data, even though they themselves may have no desire or intention to use statistical methods of research.

There are many fallacies and errors connected with vital and medical statistics as ordinarily collected and used, and it is highly desirable that the physician should be aware of the more important of these, since he is constantly appealed to for decisions as to their true significance and value. "It is as easy to tell lies with figures as with words, and bigger ones;" but while we occasionally meet with deliberate falsifications of the records, made for the purpose of magnifying or diminishing the apparent mortality or prevalence of a particular disease in a given locality, or to maintain an anti-vaccination thesis, these are not so frequent as are the errors of involuntary misstatement and misinterpretation into which those not familiar with methods of collecting and tabulating statistics are so liable to fall.

My experience with those seeking statistical data is, that the majority begin by looking for data which are in favor of some particular conclusion with which they commence, rather than by selecting data with reference to their probable completeness and accuracy, and accepting the conclusions which may be legitimately drawn from them, whatever they may be.

Those who are engaged in the collection and compilation of official mortality and vital statistics are often at first the most sceptical as to their accuracy and utility, for their attention is so frequently and forcibly drawn to errors in the individual data that they conclude that the whole mass is unreliable, and the difficulties in the way of obtaining complete and reliable figures are seen to be so great that they incline to give up the whole matter in despair. Continued study of the subject, however, shows that many valuable conclusions or suggestions can be derived from imperfect data, and that in large masses of figures the errors either tend to neutralize each other, or to produce a constant effect in one direction which can be calculated and allowed for, so that those who have had the greatest experience are most convinced of their value. It is true that, in statistics, the inferences cannot be more accurate than the data on which they are founded, but we do not look for scientific exactness from them so much as for an estimate of probabilities.

[1] Properly speaking, there is no such thing as the science of statistics in the sense in which that term is used by French and German writers, but there is a method of statistical analysis which may be applied in a number of fields of science, and which is essential in the study of sociology.

The methods which we have for advancing our knowledge of the laws of human life, of the causes of abnormity, disease and death in man, and of means of sanitation or therapeutics, may be grouped into two classes, viz.: observation and experiment, which, however, are often combined.

In the experimental method we seek to make a direct test of the variation of one particular condition, or set of conditions, upon the living organism, all other conditions being kept uniform as far as possible. Some such experiments can be made on man, but the greatest number of the problems which we may hope to solve by this method, and among these the most important, can only be approached by experiments on the lower animals. Within the last twenty years, experimental physiology and pathology have made great advances, and these methods, so far as they are applicable, give more definite results, and are more immediately satisfactory, than those derived from comparison of observations in which no definite experimental variations have been made; but so far as regards causes of disease, or the action of supposed methods of prevention, or of remedies, it is unfortunately the case that we cannot draw accurate conclusions as to what will happen in man from what is observed to happen in animals. In the first place, there are many important forms of disease in man which cannot, with our present knowledge, be experimentally produced in animals, and which rarely or never occur in them.

For example: Yellow fever is a disease which, from analogy, we have every reason to believe is due to the action of one or more specific microörganisms, or, perhaps, I should say, to the products of such organisms. We find a dozen different kinds of bacteria in persons suffering from yellow fever, and, by dint of much labor, these have been isolated and cultivated outside the human body. The problem is to determine positively, and with scientific precision, which, if any, of these is the true essential cause of the disease. The mode of doing this is by producing the disease in a perfectly healthy person or animal by the inoculation of the suspected organism. But, thus far, we have failed to find any animal in which a disease, which can be considered as specifically identical with yellow fever, can be produced by any method; and I need hardly tell you that inoculations of such a disease as this in a human subject, under conditions which would make the results of such inoculation scientifically trustworthy, are impracticable and unjustifiable.

Those forms of disease which are common to animals and man, such, for instance, as anthrax, tuberculosis, tetanus, hydrophobia, the ordinary forms of suppuration, and, possibly, also typhoid fever, are being pretty thoroughly worked out by means of such experimental inoculations as I have just referred to; and we are able to say, with a great degree of precision, not only that these diseases are due to specific forms of bacteria, but to determine enough of the characteristics of these forms to be able to identify them wherever they are found.

For the great majority of diseases, however, this experimental method of determining the causes, and, therefore, necessarily, experimental methods of prevention and treatment, cannot be employed in such a way as to isolate distinctly the effect of the particular agent or circumstance which we are investigating, and we must therefore resort to the other mode of advance of knowledge which has been referred to, namely, that of observing the phenomena as they occur in man, and endeavoring so to group the results of these observations as to determine the influence of a particular condition or set of conditions while all other circumstances remain uniform.

This method of observation may, for our purposes, be again divided into two categories. The first is that which is used in individual cases, being the form applied by the physician to each case which he has to treat. It also includes the sort of investigation which may be made in a single household, a small community, or a thinly populated district to determine the course and cause of a particular form of endemic or epidemic disease, where the conditions affecting each family or dwelling can be studied in detail. By the combination and comparison of detailed studies of this kind, the greater part of our present system of diagnosis, prognosis, and therapeutics has been evolved; but it has been and will be a slow process, for each man differs from every other man in structure and mode of function, and the conditions of the environment are so multiform, and so variable in space and time, that "experience is doubtful, and judgment difficult." We must, therefore, try to supplement the information thus obtained by that derived from the second kind of observation above referred to, namely, that of collecting a few data with regard to great numbers of people, especially where these are accumulated in thickly settled localities, forming what is called the statistical method as applied to different communities. By the first method we compare individual with individual, and do so with considerable minuteness of subdivision of the conditions studied; by the second method we compare the vital phenomena of communities with those of other communities, but only on broad lines and in relation to circumstances easily noted.

The object of vital statistics is to classify and arrange the facts relating to the quantity and character of human life under different circumstances, for the purpose of determining the effect upon it of each of these circumstances taken singly, or of two or more of them acting together. The results thus obtained form an important part of the scientific foundations of sociology, of political economy, and of preventive medicine. It deals with masses of men and not with individuals, and its conclusions are, for the most part, applicable only to large bodies of people; yet its data are derived from individual records, and its results are accepted in many cases as a sufficient guide for individual action. They do not, in this respect, differ essentially from most of the motives which actuate us in daily life. The farmer sows his seed, the manufacturer builds his mills, the physician writes his prescriptions, and you come to hear this lecture from motives of probability, not carefully formulated in most cases or capable of expression by a formula, but, nevertheless, in accordance with the doctrine of chances as determined by previous experience.

The term "vital statistics," in the sense in which I use it in these lectures, corresponds almost precisely to the French term "demographie" or the German "demologie," being applied to the circumstance of human life only in the sense of Korosi's definition that it is the science of the physical life of human society. We will first consider briefly the sources of information and the character of the original data available for this study;

second, the methods of arranging and using these data; and, third, the value and applicability of some of the conclusions which may be drawn from them, especially in that branch known as medical statistics.

The essential data of vital statistics are derived from enumerations of the living population and from records of births, marriages, and deaths.

The numbering of the people is effected by a census, a term derived from the Roman Censors, a part of whose duty was to make such counts. Such enumerations were made by Moses (1490 B.C.), David (1017 B.C.), in Greece, 650 B.C., and in Rome beginning 566 B.C. In modern times the first country to make a count was Sweden in 1749. The first census in the United States was taken in 1790 as a necessary means of carrying out the constitutional provision that the basis of representation for the several States should be the number of the population in each. The first census in England was taken in 1801, and showed the number of persons, with distinction of sex, the number of houses, the number of families, and a rough statement of occupations under the general classification of agriculture, trade, manufactures or handicraft, and all others.

The first satisfactory English census, giving distinction of age, sex, occupation and birthplace, the number of persons blind and deaf and dumb, was the census of 1851. This was the first census whose data could be used in connection with the general system of registration of births and deaths.

The first attempts to take a census in a country have usually excited more or less suspicion and opposition, from fear that the information obtained would be in some way used to oppress the people. For example, several attempts to take a census have been made in Hayti, but have always given rise to insurrection, and have always been defeated, owing to the belief of the people that it would in some way lead to their losing their liberty.

In the first censuses the object was to determine the number liable for military service or qualified to vote, or to fix rates of taxation, and the records were very brief. In the first United States census the only data called for on the schedules were, names of heads of families, free white males over sixteen, free white males under sixteen, free white females, all other free persons, and slaves.

The record of age was first made in the English census in 1821, was omitted in 1831, and resumed in 1841. As the census records came to be more and more relied upon as a basis for legislation, additional details were introduced, until at the present time we have such records from some of the principal countries of the world.

The relative importance of each of these details in studies of vital statistics varies greatly according to the purpose to which they are to be applied; but to physicians, sanitarians, and those interested in life insurance, the dominating factors are age, sex, and race. The power of reproduction, the tendency to death, and the liability to certain forms of disease, vary greatly at different ages of the two sexes, and this gives rise to corresponding variations in the disease, and death-rates of populations of different localities, or of the same locality at different times, when those populations differ as to the relative proportion of young and old or of male and female which they contain. These variations we must ascertain if possible, and estimate the influence of, in order to make reliable and useful studies of the effects upon human life of climate, altitude, race, occupation, or other conditions of the environment. In the course of these lectures I shall often have occasion to refer to this dominating influence of age, and to point out errors due to neglect of this factor, which is by no means an easy one to determine for many places at many times. Even the census data require corrections, since people do not give their ages accurately to the enumerators. The tendency is to answer in round numbers, as 20, 30, 40, etc., and to a less but still marked extent, as 25, 35, 45, etc.; but the effect of this can be done away with to a considerable extent by properly grouping the individual data, as I shall explain presently. Ages over 90 are largely overstated, and the ages of women between 25 and 50 are largely understated; but those errors being comparatively constant, and influencing the data of all communities, do not lead to erroneous conclusions of importance in comparing different communities, if the distinction of sex be observed.

One of the most interesting fields of study in vital statistics is the relation of race and color to birth-rate, to certain forms of disease, or to the liability of death at certain ages.

This country is, as you know, the great mixing ground for different races of the human family, and, while the mixture is rapidly becoming so intricate as to make it impossible to distinguish the several strains, it is still true that there are large groups of men of quite distinct races, the record of disease and death in which would form valuable material for study upon this point were it possible to collect them.

From the sociological and political point of view this is particularly the case with regard to the negro and to those having a mixture of negro blood; and in the Southern States such questions as the following are of great practical interest: Is the negro population increasing faster than the white? Is the proportion of mixed bloods, such as mulattoes, quadroons, etc., increasing in proportion to the general population? Are the fertility and expectation of life of mixed bloods greater or less than those of pure whites or pure blacks under the same circumstances of environment? We will return to these questions hereafter; at present I merely refer to them as being the probable reason for the introduction into the law for taking the next census of a special clause providing "that the population schedule shall include an inquiry as to the number of negroes, mulattoes, quadroons, and octoroons," an attempt to obtain information which has not heretofore been sought in this way. In obtaining the records of deaths occurring during the census year beginning June 1, 1889, an effort will be made to have the deaths of colored persons distinguished into those of pure negroes and those of mixed blood. It will probably be impossible to obtain the data for either living population or deaths with the minuteness of subdivision indicated by the words "mulatto," "quadroon," and "octoroon"; but there is reason to hope that in many sections of the country we shall be able to distinguish those of mixed blood from the pure blacks and the pure whites, and to give some opinion with regard to their diseases and death-rates.

The results of the last census, although imperfect, show such marked differences as regards the mortality from certain diseases, not only between the whites and the blacks, but between those of English, Irish, and German descent, as to make it certain that it will be worth while to pursue this branch of inquiry more minutely as opportunity is offered to us hereafter.

The influence of race upon mortality is specially manifest in the death-rates of cancer. The number of deaths from cancer per 100,000 population in certain portions of the United States, with distinction of white and colored, was as follows:

White.	Colored.
27.96	12.67

In the northern part of the United States the proportion of deaths from cancer in proportion to 1000 deaths from known causes, with distinction of white, colored, Irish and German parentage, was as follows:

White.	Colored.	Irish parentage.	German parentage.
19.1	7.8	24.3	25.8

It will be seen from these that the liability to death from cancer is not half as great among the colored people as it is among the whites, and that there is a greater tendency to death from cancer in persons of German parentage than in all the average white population, especially between the ages of fifteen and sixty-five.

The relation of race to vital phenomena in general, and to disease and death-rates in particular, forms one of the most interesting branches of what Galton calls the "science of heredity," but it is a branch in which little progress has been made, and for the study of which the United States offers greater opportunities than any other country. "The question of race influence is not merely an abstract matter fitted only for well-rounded periods in the discussions of the schools, but it profoundly affects vital and national life." It is a force which acts incessantly upon and menaces us, and, so far as we can now see, it is mainly upon the outcome of the distribution and prevalence of race that depend civilization, religion, and the future of man upon the earth. In so far as the conditions of things tend to preserve the best types, progress is favored. In so far as they tend to destroy or to debase them with inferior types, progress is hindered. Not every mixture of race prevails, or persists, but there has been a certain amount of mixture wherever there has been progress in human affairs. Such mixture appears to have been a consequence rather than a cause, yet it may become an important secondary cause in changing or modifying the course of human events.

The census gives us a view of the population on a certain day, and, if well taken and properly applied it gives a general view of the stream of life as it flows on that day, with its variations of breadth and depth, from which it is possible to calculate, within certain limits, the velocity of the current, the rapidity of change, and the probable rate of increase or decrease, especially if comparisons can be made with the results of a previous census taken in the same way. It may also indicate periods of widespread disaster or of migration.

The proportions of the living population in 1880 show that the decrease in the number living at each quinquennial group of ages was tolerably regular for the whole population for the native-born whites and for the colored as we proceed from the lower to the higher ages, as it should be under ordinary circumstances; but that there is one marked exception for the age-group 15 to 20, in which the line makes a sudden angle, indicating a relative deficiency in the number of persons living at this age.

It will be observed also that the age-group in which there is the largest proportion of the foreign-born population is that from 35 to 40.

Comparing these figures with those of the census of 1870, we find that this peculiar deficiency in the age-group, and the maximum proportion for foreign-born occur in those age-groups which precede by ten years the groups in which they occurred in 1880. The break or step in the descending line is in the age-group 5 to 10, instead of that 15 to 20, and the maximum proportion of the foreign-born is in the age-group 25 to 30, instead of that 35 to 40. Now if we go back between five and ten years from the census of 1870, to see what special cause existed in that period for a diminution in the number of births, we find ourselves in the period of our civil war. These breaks or angles, then, are the scars of one of the wounds which the war inflicted. The shifting of the maximum point in the line of the foreign-born population indicates the unusually great immigration of Irish and German families containing young children, which occurred between 1850 and 1860, forming a wave whose crest is still perceptible. It is safe to predict that in the census of 1890 the break or step showing a deficiency in births will be shifted forward to the age-group 25 to 30, and that the maximum proportion of the foreign-born will be in the group 45 to 50.

In general, however, we may say that the census indicates the state of the population at a given period. Vital statistics, however, consider both the state and the movement of the population, and, therefore, for these we must have something more than the census, viz.: a record of the deaths and births occurring in successive periods, from which we can compute mortality and natal rates.

Mortality, or mortality rate, refers to a ratio between the number of deaths occurring and the number of living population furnishing those deaths. It is to be distinguished from a statement of the number of deaths, since to determine the mortality in a given population, we must not only know the number of deaths, but also the population furnishing that number. This may be expressed in the following formula: $M = \frac{D}{P.}$

In the same way natality does not mean the number of births, but it means the ratio of the number of births to the population in which they occur: $N = \frac{B}{P.}$

The relations between mortality and natality are very important, as I shall have occasion to explain hereafter. The value of such statistics depends, of course, on the accuracy of the individual data and the completeness with which these data are gathered for the given locality to which they relate.

Accurate data with regard to deaths can only be obtained by a system of registration of deaths made at the time they occur. Repeated experience has shown that it is utterly impossible to collect, at the end of a year, by any mechanism of enumeration, more than 70 per cent. of the deaths which have occurred during the preceding year; and it is now well recognized that a complete regis-

tration of deaths can only be secured by legislation which forbids a burial until a permit has been granted from a central office, which permit is issued only on the certificate of a physician, setting forth the cause of death and other facts connected with it which are of importance, and which will presently be referred to. In the great majority of cases it is comparatively easy to enforce the law, even in thinly settled rural districts, and the community soon learns to consider any attempt at burial without a permit as a suspicious circumstance, indicating a desire to conceal either the death or the cause of death, and justifying a special investigation by the authorities. When it has been decided to require a burial permit in all cases, it is not usually difficult to require the data for registration as an indispensable preliminary to the issuing of such permit.

Any system which depends upon the returns of undertakers for a record of deaths gives incomplete and unsatisfactory results. It is only where the permit must be obtained before burial, and the certificate must be filed at a central office before the permit is issued, that a complete record of all deaths will be obtained. Any complete system of death registration should include some method of verification of the death and of its cause, which must be certified to by some person having the special knowledge which alone can enable him to give such a certificate.

In the first place, we must have this verification to insure the fact of a death having taken place. In its absence, in a large city, there is little or no difficulty in having recorded the death of a person who may be either alive and well, or non-existent, and the door is thus opened to frauds of various kinds, some of which have actually been attempted and discovered, while others, no doubt, have been successful and remain still unknown. Such verification is also necessary to insure the fact of real as opposed to apparent death in any case, and thus prevent premature burial,

The utility for this latter purpose is, of course, small, for the popular idea as to the frequency of trance or other conditions simulating death, so that the true state of affairs is not detected, is, as you all know, grossly exaggerated. Nevertheless, this consideration may enter as a factor into an argument in favor of such skilled verification.

The main reason, however, for the verification of a death by expert testimony as to its cause is, that it is necessary to establish the fact that a death has taken place from what may be called natural causes as opposed to criminal causes.

This verification of death, and of the causes of death, may be made either by physicians employed for that particular purpose and paid by the State, or by the physician under whose charge the deceased person has been immediately before death, in which latter case only those cases which have not been under the treatment of a physician are referred to a public medical officer, or the coroner, for verification and determination of the cause of death.

The first system is that which is employed in France, Austria, and Belgium. The second is the one made use of in England and in this country.

All registration laws include the certificates of physicians as an essential part of their machinery. Some do this directly, requiring that physicians keep a list of all deaths occurring in their practice, and shall forward this list at stated times to the registrar. This method has invariably proved to be a failure, as has also the similar attempt to require of clergymen that they shall furnish lists of the marriages which they have solemnized. It is utterly impossible to enforce such laws under penalties, and not fifty per cent. of either clergymen or physicians will carry out their requirements under ordinary circumstances.

Where burial permits are required, a physician may be made responsible for a certificate as to those matters only with regard to which his special professional knowledge is necessary, such as the cause of death, duration of sickness, etc.; or he may be required also to certify as to the age, birthplace, parentage, occupation, etc. The great majority of physicians accept without hesitation the data furnished on these points by some member of the family, or whatever appears set down in the form of a certificate brought to them by the undertaker for signature. But there are always physicians who question the propriety of the law, and object to certifying to that of which they can have no personal knowledge, while some few may possibly decline.

The requirements of a registration law impose upon medical men who sign certificates as to causes of death a very considerable responsibility, much more considerable, in fact, than many of them probably realize. The physician is to consider whether his knowledge of the case is sufficient to enable him to determine whether or not the death was due to what are called natural causes, whether there is reason to suspect that violence, poisoning, criminal neglect, etc., may have been more or less factors in the result, and whether any certificate as to the nature of the cause is justifiable. The pressure upon the medical man to certify to more, or, sometimes less than he knows, is occasionally very strong, but the only course in doubtful cases is to indicate clearly what one knows, as distinguished from what he merely believes on the faith of statements made by others. In ordinary matters of daily routine occurrence, in which there is no apparent motive for falsification, we constantly do and must accept the statements of others, the physician acts as the primary judge of the evidence submitted by relations and friends as to the time of death, the age and race of the decedent, the duration of the disease, etc., and is justified in certifying to his belief in this evidence, very much as he is justified in certifying to the date of his own birth.

It has been objected[1] that registration laws may do very well for countries where people have been trained for generations in that line of action, but that they are at war with principles of democratic action and with individual freedom, and that the reason why physicians do not execute the law is because they not only have no personal interest in its execution, but because of a feeling of revolt against the injustice of a law which inflicts a special tax in the shape of time and trouble, and affords no compensation for the extra labor and expense.

These views are not those held by the majority of the medical profession, and it is not probable that the payment of a fee would add much, if anything, to the completeness or accuracy of the registration data furnished

[1] Dr. H. M. Lyman, in the Chicago Medical Journal, 1878, p. 252.

by medical men. Nevertheless, these objections have some weight from a legal standpoint, and should be borne in mind in attempts at legislation. Any attempt to compel a physician, under penalty, to report the age and birthplace of his patients, would, certainly, be worse than useless. The policy is not to call upon medical men to submit the information which should be demanded from the parent or householder. Under the police power of a State, certificates of the cause of death may be required from physicians as being necessary to secure life and protect property, but returns for merely statistical purposes, such as of births, cannot be required of any other than the parent.

There is no good reason why reports of births should be required from medical men. But as regards reports of deaths, it is to the interest of properly qualified members of the medical profession that such certificates should be demanded from them. Whenever and wherever certificates as to the cause of death from physicians are required, there must also be established some system of determining who are physicians within the intent of the law.

At first it may be necessary to accept certificates from anyone and everyone who chooses to call himself or herself a physician; but the character of some of the documents of this kind which will come in, will very soon indicate the necessity for some discrimination. Thus it is that the certification of the causes of death by physicians is the essential foundation, and it is the only essential foundation of legislation with regard to the qualifications which the State has a right to demand from practitioners of medicine.

The registration of marriages, births, and deaths is important to the individual, because it gives him increased security in his rights to property and to life, by enabling him to furnish proof of parentage and legitimacy, by increasing the chance of detection of fraudulent claimants to property of which he is the true heir, and by discouraging criminal attempts to shorten his life, owing to the fact that evidence must be furnished that death was due to natural causes, or a special legal investigation of the circumstances will be made. Of its importance to the community as a means of protection of health and life, and to scientific men and physicians as a means of investigation of some of their problems I need give no proof to this audience.

We can hardly be said to have a complete system of registration of births in any State or city in this country. Probably, the city of Providence, R. I., has the most complete records of this kind of any of our cities. As regards the registration of deaths, Massachusetts, New Jersey, the greater part of Connecticut and New York, a large part of Alabama and Minnesota, and most of our large cities, have now a fairly satisfactory system and complete record. For the rest of the United States, there is either no system of registration, or, if any exists, it is a very imperfect and incomplete one, the results of which cannot be depended upon, and which cannot be compared with the results obtained in the localities above referred to as having a complete system, and the only means which we have of estimating the mortality of these localities is by the reports of deaths for the preceding year collected by the census enumerators.

It is for this reason that the decennial United States Census is a matter of such great importance to scientific medicine and to practical sanitation—of much greater importance, in fact, than most physicians and health officials seem fully to appreciate. It is true that the death records thus obtained in the large areas of the country in which there is no registration are incomplete, and, as regards causes of death, especially inaccurate; but they are the best we have; they are becoming better at each census, and the death records in the registration areas serve to measure their reliability, and to indicate to some extent useful corrections.

As the value of statistics of deaths depends very largely upon the possibility of comparing them with corresponding statistics of the living population furnishing those deaths, it is evident that the modes and times of obtaining and of publishing the results of the census are matters of great importance to medical and sanitary statisticians. This is especially true as to the frequency with which a census is taken, the units of area made use of in its published tables, and the combinations of age, sex, race, and occupation data given in connection with such units of area.

Let us first consider briefly the time of taking the census.

The conclusions of the various statistical congresses with regard to the methods of the census are summed up by Korosi in his project for a census of the world, published in 1881.

The first of these conclusions was that the census should be taken every ten years in the month of December, and in those years the number of which terminates with zero; recommending, however, that intermediary censuses should be taken at the discretion of different governments.

The taking of the census at the end of December has the advantage that a relatively greater number of population are in their own homes than at any other time, and that it corresponds to the termination of the calendar year, at which date many State and municipal reports terminate, so that all the figures being for one date are readily comparable with each other. For a very large part of this country it would be quite as easy to take the census at the end of December as on the first of June; but there are some sections in which attempts to take the census in the midst of cold and rainy weather, for a thinly scattered population, would be made under very great difficulties.

In a paper read at the British Health Congress in May, 1889, Sir Edwin Chadwick urges the desirability of an annual census for the improvement of public administration, referring to the fact that "in commerce and in manufactures, as in every large company, there is an annual stock-taking, and upon that stock-taking a report and declaration of the results are made to the stockholders. But what is the state of the political administration which has only attained to a stock-taking of the living people, of the healthy and the weakly, on whom the power and prosperity of the country depend, which is only attempted every ten years, and is only completed in three years, leaving the numbers, meanwhile, to be got at by estimates, necessarily erroneous—often widely erroneous. An annual census of the more numerous animal stock has been lately striven for and attained, and is worked out by the Agricultural Department of the Board of Trade. It is some forty-five millions of the agricultural stock, whilst the population of England and Wales is about twenty-eight millions. Other nations, as France

and the United States, have halved the inconvenience of the stock-taking of the human population."

Sir Edwin is in error in this last statement, for the United States Census is taken but once in ten years, and but a few States have thus far taken the intermediate census, which would make the enumeration come at quinquennial periods.

In the law providing for the last census an attempt was made to induce the States to take this intermediate census, by an offer that the United States should pay one-half of the amount paid to all supervisors and actual enumerators in the State, increased by one-half of the percentage of gain in population in the State, provided that the schedules used should be similar to those used in the census of the United States, and that a full copy of all schedules returned, and reports made, shall be deposited with the Secretary of the Interior on or before the first of September following.

This proviso, however, has not had the effect designed, probably for the reasons set forth in the report on the census of Michigan for 1884, namely, that at least two months are required to make the enumeration, transmit the blanks to the Secretary of State, and arrange them, which leaves but one month (August) for correction of errors and for making the full copy of the schedules. As applied to the State of Michigan, this would require a thousand or twelve hundred clerks for twenty-five days. The amounts paid the supervisors and enumerators for the United States Census of 1880 were $71,192.06, the one-half of which, increased by one-half percentage of gain, gives $42,401.99 as the amount Michigan would have received from the general government if its census had been taken in conformity with the national census law. But it would have cost from $60,000 to $70,000 to copy the schedules and reports, or from $18,000 to $20,000 more than the amount that would have been received from the national treasury to compensate for the work. A few sets of territorial schedules were sent in, but nothing was done with them.

Sir Edwin, however, urges that even the quinquennial census would be considered insufficient for business purposes in the ordinary affairs of civil life, and refers to the fact that the proposition for an annual census in the European governments was discussed at the International Statistical Congress at the Hague, having been proposed by himself and strongly seconded by Prof. Engel, the head of the Statistical Bureau of Prussia. The matter was appointed to be the subject of discussion at a future Congress; but, in the meantime, the meetings of the Congress were interrupted and the matter has never again come up as a subject for international discussion.

Annual censuses have been tried and abandoned in Canada. Triennial censuses have also been tried, but the general conclusion seems to be in favor of five year periods.

In Austria, Belgium, the greater part of the British Empire, Denmark, Holland, Hungary, Italy, Norway, Sweden, Switzerland, and the United States, the census is decennial.

In the Sandwich Islands a census has been taken every six years since 1853.

In France a census was taken in 1801, 1806, and every five years since 1821.

In Sweden, every five years from 1775 to 1860.

In Germany, every five years since 1866.

In Finland, every five years since 1875.

In Sweden, every three years from 1749 to 1775.

In Baden, every three years from 1818 to 1867.

In Hanover, every three years from 1830 to 1864.

In Prussia, every three years from 1834 to 1867.

In Saxony, every three years from 1834 to 1867.

In Bavaria, every three years from 1834 to 1867.

While in Upper Canada (now the Province of Ontario) a census was taken annually for nineteen years, from 1824 to 1842.

In New Zealand nine censuses have been taken since that of 1861, at intervals of from three to seven years, the last interval being five years.

In Queensland there is also a quinquennial census.

While it is not probable that any agreement for an annual census for the whole country will be made in the near future, either by the United States or by State Governments, it is certainly quite possible that the desirability for more frequent enumerations in the larger towns and cities will soon become so evident as to lead to systematic arrangements for carrying it out. Even now, many cities take what they call a police census, at irregular intervals of from three to five years, for the purpose, mainly, of making rough subdivisions of the voting populations in the form of precincts, and of obtaining information for the purpose of levying taxes, more especially for school purposes. These police censuses, however, relate only to adult males, and upon them are based estimates of the number of the remaining population, which are used by the sanitary officials in computing death-rates. These estimates, however, are almost invariably too high, as is shown by the next State or national census, and, in any case, afford no satisfactory basis for computation as to the number of inhabitants in the different wards of the city, owing to the great variations in the ratio between the voting population and the rest of the people in different classes of society and in different parts of a town.

By the use of proper schedules, somewhat on the English system, left at each house, there should be very little extra expense over that of the ordinary police census in collecting sufficient data with relation to the entire population of a city, to give accurate data with regard to the vital statistics of the population, and these, combined with a good system of registration of deaths and of marriages, would give the means for a system of vital statistics of a place such as, at present, no city in England or in this country possesses.

The unit of area made use of in furnishing the census data is a very important matter in connection with the statistics of deaths, for, practically, these last must be classified by the same areas. The census units of area have usually been fixed by political considerations with reference to votes, to taxation of various kinds, and to military service. In this country, the smaller unit is usually the county or city, or, in some cases, the wards of a city, the larger units being the State or Territory.

For the purposes of vital and medical statistics, such units of area are often of little or no importance, because the boundaries of wards, of cities, of counties, and of States are not fixed with reference to the peculiarities of topography, drainage, character of habitations, or of the people, which are important factors in the causation of disease and death, and which, therefore, require study, with the object of properly dividing the population for purposes of representative government. Moreover,

in the publications of the several censuses prior to that of 1880, the population of the smaller areas, such as cities and counties, was, as a rule, given with distinction of sex and of color only, while the most important factor in vital and medical statistics, namely, age, was stated in detail for States only. In the census of 1880 an important advance was made in this respect, for in connection with the mortality statistics the population of each county having 10,000 inhabitants and upward, and of the large cities, was given with distinction of age under one year and under five years for each sex of each color.

In the next census the population by counties will be given with still further distinctions of age; it will be given with distinction of age under one year and under five years for wards, and in about a dozen of the largest cities it is proposed to select certain areas which present peculiarities as to topographical features, or as to the character of the people inhabiting them, and to give the population of these by age, sex, and color, as a basis for the study of the death-rates of these localities. In a large city like New York, even the ward is usually too large to be a satisfactory unit of area for statistical study, since one ward will contain some of the best and some of the worst habitations, and include classes of people having very different means, habits, and death-rates.

In the annual report of the city of Brussels the population, births, and deaths are given by streets, courts, and alleys. This does very well for Brussels, where the streets are short; but in our large cities, regularly laid out in rectangles, where the streets are miles in length, and traverse localities differing widely in topography and in character of population, it does not seem to be applicable.

The data required on individual certificates of death should correspond to those required on the schedules of living population, and, in addition, should give the cause of death.

The death-rate, or mortality, is the ratio between quantity of life and loss of life. It refers to a definite unit of time, viz., one year's life of one person, and the quantity of life is the sum of the time lived by each of the population expressed in years. Two persons living six months each, or twelve persons living one month each, have one year of life. If the population is assumed to be stationary, that is, one in which the births and deaths and the emigration and immigration are exactly equal to each other, and similarly distributed throughout the year, then the number of the population multiplied into the time under consideration, expressed in years and fractions of years, gives the quantity of life.

A population usually, however, increases in geometrical progression, and in such case we must find, by means of a well known formula, the mean population of the period, which will be less than the arithmetical mean of the populations at the beginning and end of the period, and greater than the population living in the middle of the period; but the differences are small, and, in most cases, either figure may be employed.

For example, suppose we wish to calculate the death-rate of New York City for the year 1888. By the censuses of 1870 and 1880, we know the population on June 1st in each of those years. From these we determine the ratio of increase, and thence the population on January 1 and December 31, 1888, from which the mean population can be computed, or the arithmetical mean be taken. Or we can compute directly the population on July 1, 1888, and it makes little difference as to probable accuracy which of these three estimates of population we take.

You will perceive that this method rests on the assumption that the ratio of increase of a locality during ten years as determined by the census, continues unchanged and uniform thereafter. This is hardly ever true, and, for many localities in the United States, and especially in the rapidly growing West, it is very far from the truth, which is a strong argument for more frequent counts.

Various methods are used by statisticians to correct the estimates of population made for a city at periods other than during a census year, as determined by a formula of arithmetical or geometrical proportion, among which may be mentioned the use of the ratios supposed to exist between the number of houses or the number of voters, or the number of school children and the total population. The number of houses is determined from tax records or by a special count; the number of voters by registration lists or by a police census; the number of school children by a special census; and the ratio which these bear to the whole population is guessed at, or is calculated from the data obtained at the last census.

The most useful and reliable of these methods is the use of the average numbers of presumed occupants of inhabited houses, the other ratios being of very little value.

This has been very well shown by Dr. Russell, Medical Officer of Health at Glasgow.[1] In the case of Glasgow, he considers the estimate of the population based on the number of inhabited houses and the estimate based on preceding censuses, and finds that both methods give a population above the actually existing one as shown by the next census. The error in the estimates based on the previous census was due to a change in rate of growth. The error in that based on the number of houses was due partly to incorrect data of the number of inhabited houses, and partly to an error in calculation.

In the United States Census of 1870 the number of persons in a dwelling in the large cities varied from 14.07 in New York to 5.20 in Toledo, these differences being due, to a considerable extent, to the counting of large tenement houses containing numerous families as a single dwelling.

If we take the data by families, we find in the same census that the largest number of persons to a family was in Kansas City, the number being 5.78, while in New York it was but 5.07.

In 1880 the proportion of persons to a dwelling ranged from 16.37 in New York to 4.68 in Memphis. In Baltimore it was 6.54; in Boston 8.26; in Philadelphia 5.79. The number of persons to a family was: in Baltimore 5.8; in Memphis 4.23; in New York 4.96; in Philadelphia 5.13.

It is evident that no value can be placed on estimates of population of a city based upon the number of habitations it contains, if a cottage and a tenement house are to be equally reckoned as a habitation.

Estimates of the population based on police censuses, on the number of school children, or on city directories,

[1] The Decennial Census as a Basis for Statistics in Intervening Years. Glasgow, 1881.

are of very little use, being, in almost every case, in excess of the truth. No general rules can be laid down for the estimation of the population of a city at a period between two censuses. It is a special problem in each case, for the solution of which there are needed an acquaintance with the locality, to be sure that boundaries have not changed, the information which can be obtained from special local censuses, from the number of inhabited buildings, from migration statistics, etc., all of which must be applied to the data furnished by the last general enumeration of the people, which, in any case, must be resorted to for the ratios which are to be used.

It is to be observed that municipal statisticians and registrars rarely make use of the means afforded by a general census to correct the figures of population; and, therefore, rarely alter death-rates which they have given for the years intervening since the last census; yet it is highly desirable that this should be done in order to prevent the use of misleading figures. For example, in Chicago, in 1873, the registrar estimated the population of the city at 400,000, and deducted therefrom the death-rate for the year as 23.89. Comparing the populations in 1870 and in 1880, it is apparent that the true population was about 350,000, giving a death-rate of over 27.

In Boston, in 1876, the estimated population at the time was 352,758, giving a death-rate of 23.39, while the true population, as shown by comparison of census data, was about 313,000, giving a death-rate of over 26.

The shorter the period for which a death-rate is given the greater is the liability to error. The ordinary forms of weekly death-rates reported for large cities are annual death-rates—that is, they represent what would be the annual death-rate if the proportion of deaths to the population for the week continued for one year. If, for example, a town having a population of 100,000 reports as its weekly death-rate for a given week 25 per 1000, this does not mean that during the week there occurred 2500 deaths, but it means that if the population and number of deaths each week continued the same during the year, 2500 deaths would have occurred in the course of the year, or that for the week in question the number of deaths was 2000 divided by 52.17747. A weekly death-rate is useful to show where the greatest variations have been in the year's mortality, but it is no indication of the health of a town for a particular week, and it is useless as a means of comparison of the healthfulness of one town with that of another. This is largely due to the law of probable deviation or error in mortality statistics in relation to the number of instances used as data without reference to their accuracy. This law of probable error in relation to number of data is an exceedingly important one to be kept in view in all statistical inquiries, and especially in those relating to vital and medical statistics.

For example, suppose that in a village of 1000 inhabitants there occur 25 deaths in the course of a year, and in a neighboring city of 10,000 inhabitants there were 200 deaths in the same time. What is the probability that the death-rate of 25 per 1000 for the first and 20 per 1000 for the second, indicate the relative healthfulness of the two places, supposing the data to be perfectly accurate, and that we have no other information in regard to them than that stated?

Or suppose that during one year, in a population of 100,000 persons there occur 2000 deaths, what is the probability that in a second group of 100,000 persons under the same circumstances, the number of deaths in a year will not be less than 1950 nor more than 2050?

The answers to such questions as these are furnished by formulæ derived from the mathematical laws of probability. The simplest of all these formulæ, and the one most practically useful for rough and ready calculations in cases such as that given in the first example, is, that the mean or probable error is equal to the square root of the number dead. By this rule the probable error for the village of 1000 inhabitants for 25 deaths would be 5, and, therefore, the mortality in this place might vary between 20 and 30 per thousand, without any certain indications of variation in the sanitary conditions of the place. In the city of 10,000 inhabitants with 200 deaths, the probable error is a little less than 15, the variation between 185 and 215 corresponding to an average mortality of 18.5 to 21.5 per thousand, being a probable variation of only 3 per thousand instead of 10, as in the first case. It is very clear, then, that in comparing these two mortality rates, no positive conclusion can be drawn as to the relative healthfulness of the two cities, seeing that the probable variations overlap, as it were, for the rates ranging from 20 to 21.5.

The formula that the probable variation in the number of deaths is the square root of that number gives results that are somewhat too great, being merely an approximation to the true formula, which is of much more general application, but requiring too much computation for general use. I shall refer to this matter of the law of error in more detail in speaking of medical statistics. For the present, I only call your attention to the fact that it is necessary to bear in mind the absolute numbers as well as the percentages, and that, therefore, statements of ratios only are insufficient for definite conclusions.

What is a fair or normal death-rate? Taking an average healthy rural district in the United States where there is little migration the annual gross death-rate for the whole population will be from 13 to 15 per 1000. In towns of from 10,000 to 15,000 inhabitants, having a good general water supply and proper sewerage, the gross death-rate should not exceed 16 per 1000. In cities of from 20,000 to 100,000 inhabitants it should not exceed 17 per 1000, while in cities of over 100,000 inhabitants it should not exceed 19 per 1000. The great causes of high death-rates are poverty, overcrowding, intemperance, excess in heat and cold with moisture, foul air, bad food, impure water, uncleanness, contagion, ignorance, etc.

The statistics of births are of much importance in vital statistics because of the influence of the birth-rate upon the sex and age distribution of the population. Unfortunately, in this country, as I have already explained, hardly any locality possesses such an enforced system of registration of births as to permit of an annual calculation of birth-rates and their comparison with the deaths of children under one year of age, or those born within the year. We can only obtain this data for any large extent of country by referring to the census records.

The usual method of indicating the birth-rate is by giving it as the proportion per 1000 of births to the population of all ages; but a much better and more satis-

factory mode of computation is to calculate the number of births to the number of women between the ages of 15 and 50 or 55, living in the community referred to.

The general subject of birth-rates is interesting chiefly, in relation to social statistics, to the fecundity or rate of increase of population or of people of different races; but in relation to mortality statistics it may also become an important factor in the calculations.

There has been from time to time some controversy between statisticians and health officers with regard to the influence of birth-rates upon death-rates, or as to the precise relations which exist between the two. As the death-rates of infants are much greater than those of the population at higher ages, it has been claimed by some that where there is a high birth-rate there is also a high death-rate; but it cannot be said that this will invariably be the case, or that the one is directly the cause of the other, except in certain cases for a comparatively short series of years.

Starting with a population, if possible, numbering in all 308,378, supposing that there are no migrations, and taking the death-rates for each group of ages to be shown by the New York life table, we have calculated the progress of such a population for 100 successive years under two suppositions, the first for a constant birth-rate of 35 per 1000, and the second for a constant birth-rate of 45 per 1000. The death-rate at the commencement was 32.42 per 1000. Under the influence of a constant birth-rate of 35 per 1000 this death-rate increases during the first period of five years to 33.17, and after that steadily sinks until at the end of fifty-five years it becomes less than the original death-rate, and at the period of sixty-five years has sunk below it, after which it again rises until at the end of 100 years it has reached the rate of 32.44.

Taking now the same population under the same circumstances at a constant birth-rate of 45 per 1000, we see that the death-rate rises in the first five years to 36, after which it steadily sinks as it did in the former case, until after the lapse of sixty years it is only 32.01, after which it again rises, and, finally, comes down to a point a little below that from which it started. In both these cases, then, it is evident that the high birth-rate for a time produces an increased death-rate, since there are no other circumstances present to account for the change. But after the first five years the proportion of those living at the ages at which there is the lowest mortality has been so much raised as more than to counterbalance the large number living in the first years of life, and, therefore, the death-rate steadily descends.

But to understand the full effect of this change it is also necessary to consider the average age at death. Here it will be found that the average age at death at the commencement being 31.37, decreases to 29.65 under the influence of a constant birth-rate of 35 per 1000, while, with the higher birth-rate of 45 per 1000, it diminishes as the death-rate diminishes to the age of sixty-five, at which period it is only 23.02, after which it again rises as the death-rate increases.

Comparing with this the proportions of the population living at each group of ages at the beginning and end of the 100 years under each of these two different birth-rates, it is found that under the influence of the higher birth-rate the proportion of the population under twenty-five remains high, while after that age it falls below the original figures.

As a rule, high birth-rates occur in cities and in the crowded parts of cities, among the laboring classes of the population where the causes of disease and death in infants are especially prevalent.

On the other hand, it is to be noted that a high death-rate among infants has some tendency to increase the birth-rate, because the interval between childbearing is shortened by the early death of the infant; and in the effort made by poor women to avoid frequent childbearing, a common means is to suckle the infant up to at least two years of age, in order to prolong the interval between pregnancies, which is a practice injurious both to the mother and to the child.

If we had under consideration a community in which there were no migrations, and in which the population neither increased nor diminished, the relations between birth-rate and death-rate and the average duration of life could be expressed by a simple formula in such a way that, given either two of these quantities, we could determine the third. If, for example, in a population of 1000 persons five births and five deaths occur annually, and if we assume that every individual lives to the same mean age, evidently just 200 years would elapse before the whole of the original 1000 would have died. This 200 years would be the mean duration of life; and this would be the case also if deaths occurred at different ages; only in such a case many would die below the mean age, when some would greatly exceed it. This subject has been considered by Dr. J. S. Bristowe,[1] who says that "there can be no difference in the healthiness of two localities, in one of which the death-rate is twice as high as that of the other, provided other conditions are such that in both cases the inhabitants attain the same mean age; or, conversely, supposing different populations to enjoy the same mean duration of life, any differences which may be presented by their respective death-rates are due to other circumstances than differences of health." He also says that the average duration of life can be determined by the birth-rate and death-rate taken together, but not from the death-rate alone. If he means by healthiness, mean duration of life, this statement is equivalent to saying that where the mean duration of life is the same it will be alike, an indisputable proposition, though not a very instructive one. But if by healthiness is meant the sum of the conditions of the locality as to altitude, drainage, cleanliness, etc., which tend to lessen or increase deaths in the people living in it, then the statement is incorrect, for it does not take into account age, sex, or race distribution, occupations or migrations. Setting the question of migrations entirely aside, it is perfectly possible that two populations attaining the same mean age, and having the same death-rate, may live in two localities, one of which is decidedly healthier than the other, so that if the two communities exchanged habitations, a marked difference in the death-rates and mean age at death would result.

Putting aside all these purely speculative considerations with regard to what might happen in a stationary population, where there is no migration, let us see what the significance of death-rates is in our cities and rural

1 "On the Mutual Relations of the Birth-rate and Death-rate." St. Thomas's Hospital Reports, New Series, vol. vii. p. 245, London, 1876.

districts as they now exist. We wish to know how much of the death-rate is due to peculiarities in the character and occupation of the population itself, and how much to peculiarities in the locality, and for each of these classes we wish to know how much is necessary and unavoidable, and how much is due to causes which may be modified or done away with. Precise knowledge on these points we can never have, but we can obtain a sufficient degree of probability to guide our action in the premises.

If we wish to study carefully the influence exerted upon health and life by race characteristics, by residence in a given locality, by marriage, occupation, social standing, etc., we must have the means of comparing results given in different localities, or in the same locality at different times, or for different races, occupations, etc., under like circumstances.

To accomplish this we must, as far as possible, estimate the influence of other circumstances not connected with the particular point which we are investigating, but which, notwithstanding, exercise a powerful influence upon sickness and death-rates, and of these, the two most important influences are those which differences in proportion of sexes and ages of the population to be compared exert.

The means recognized as best calculated to eliminate the influence of sex and age by, as it were, reducing the population to one uniform scale in these respects, is by calculating the expectation of life at each age for all the several conditions of locality, occupation, etc., which we wish to investigate; in other words, by the preparation of what are known as life tables. A life table shows what would be the tendency, or liability, to death at each age in a population in which there is no migration, and in which the births and deaths just equal each other, if such a population were subjected to the same influences tending to produce disease and death as have affected the actual population under consideration, and from which the data are derived. It is, of course, impossible to prepare life tables which shall be strictly accurate and exactly comparable one with another, because it is impossible to obtain strictly accurate data. A life table is intended to answer the question, "Of a million children born, how many of each sex die at each age?" or "What is the time which a man or woman of a given age may be expected to live?" A strictly accurate answer to this question could be given only if we knew the precise dates of birth and death of each of a million of children born under the circumstances we are investigating; and, strictly speaking, this million of children should all be born on the same day. Notwithstanding, by using large masses of data which are more or less attainable, and by applying certain well-known corrections, the individual errors tend to neutralize each other, and we can prepare tables which will be quite accurate enough for purposes of comparison.

A vast amount of labor has been expended upon, and study given to this subject; for immense business interests and important points in the jurisprudence of inheritance depend upon the existence and accuracy of these tables. Hundreds of millions of dollars have been, and now are, invested in life insurance on the faith that certain life tables truly represent the average course and duration of the life of a particular class of the community —and the result of more than a hundred years of experience has been applied to their correction under the powerful stimulus of urgent need, from a pecuniary point of view, to have them as accurate and reliable as possible.

Probably the earliest form of such a table known is that given in the Pandects of Justinian by Domitius Ulpianus, commonly known as Ulpian, a distinguished lawyer, who was the secretary of Alexander Severus, and who wrote in the beginning of the third century of the Christian era. This table is found in an extract from his writings given in the Pandects in a treatise by Æmilius Macer. Ulpian states that in Rome registers of Roman citizens, including the data of age, sex, and death, were kept by the city from the time of Servius Tullius to that of Justinian, including a period of 1000 years. From these data, which applied to the more prosperous class, Ulpian gives a scale for estimating the purchase value of communities according to the different value of life at different ages, and sums it up in saying that it is usual to compute thirty years maintenance for all those under thirty years of age, and that for all over that age as many years are allowed as they lack of sixty.

In connection with the question of annuities, Ulpian gives a scale for estimating them, which is apparently the probable length of life of persons of the ages named.

The first life-table of modern times was constructed in 1692 by Dr. Halley from the registers of the city of Breslau for five years, and was printed in the *Philosophical Transactions* in 1693. The data for this and for other similar tables constructed in the 18th century were too imperfect to permit of good results, and the first life-table which was selected as of sufficient accuracy for business purposes is what is known as the Carlisle life-table, compiled by Mr. Milne in the early part of the present century.

We now have a considerable number of life-tables applicable to the special classes of those who are likely to insure their lives, derived from the experience of a large number of insurance companies in Europe and in this country; and also a number of life-tables derived from the data of the whole miscellaneous population of the country for England, France, Germany, Sweden, and for certain parts of this country.

In order to prepare a life-table for a given locality or occupation we must know the number of persons living at each year of age, and the number of deaths at each age which have occurred among these persons for one or more years. We assume that deaths have occurred at regular intervals during the year for each age, and proceed to compute the number of persons at each age who were living in the middle of the period for which the deaths are registered.

In using census data, however, we cannot directly compare the deaths at each single year of age with the number reported by the census as living at that age, because of the strong tendency of the average man or woman to report ages either of the living or the dead, but especially the former, in numbers which are multiples of ten or five, or in so-called round numbers.

An examination of the census of Massachusetts and New Jersey for 1880 will show that the death-rates calculated from it would indicate that the mortality at 25, 30 and 40 is much less than at the ages immediately preceding and following them. Thus, it would appear that in Massachusetts the mortality of white males at the age of 50 is only 9.42 per 1000, while at the age of 49 it is

16.11, and at the age of 51 it is 19.16 per 1000. There is, however, no such abrupt change in the law of mortality at the age of 50 as these figures would indicate, and it is necessary, therefore, to make corrections for this source of error. It is true that the error in the number of deaths reported at the even decades is usually in the same direction as the error in the number of the living population, and therefore tends to neutralize the error in the computation of ratios; but this is not always the case, and the error is almost invariably in the direction of making the mortality at the even decades too low, and for the adjacent years too high.

The error in question may be corrected in distributing the excess reported at the even decades to the adjacent years, by aid of the calculus; but the easier and usual way is to calculate the mortality rates by groups of ages, including five or ten years in each group—that is, for the periods 20–24, 25–30, 30–34, etc., or for the periods 20–29, 30–39, etc., or for the periods 25–34, 35–44, etc. Of the three modes of grouping, the last is the best, because it properly distributes the excess about the even decades, which is the greatest.

If we take the group of ages 20–29, 30–39, etc., the whole excess for the year 30 is distributed in the succeeding years, whereas a part of it really belongs to the years in the preceding group. This objection applies to a much less degree to the grouping of 35–44, 45-54, etc., for the excess at 45 is much less than at either 30 or 40; still it is well to remember that approximate life tables, calculated as I shall indicate, give for this reason somewhat less than the true mortality, and somewhat too high an expectation of life for adult ages.

This source of error affects all mortality statistics derived from the results of a national census, and from the ordinary system of registration, but it does not affect mortality statistics derived from the records of life insurance companies, in which it may be presumed that the ages of both the living and decedents are accurately stated.

I do not propose to describe the methods of constructing a life table. To make one sufficiently accurate to be used for the purposes of life insurance requires elaborate calculations and corrections, and the use of complicated mathematical formulæ; but the construction of an approximate life table in which no attempt is made to secure regular gradation is a comparatively easy matter, and has been fully described by Mr. N. H. Humphreys in a paper in the *Journal of the Statistical Society* for 1883, which method was made use of in calculating the approximate tables given in the mortality statistics of the last census.

ORIGINAL ARTICLES.

PURULENT PERITONITIS, WITH PERFORATION OF THE APPENDIX VERMIFORMIS.[1]

BY ARTHUR V. MEIGS, M.D.,
PHYSICIAN TO THE PENNSYLVANIA AND TO THE CHILDREN'S HOSPITALS.

THERE was admitted to the Pennsylvania Hospital October 19, 1889, a woman, who gave the following history: She was twenty-three years of age, single, and was born in England. She had been three months in America, and six weeks ago had a miscarriage in the Preston Retreat. She got up and went to work too soon, she thought. Three days before her admission, after having been exposed to cold, she was taken ill. Upon admission the pulse was small and rapid (146 per minute) and her temperature 101⅘°; there was severe abdominal pain, the belly was swollen and tympanitic, and induration was present in the right iliac fossa over the region of the cæcum. There was frequent vomiting, and she said she had had diarrhœa, though while in the hospital she had but one movement. She also declared that she was passing flatus freely, and even in great amount. It was easy to make a diagnosis of peritonitis, and it was thought likely that its origin had been in the reproductive organs, in view of the fact that there had been a miscarriage so recently. As there seemed to be no obstruction of the bowel, operative interference was thought, for the time at least, entirely uncalled for. She was ordered liquid diet and one-quarter grain of opium and one-twelfth grain of extract of belladonna every two hours. Fifteen hours after her admission she died in collapse.

At the autopsy, made twenty-four hours after death, the following was found: Upon opening the abdominal cavity a large quantity of offensive yellowish pus containing flakes gushed out. The quantity was estimated at two pints. The tissues and organs were everywhere glued together by fresh yellowish lymph, the adhesions being quite firm though not difficult to tear. The under surface of the liver was adherent to the stomach, the stomach to the colon, the colon to the small intestine, the various turns of the small intestine were matted together, and all was covered by the omentum, which was everywhere more or less adherent. The appendix vermiformis was as large as the little finger, being much dilated, and was fixed quite firmly by fresh adhesions, which were easily separated, to the inner surface of the *os ilium*, and near its proximal end contained a mass of inspissated material about half an inch in length by one-third in diameter, and pointed at one end; it had the shape of an ordinary conical rifle ball. Between the position where the concretion lay and the outlet of the appendix into the cæcum was a perforation about a quarter of an inch in diameter and circular in form. The inner surface of the intestines was here and there much injected, and in some areas looked as if there had been actual inflammation of the mucous coat, which was intensely red and thickened at such positions. The uterus was slightly increased in size, and its suspensory ligaments were opaque and thickened. The liver presented upon its surface several broad yellowish areas, and upon section it was found that the same yellow discoloration penetrated into the substance to the depth of about one-quarter of an inch. The other organs presented no noticeable abnormal conditions.

It is sad to contemplate the shortcomings of the application of the science of medicine in this case, for certainly the disease was one which might have

[1] Read before the Philadelphia County Medical Society, Nov. 13, 1889.

been cured if it could have been recognized in its early stage, and surgical operation undertaken before it had produced results incompatible with life. It is of little avail, however, and would ill become us as physicians to sit down and moan over the imperfections of our art; rather must we hurry on to improve our means of dealing with such conditions, and of all the directions in which we may turn our efforts for improvement, there is none which calls so loudly for study as diagnosis. The most serious difficulty that besets us in our management of these cases of peritonitis is the uncertainty of diagnosis, and whether surgeons or physicians we must alike struggle to increase the degree of precision with which we may diagnosticate such conditions. I say this with full knowledge of the great difficulties that are to be encountered from the standpoint of treatment and of the somewhat radical differences of opinion that exist in regard to treatment in some particulars, for, unless a diagnosis can be made, treatment has almost no existence, and certainly is of little avail.

In considering my case, as may now be done in retrospect, I am quite satisfied that under the circumstances nothing better could have been done for the patient.

The error of supposing that the peritonitis, which it was easy to recognize, had its origin in the reproductive organs, though the objective evidences which were present—induration over the region of the cæcum and its absence over the uterine region—pointed in a contrary direction, was natural enough, in view of the fact that the woman had had a miscarriage only six weeks before, and that none of the well-recognized signs of obstruction of the bowel were present—fecal vomiting, constipation, and interference with the passage of wind, being all conspicious by their absence. My decision to wait twenty-four hours at least before calling for surgical aid was also, I think, proper; for, as there were no signs of obstruction, I would have been unwilling to countenance immediate operation, nor do I think the surgeons would under the circumstances have wished to undertake it. This determination to wait was further justified by what was found at the autopsy; that the disease, though arising in the appendix, had, when the patient came to the hospital, progressed so far in causing the various abdominal tissues and organs to adhere to each other, and had already so nearly caused the death of the patient, that no operation would have been of any avail. Finally, with regard to the best measures for relief after it had been decided that at the moment no operation was desirable. About a year ago I read before this Society asshort paper upon the treatment of peritonitis (THE MEDICAL NEWS, December 8, 1888), in which I advocated the use of opium and belladonna in moderate doses in such cases as did not seem to require surgical treatment. From the views then expressed I have as yet seen no reason to recede, and the case the history of which I have recounted seems to me an unusually striking instance of the kind in which the treatment with salines not only could by no possibility have been beneficial, but must have been positively injurious. In a woman without obstruction of the bowel, having diarrhœa and passing wind freely, and, as the autopsy showed, having a large amount of pus in the abdominal cavity, and many adhesions, the utmost that the most ardent advocate of saline treatment could claim would be that it might have relieved by locally depleting the congested blood-vessels; but, surely, this must have been more than offset by the weakening effect of the increased diarrhœa, the increased pain and general irritation produced by the already overtaxed bowel being thrown into violent activity. If acute peritonitis of this character is best treated by large doses of saline purgatives it is the only acute inflammation existing which requires such treatment, for it is universally agreed that elsewhere they call for rest and soothing measures. On the other hand, I do not wish to be understood as altogether opposed to the saline treatment, for in properly selected cases requiring surgical aid I should be quite willing to accept it as a fact that the surgeon's knowledge was paramount, and to use salines.

In conclusion I wish to add that the case has in one particular been very interesting from a pathological standpoint, as an illustration of the wonderfully migratory habits of inflammation—a fact with which I am constantly struck. Here was an inflammation which had its origin in the irritation of the inner coat of the appendix by a concretion; the effect was ulceration and inflammation of all the coats, and perforation at the point of pressure; next came general peritonitis, and this by extension, the process of inflammation attacking contiguous tissues, set up in spots a true enteritis, for microscopical examination showed the presence of extensive inflammation of the entire thickness of the small intestine in pieces studied.

A SUGGESTION AS TO THE ACTION OF OLIVE OR COTTON-SEED OIL IN GALL-STONE COLIC:

Observations on the Use of the Oils and Reports of Cases.[1]

BY DAVID D. STEWART, M.D.,

LECTURER ON THE DISEASES OF THE SPINAL CORD, AND, LATELY, CHIEF OF THE MEDICAL CLINIC, JEFFERSON MEDICAL COLLEGE; PHYSICIAN TO ST. CHRISTOPHER'S HOSPITAL.

WITHIN the past three years the old plan of treating gall-stone colic with large doses of olive oil has

[1] Much of the oil sold as olive oil is really refined cotton-seed oil. The difference in chemical composition and properties is not very great. Olive oil contains a rather larger proportion of the more fluid fat, olein. In one of my cases olive oil was prescribed; in the other cotton-seed.

come much in vogue, and many communications have appeared in the journals at home and abroad as to its efficiency, but no adequate explanation has yet been offered as to its *modus operandi*. The lack of a wherefore might seem a matter of slight moment, in view of its efficiency were it not that, because no plausible theory of the action of the oil has been suggested, the method has not only failed to receive recognition by therapeutists, but has been subjected to much adverse criticism, efforts having been made to bring it into disrepute, the supposed success of the oil being attributed to errors in diagnosis. This last is perhaps due to the fact that in none of the reported cases in which the oil treatment was used has it been stated that calculi were found which by analysis were shown to be true gall-stones, it either being carelessly taken for granted that the concretions passed were of this nature, or it was stated that masses of soap alone were met with.

Excluding the rare instances in which entozoa mislead, it is unquestionably true that to establish a diagnosis of hepatic colic due to the passage of gall-stones or of inspissated bile, the finding of concretions in the feces is not essential: certain unmistakable subjective and objective symptoms determining the matter very readily. But where these are not detailed, and the ability of the reporter both to apprehend the facts and to make proper deductions therefrom is unknown, an element of doubt as to the verity of the diagnosis is present which renders the conclusions reached valueless. Perhaps for this reason the oil treatment of gall-stone colic has until lately received such scant recognition.

Although at first I was altogether sceptical of a method which seemed founded on no sound theoretical basis whatever, and very naturally viewed with suspicion reports emanating from observers who made the extraordinary blunder of mistaking easily recognizable lumps of soap for gall-stones, their physical appearances in the quantities passed when large doses of oil are taken, being such as scarcely to mislead even the most careless,[1] communications favorable to the treatment continuing to appear, some emanating from known reliable sources, induced me, somewhat less than a year ago, to look upon it with favor and to search for an explanation of the efficiency of the oil. On giving the matter a little consideration then, it occurred to me that if the treatment were efficient the effects attributed to the oil were more likely due to a product of its chemical decomposition, glycerin.

That oils and fats are decomposed in the duodenum into their fatty acids and glycerin there seems no doubt, and this decomposition is probably effected by the pancreatic juice through the action of a fat-splitting ferment, steapsin, as was shown by Bernard. It is now well known that the ingestion of a large quantity of oil is succeeded by the presence in the feces of innumerable masses of soap, the base of which is principally sodium,[1] formed no doubt by the union of the fat acids with the alkali of the pancreatic juice and the bile.[2] It would appear not improbable that glycerin so liberated exerts in the duodenum an action similar to that which takes place when it is introduced into the rectum; withdrawing water, and causing hyperæmia and irritation of the afferent nerves of the part with which it comes in contact, thus leading to powerful reflex peristalsis.[3] In addition to the active contraction which would be caused by the presence of glycerin in the duodenum, and which of itself would probably lead to energetic reflex contraction of the gall-bladder, cystic and common bile-ducts, so that concretions lodged therein, sufficiently small to be expelled, would be rapidly passed onward into the bowel, it is not unlikely that the power of diffusion possessed by glycerin would enable it to enter the ductus communis and even the cystic and the hepatic ducts, and, perhaps, reach the gall-bladder and the liver, producing a similar depletion of the vessels there and, reflexly, exciting the muscular fibres of these ducts to contraction. In consequence of this action of glycerin a copious outflow of diluted bile would also probably occur, which would materially assist in expelling the stone. These, I believe, would be the probable results of the introduction of glycerin into the duodenum in a case of gall-stone colic, in which the stone was not too large to pass readily through the duct: its extrusion following and pain ceasing. As I shall subsequently show, by relating two cases in which this treatment was resorted to, oil in large quantity apparently has the power to check hepatic colic by promoting expulsion of the calculus. That this result is brought about neither by a lubrication

[1] It might be well to recall here a fact not generally known, that gall-stones may rarely be perfectly soft and pultaceous, and as susceptible of being kneaded into various shapes as a piece of putty. This form of stone is believed by Harley to be composed of cholesterin in the preliminary stage of crystalline formation. They may easily mislead, resembling, as they often do, dirty-white barleycorns, orange-pips, grapes, etc. See Harley, *Diseases of the Liver*, Amer. edit., pp. 336, 337. A case of this sort is related by Harley, where he mistook two oblong steatomatous concretions, moulded into the shape of lemon seed, for the latter. *Idem*, p. 344.

[1] See report by Wiley in Prentiss's case, MEDICAL NEWS, May 12 and July 28, 1887, and many others scattered through the journals, in which these masses, by analyses, are shown to be saponified oil. In Prentiss's case complete saponification of nearly a pint of oil is stated to have occurred.

[2] The question whether the intestinal canal contains sufficient alkali to unite with a large quantity of fat acids has no bearing on the well-recognized fact that these acids and glycerin are liberated through a decomposition of the oil in the duodenum.

[3] As was suggested by Anacker (Deutsche med. Woch., Sept. 15, 1887), to whom we are indebted for its recent reintroduction into practice as a laxative, by enema.

of the duct in which the stone is lodged nor by a partial solution of the calculus, has been shown by Chaffard, and as these are the only modes of action at all conceivable if oil itself, and not a product of its decomposition, is the efficient agent, it is likely that oil is not. Since no explanation can be offered as to the efficiency of the oil, and it is known that glycerin is formed from it in the duodenum, and since it is probable that glycerin can produce the effects attributed to the oil, it is likely that these are due to glycerin.[1]

Though this suggestion is sufficiently plausible to meet the facts, I should have hesitated to offer it now, unsupported by experimental evidence, were it not that, since it occurred to me, an enforced absence from my work for a number of months has prevented me from carrying out some experiments on dogs, projected last spring, to determine its value. I should not have placed it on record at this time, but that I desire to report without further delay two cases of cholelithiasis recently encountered, about the diagnosis of which there is no uncertainty, and in which oil was resorted to, to relieve the attending hepatic colic. I thought this a fit opportunity to offer my theory of the action of the oil, that the use of what has been an efficient remedy in my hands might be placed on a rational—if yet theoretical—basis.

CASE I.—Mrs. K., aged forty-two, of short stature, weight 185 pounds, had had attacks similar to that for which she sought relief, for six years. These had occurred at intervals of about six months, for the first three and a half years. She was then free from them for two years, but in the previous six months she had had several. The attacks were usually of long duration, and associated with jaundice. The state of cholelithiasis had never been treated, the attacks alone receiving attention from her physician; morphine being freely used hypodermatically and by the mouth. She was not aware of the nature of her ailment and had never been told to search for gall-stones. I was first sent for on September 29th. As I was then absent from the city, Dr. Pottberg called in my place. Her symptoms were those of pronounced gall-stone colic. She had been in great pain for two days. Dr. Pottberg informs me that having once before administered a half pint of olive oil to a case of gall-stone colic, with the result that all pain entirely ceased shortly after without a resort to anodynes, he concluded to use it in this case. After some persuasion the patient was induced to swallow a half pint of oil, no other medication being used, save heat to the hypochondrium. Pain continued very severe for a half hour and then ceased abruptly. A saline purge was taken a few hours after. The feces were not searched for gall-stones, but an inspection of them by Dr. Pottberg the day following the administration of the oil, showed a great quantity of semi-solid lumps which he very naturally looked upon as concretions resulting from the use of the oil.

The patient remained entirely free from pain until the morning of October 3d. An attack then began, as before, with sharp paroxysmal pain in the right hypochondrium; rigors, followed by fever, gastric irritability and flatulence. I first saw her on the afternoon of October 4th. The liver was found to be enlarged and the lower margins painful on pressure, especially in the region of the gall-bladder. The skin was slightly icteroid, but, it was stated, not more so than was usual in the interval of the attacks. A full dose of morphine and atropine was administered, and inhalations of ether resorted to, with digital manipulation of the gall-bladder, followed by hot poultices to the hypochondrium. Heat was also applied to the feet, which were cold. Draughts of hot water containing sodium bicarbonate were taken at intervals. Under this treatment the pain ameliorated after an hour, but soon became intense again, requiring the use of morphine and atropine, hypodermatically, at intervals. On October 6th, jaundice was more decided; stools were pipe-clay colored and urine high-colored. Pain was now very great, and inhalations of ether, manipulation of the gall-bladder and the abdomen seeming to have no effect in promoting extrusion of the stone, she expressed a willingness to have recourse to the oil. She had objected to it at first as, although the former dose had been followed by such prompt cessation of pain, it had been so intensely disagreeable to her, and so difficult to swallow and retain that I had not urged its use. But now, having determined to take it, she did so resolutely, swallowing three quarters of a pint containing a drachm of ether[1] without demurring. The oil was retained, and, to my gratification, pain ceased suddenly and absolutely within three-quarters of an hour. This was the first time I had used oil to relieve gall-stone colic, and though I had faith in the treatment and had formed a theory to account for its efficiency, I still felt no little surprise at the result.

The bowels moved freely, without a purgative, fourteen hours after the oil was taken. I had already begun a careful search for stones, using a sieve consisting of several thicknesses of cotton-netting of a very fine mesh. Every fecal evacuation after the date of my first visit was most thoroughly washed and filtered, and the scrutiny is still as carefully continued by the patient, who has a very intelligent idea of the matter, saving everything for my inspection which at all differs in appearance from the general semblance of fecal matter. The first three passages following the ingestion of the oil contained upward of fifty semi-solid lumps, of various sizes, similar to those passed before. These I had no doubt were concretions of soap. A few were sent to Dr. Leffmann for analysis, who confirmed my

[1] Rosenberg (Fortschritte der Medicin, No. 13, 1889) has recently ascertained an important fact which tends to support my suggestion. He has found, by experiments on dogs with gall-bladder fistulæ, that large doses of olive oil greatly increase the quantity and diminish the consistency of the bile excreted. It would appear inconceivable that olive or cotton-seed oil could have such an effect, save in the manner I have proposed.

[1] The ether was added with the idea of assisting the retention of the oil, and also, of promoting a flow of pancreatic juice.

opinion. In the third passage two gall-stones were found. One, unfortunately, on too rough handling broke into small bits and was lost. It had a similar appearance to the other, though it was a trifle smaller. This latter was about the size of a large pea, somewhat cubical in shape and of a brownish exterior. On light pressure with the finger it crumbled, showing a white, crystalline interior, presumably of pure cholesterin. Sulphuric acid, placed in contact with a small crumb, gave the play of prismatic colors. Another small portion was dissolved in boiling alcohol and the precipitate examined microscopically after evaporation of the spirits: the characteristic rhombic plates of cholesterin were shown. The remainder, quantitatively examined by Dr. Leffman, was found to consist wholly of cholesterin. The patient stated she found what appears to have been another stone, a few days later. It was globular in shape, and about three times the size of the one tested. As it fell into bits on her attempting to rewash it, and as she neglected to save the fragments, I failed to see it. Though some suspicious-looking concretions have been passed since, and brought for my inspection, none have answered to the tests for gall-stones or inspissated bile. The patient has had one or two slight attacks of colic since, but not severe enough to require medical interference. She is on appropriate hygienic and medical treatment to prevent the redevelopment of stones, and to bring about the solution of any remaining.

CASE II.—Mrs. C., aged forty-five, weight 225 pounds, of medium height, presented herself for treatment on October 23d, last. She had had paroxysmal, cramp-like pain in the epigastrium and the right hypochondrium, with flatulence and nausea, for several days. On questioning her, I learned that this was but a very light expression of similar seizures which had affected her for twelve years. The attacks appeared at intervals of from two years to two weeks, and lasted from a few hours to many days. In the past three or four years they had occurred more frequently than formerly, and were of several days' duration. The shorter attacks usually occurred at night. Decided pruritus and jaundice were often present, after the pains had continued for three or four days. She was not aware that she was passing gall-stones, and had never been treated for them so far as she knew.

On examination, I found it difficult to outline distinctly the lower limit of liver dulness, because of the great amount of adipose tissue. It was, however, found to be extended, and the situation of the gall-bladder was exceedingly tender on pressure. Her diet and habits were regulated, and sodium bicarbonate and sulphate prescribed, to be taken in a bitter infusion a half hour before meals. An opiate mixture was ordered, in case the pains became too severe to be borne. She was carefully instructed how to search the passages for biliary concretions.

On the night of October 27th I was summoned to see her in well-developed hepatic colic. The slight pains had continued, with remissions and exacerbations, without growing very severe until the afternoon of that day, when suffering suddenly became so intense that she resorted to dose after dose of the opiate, entirely without relief, as, owing to the great gastric irritability, each was vomited as soon as swallowed. I gave, hypodermatically, a half grain of morphine and $\frac{1}{100}$ of atropine; applied heat to the feet, and afterward to the liver, first attempting digital manipulation of the abdomen in the region of the gall-bladder. Draughts of hot water, containing sodium bicarbonate and essence of peppermint, were also administered. Relief was soon felt, after which she fell into a broken sleep, to be thoroughly awakened, in the course of two hours, by the pains recurring as severe as before. Another half grain of morphine with $\frac{1}{100}$ of atropine was taken—this time by the mouth. This failing to give ease, and it being daylight, she sent for some cotton-seed oil, a full dose of which I had told her might tend to check the pains, should other remedies fail. I saw her at eleven that morning: she was then suffering very acutely. She had taken seven fluid-ounces of the oil at five, but had vomited it at once after it was swallowed. I persuaded her to take ten fluid-ounces while I was with her, adding a teaspoonful of ether to the dose, and administering a tablespoonful of undiluted brandy immediately after. Emesis did not occur again for an hour: then about half the oil was ejected. Shortly before this, or, as nearly so as could be arrived at, forty-five minutes after taking the oil, the pain markedly diminished, and three hours later ceased entirely, indicating that a stone had been passed into the duodenum. A mercurial purge was taken on cessation of the pain, followed six hours later by two drachms of sodium sulphate in hot water. The bowels moved freely that night and the subsequent day, but no stones were found. Though great tenderness, on pressure, was felt over the lower margin of the liver, and especially above the situation of the gall-bladder, she remained entirely free from unprovoked pain for thirty-six hours. At the end of this period it recurred with great intensity. Feeling that the oil had been instrumental in checking it before, she was quite willing to resort to it again, if there was any chance of it being retained; as she constantly vomited all fluids swallowed, there seemed slight hope of this. It occurred to me that cocaine might aid in its retention. Thinking it worth a trial, I prescribed one-third of a grain, with ten minims each of compound tincture of cardamom and spirits of chloroform, in a tablespoonful of water, to be taken a half hour before the dose (a half pint) of oil; and directed that the oil contain a teaspoonful of ether, as before, and that a swallow of undiluted spirits follow the oil. On visiting her again a few hours later, I was told that vomiting had not occurred until three hours after taking the oil, and only then on attempting to swallow some meat broth. The vomit contained but little oil. It was also stated that the pain, which had been excessive, decidedly diminished within two hours after taking the oil, but did not cease entirely until seven hours later. Morphine was not resorted to during this attack. On its termination, the bowels were kept

relaxed by calomel and sodium sulphate, and the feces searched in the most thorough manner—a forty-mesh wire sieve being used to wash them.

As I had directed that every particle passed of the slightest suspicious nature be saved for my inspection, the soapy concretions and all sorts of foreign substances, such as fruit seed, and concretions evidently formed in the intestines from undigested food, were preserved and carefully tested, chemically and microscopically, when their nature was not apparent by inspection. On the fifth day after cessation of the last attack of colic, a triangular-shaped stone, about the size of a beechnut, was voided. It consisted of cholesterin with a nucleus of mucus and inspissated bile: the tests for these being applied by myself and confirmed by Dr. Leffmann. None has been found since, though the search is still being prosecuted with care.

This calculus, and especially the first one tested in the case of Mrs. K., had the smooth, eroded appearance of a biliary concretion that had undergone partial disintegration within the body. As neither of the cases had been under treatment directed to bring this about for more than a few days, it occurred to me that it might be due to some solvent action of a product of the decomposition of the oil. To determine if either soap or glycerin, when brought in contact with gall-stones, would have the tendency to promote softening of their mass and partial solution of their exterior, I took the halves of a very large and firm cholesterin stone, which I had removed two years before (*post mortem*) from a gall-bladder, and placed one in glycerin and the other in a strong solution of sodium soap, keeping both liquids at a temperature somewhat below the body heat, and noted the result in twelve hours. While the portion suspended in glycerin had remained firm in consistence and was altogether unchanged, that in the soap solution had stained the latter very decidedly and crumbled readily when taken between the fingers. This result is not surprising, when it is considered that soda is the alkali of the bile that tends to maintain cholesterin in solution, and that sodium salts, administered for long periods, in cases of cholelithiasis, have the tendency to promote dissolution of gall-stones and concretions of inspissated bile. This little experiment may, in a measure, account for the failure to find gall-stones where search has been properly made in cases of hepatic colic treated by large doses of oil; for intestinal peristalsis, bringing the recently passed stones constantly into contact with warm solutions of soap, may, in some instances, cause their entire disintegration.

Although I do not claim to have fully demonstrated by the recital of these cases that oil is efficient in checking hepatic colic, since the length of time taken by the passage of a stone into the duodenum can never be exactly determined beforehand, yet I think that the prompt cessation of the attacks in Case I., in which oil was used, and in Case II., their less prompt yet really speedy discontinuance, in comparison with the duration of the last few previous seizures, when ordinary means of relief were tried, indicate, when placed with the accumulating evidence in favor of this treatment, that it is not without utility, and that it is at least worthy of intelligent and extended trial—especially when we reflect that none of the methods ordinarily resorted to have much influence in promoting extrusion of biliary concretions. A stone is probably passed into the bowel, through the action of the contractile muscular fibres of the duct in which it is contained, and the accumulation of liquid bile behind it, urging it along. Opium and belladonna in the full doses necessary to allay the pain of colic, and inhalations of ether and chloroform, tend to impede rather than assist expulsion, by arresting peristalsis in the duct. Opium and belladonna tend to retard, also, by checking the formation and outflow of bile. It is true that dilatation of the duct is necessary for digital manipulation of the gall-bladder to be practised with success, yet few, save the most skilled, are able to apply this procedure properly. The abdomen of gall-stone subjects is usually so adipose that it is difficult to feel and still more to grasp the fundus of the gall-bladder, unless much distended—a condition unlikely to obtain unless a calculus has been some time impacted in the common bile duct.

If the theory suggested as to the action of the oil is correct, the method, as now practised, is open to many sources of failure. Glycerin may not in all cases be formed in sufficient quantity to exert its peculiar effects. A free flow of pancreatic juice is necessary for the splitting up of the oil. The pancreatic juice may not be present in sufficient quantity to act on any amount of oil. Belladonna, or its alkaloid, atropine, much resorted to in hepatic colic, suppresses the pancreatic secretion. If full doses are given before oil is tried, the result will be *nil*. Any fluid taken with the oil may so dilute the glycerin formed in the duodenum that its hygroscopic effects on this part will be prevented. The calibre of the offending calculus may be too great to be influenced by the contractions of the duct and a full outflow of bile, induced by glycerin. If further trial justifies faith in the use of oil in the treatment of gall-stone colic, and my theory of its action is proved by experiment, some of these elements of failure may be removed.

The great objection to the use of oil is the difficulty patients have in swallowing and retaining it in the quantites ordinarily administered. The method practised in Case II. might be tried where considerable gastric irritability exists. Whether a less dose than half a pint will be efficient remains to be determined.

It would, I suppose, be useless to administer glycerin by the mouth with an idea of obtaining the result anticipated from the oil; for, because of the hygroscopic properties of glycerin, on which would depend its action, sufficient fluid would be absorbed from the gastric bloodvessels to render it too dilute to be efficient when it reached the duodenum.

2620 N. FIFTH ST., PHILADELPHIA.

A CASE OF INTESTINAL OBSTRUCTION FROM APPENDICITIS, FOLLOWED BY PERFORATION OF THE BOWEL ABOVE THE SEAT OF OBSTRUCTION.[1]

BY CHARLES B. PENROSE, M.D., PH.D.,
OUT-PATIENT SURGEON TO THE PENNSYLVANIA HOSPITAL.

THE usual cause of death in inflammation or ulceration of the vermiform appendix is perforation of the appendix and septic peritonitis. In the case which I am about to report the phenomena which resulted in death were, first, appendicitis, producing local peritonitis and bands of adhesion; second, obstruction of the ileum from these adhesions; and, finally, perforation of the ileum from distention and gangrene above the seat of obstruction.

The patient was a delicate woman, twenty-two years old, with a phthisical family history. She had had no abdominal disease until twenty years of age, when she suffered from an attack of general peritonitis, beginning with right iliac pain and tenderness. She apparently recovered perfectly from this, and continued well until the 17th of last August, when, after excessive ocean bathing, she was seized with pain and tenderness in the right iliac region, accompanied by constipation, nausea, and vomiting. This attack lasted one week, and was relieved by mild saline purgation. Though she left her bed she was not perfectly well, and was never entirely free from pain and tenderness in the region of the cæcum.

Toward the end of September she was again obliged to take to bed: the right iliac pain increased; she had obstinate constipation and paroxysms of pain around the umbilicus. There was no abdominal distention, the abdomen being, on the contrary, rather retracted. Ingestion of food caused abdominal pain, nausea, and vomiting. At first the constipation was overcome with calomel and saline purgatives. It, however, became more difficult to produce a movement, until, by October 10th, there was absolute constipation, or, in other words, complete obstruction. The temperature—which had previously been normal—began to rise a few days before the appearance of complete obstruction, and ranged from 100° to 101.5°. The pulse was about 100. Abdominal distention first appeared when the constipation became absolute. For nine days there was no passage of feces or flatus from the rectum. The other symptoms were gradually progressive. General emaciation rapidly increased, the abdomen became greatly distended, the paroxysms of umbilical pain became more frequent and violent, there being two especially intense attacks—one five days after the beginning of absolute constipation, and the other on the night of the eighth day. The last of these attacks was followed by collapse; vomiting continued with but little intermission, though it never became fecal. She was first seen and operated on by the writer nine days after the beginning of complete obstruction. She was in a condition of collapse, with a quick, feeble pulse, rapid and shallow respiration, and a tense, distended abdomen.

Abdominal section was performed by the median incision. As soon as the peritoneum was opened there escaped through the incision a large quantity of fecal gas, followed by several ounces of very offensive, thin, fecal pus. The intestines were not adherent to the parietes, but all the loops of the small and large intestine in the lower half of the abdomen were united by recent friable adhesions. The pelvis was filled with a large quantity of unhealthy lymph, pus, old and recent blood-clots. In the region of the cæcum the intestinal adhesions were old and strong. One inch from the ileo-cæcal valve the lumen of the ileum was completely closed by a thick mass of inflammatory tissue, which bound the bowel to the posterior wall of the abdomen. The vermiform appendix was imbedded in adhesions; was two inches long, and about one-half inch in diameter. It was hard and rigid, but from the hasty examination made at removal, no sign of perforation was detected. It was unfortunately lost by the nurse. The ileum for twelve inches above the seat of obstruction was hypertrophied, distended, and gangrenous in spots. In a space of ten inches there were two minute perforations on the convex surface of the intestine.

As it was impossible to relieve the obstruction without resection of the intestine, the diseased portion of the ileum—twelve inches in length—was removed. The ileo-cæcal valve and the free end of the ileum were closed by a continuous peritoneal suture. The ileum was then united by lateral approximation with rubber disks to the anterior surface of the cæcum. The abdomen was freely irrigated, and a glass drain was introduced. The patient died a few hours after operation.

I will briefly summarize the points of interest in this case:

The disease began as an appendicitis, probably as a catarrhal inflammation with superficial ulceration. This was followed by local peritonitis, with adhesions around the appendix and cæcum The evidence of this is found in the history of the two previous attacks, which were characterized by right iliac pain and circumscribed tenderness. The adhesions which followed the second attack produced, at first, partial obstruction of the ileum. As the obstruction became more complete the patient began to suffer with paroxysms of umbilical pain, in addition to the ileo-cæcal pain which had characterized his first attacks. Distention and increased pain followed complete obstruction. A few days

[1] Read before the Philadelphia County Medical Society, November 13, 1889.

before death there was probably rupture of an intestinal bloodvessel, and, perhaps, beginning perforation during a violent peristaltic effort to overcome the obstruction. The older clots found in the peritoneum were the results of such a rupture. The perforations discovered at the time of operation probably followed a paroxysm which occurred not many hours before death, for in the exhausted condition of the patient such an accident would cause speedily fatal collapse.

I have reported this case because it adds another to the list so rapidly accumulating which illustrate the dangers that may be avoided by early operation in recognized cases of appendicitis, the operation being not only a curative, but a prophylactic measure.

In pyosalpinx and extra-uterine pregnancy operation was not many years ago deferred until rupture had taken place. We now acknowledge the value of early operation whenever such conditions are recognized. Inflammation of the vermiform appendix is attended with analogous dangers. Most operations hitherto reported have been performed after perforation had occurred, and the patient in many cases was dying of septic peritonitis. Delay is often unavoidable on account of uncertainty of the diagnosis. In other cases operation is postponed because of the delusive hope that the final attack may terminate in temporary recovery as perhaps previous attacks have terminated.

If we recognize, however, that most cases which have a history of recurring attacks of pain and circumscribed tenderness in the right iliac region, with other important though less characteristic symptoms, are due to disease of the vermiform appendix, operation is indicated, either in an interval, while the patient is in fair health, or at the beginning of an acute attack.

I have said very little about the steps of the operation in this case, because the patient died too soon for any determinate result. The rubber disks employed are similar to those which I use for making lateral anastomosis between the ileum and cæcum. Intestinal anastomosis by means of decalcified bone, catgut, or rubber disks, enables us in many cases to avoid the necessity of an artificial anus. The operation is as quickly performed as the formation of an artificial anus, and furnishes an immediate relief to the patient.

THREE CASES OF APPENDICITIS: OPERATION: RECOVERY.[1]

By J. M. BALDY, M.D.,
of Philadelphia.

On a number of former occasions I have taken the opportunity to advance the doctrine of early and prompt surgical procedures, where it seemed likely that the surgeon must interfere eventually. In appendicitis (I use the term advisedly and broadly, for I believe it well proven that the vast majority of inflammatory attacks in this region are such) this doctrine of early operative interference is imperative. In the history of surgery the greatest strides in lowering the mortality and insuring the success of any given operation have been made when the point of operating at a time of election has been reached, and that time of election has been an early one, as a rule. And so it is with the disease under consideration. In the course of progress attention was first directed toward the surgical treatment; then it began to be realized that operations, if they were to prove of benefit, must be done, not as a last resort, when the patient was dying and everything else had been tried and found wanting, but within a certain limit of time, from the third to the sixth day, or at such a time when a certain set of symptoms had declared themselves, these symptoms usually meaning the existence of an abscess. As the truth of these teachings began to dawn on operators, successes following operations began to be reported, until now there are quite a large number on record, many of them in our own city.

In spite of the number of cures by operation, the deaths, both following operation and when no operation has been performed, so far outnumber these, as to leave them as a mere spot on the horizon. At nearly the same time two surgeons, Treves and Senn, illustrious representatives of the progressive elements of England and America, publicly urge another step in advance, a most important one, and support their arguments by illustrative cases. The point chiefly advanced by both is, not to await the time when the patient's life is in extreme danger, but where there have been repeated attacks of inflammation in the right iliac fossa, to elect deliberately a time between these attacks when the patient is in good health and well able to stand the slight shock of the operation. Treves reports the case of a man on whom he did this prophylactic operation, in the *Lancet* for February, 1889. His patient had had three attacks of inflammation, at intervals of about three months, each one more severe than the previous. Treves, finally, to prevent the risks of a fourth attack, opened the abdominal cavity and removed the appendix. This he found tightly bound down with adhesions and under coils of intestine adherent to each other and to the appendix and cæcum. The organ was as thick as a man's thumb and was distended with mucus. It was singularly white in color, a peculiarity I have myself noticed in several cases. Recovery was complete and lasting. In the *Journal of the American Medical Association*, November, 1889, will be found Senn's article. He reports two cases. The first

[1] Read before the Philadelphia County Medical Society, Nov. 13, 1889.

operated upon by himself for five previous attacks of perityphlitis. He found an appendix the size of the thick part of the little finger, but not adherent. On section, after removal, an ulcer one-half inch long by one-quarter inch wide penetrating the mucous membrane of the organ and extending into the muscular tissue, was found. The patient has had no return of the old symptoms. The second case reported by Senn was operated upon by Hoegh, of Minneapolis. There had been at least twelve attacks of inflammation, more or less severe. The abdomen was opened by the advice of Senn, and the appendix, which was adherent, removed. On section, several drops of pus flowed out and two large ulcers penetrating through the mucous membrane were found. Recovery was permanent. Since, and even before, these cases were reported lesser lights were at work, and now there are quite a list of such operations on record. One of these I saw Dr. Bernardy perform on a girl who had had repeated inflammatory attacks. In this case the appendix itself, after being freed from its adhesions, was allowed to remain, it being considered healthy enough to do no harm. The patient made a complete recovery and has remained cured. I have myself, on three occasions, removed the diseased appendix.

During December, 1887, I was called to see Mrs. E., and found her suffering with an attack of peritonitis. She had been in bed much of the time for five weeks. She gave a history of a number of similar attacks during the past few years. An examination of the pelvis disclosed inflammatory disease, and consequently operation was advised. The operation revealed a double chronic salpingitis with general adhesions. To the right Fallopian tube, the vermiform appendix was adherent throughout its entire length, together with a knuckle of small intestine. The adhesions were freed, and after throwing a ligature around the appendix above the diseased part, it was removed. The surfaces denuded by the freeing of adhesions bled freely, and a few silk stitches were put in to bring the peritoneal edges together. The peritoneum was stitched over the stump. The uterine appendages were also removed. Recovery was complete and uneventful. In this case the disease was evidently dependent on the pelvic inflammation. The appendix was perforated in several places, and the whole organ was enlarged to the thickness of one's little finger, and was cheesy and friable.

In November, 1888, I was asked to see Mrs. M., of Trenton, in consultation. She had a history of pain in the right iliac fossa for some years. One month before the present illness she had marked symptoms of extra-uterine pregnancy, with rupture. At the time of my seeing her she was bedridden, and dying of sepsis. An operation disclosed the remains of a ruptured left tubal pregnancy, which was in a state of beginning suppuration. In the right iliac fossa was a mass of adherent intestines, containing in their midst a diseased and universally adherent vermiform appendix. The adhesions were freed, and the appendix found to be as thick as the little finger, cheesy and perforated at two points. It was ligated *en masse*, and cut away close up to the cæcum. The peritoneum was not stitched over the stump. The left side of pelvis was cleared of its diseased tube, and the patient after a prolonged sickness made a complete recovery, and remains to this day a perfectly well woman. No cause was found for the diseased appendix.

During January, 1889, I was called to see Mrs. F. She gave a history of repeated attacks of pain in the right iliac fossa. During the attack in question the pain was worse than ever before. No tumor could be detected, but there was great tenderness on deep palpation. A pelvic examination revealed enlarged, prolapsed, and excessively tender ovaries. I operated by a median incision, being uncertain whether the attacks of pain were not due to ovarian disease. The appendix was found universally adherent under a coil of adherent intestines. The adhesions were freed, the appendix ligated *en masse* close up to the cæcum, and cut away. The peritoneum was not stitched over the stump. Like the other two cases, the appendix was found as thick as one's little finger, or thicker, and was extremely cheesy and friable. No cause was found for the disease. The patient made an uninterrupted recovery, and has since remained well.

In none of these cases was there a mesentery of any length to the appendix.

Here, then, by the prophylatic operation we have a mortality of *nil*. Every case of which I am cognizant has recovered. What a difference between this clean record and that with which we must contrast it! The step will be, no doubt, considered a radical one by many, and there will be raised the usual hue and cry against surgical greed; but until a better record can be shown by any of the older methods, we will proceed on the even tenor of our way, and remove a diseased appendix wherever and whenever it can be found. The world has become reconciled to and looks with complacency on the removal of Fallopian tubes similarly diseased and adherent; and so it will be with the appendix vermiformis. They are even more of a menace to the patient's life than are the cases of salpingitis which we all remove, and the diseases are in many respects similar. It may be argued that these cases were successfully carried through the many former attacks of inflammation, and could be again just as successfully treated without the use of the knife. Granted that they were relieved of former attacks, —but the relief proved in every case to be but temporary; and who is to say where the limit in the number of attacks will be reached, or what one may prove fatal? It certainly is not safe to await pus formation if we can anticipate it; the operations after pus has appeared show sorry results. It was only last winter that this stage was awaited in the

case of a medical student in this city, and the student died.

It will be asked, How can we be certain that the appendix is diseased? To this I can but say that, in my experience, there is no positive, constant sign. The most constant and invariable symptoms that I have observed are pain and tenderness in the right iliac fossa. The symptoms of vomiting, tumor, peculiar drawing up of the knees, etc., are too often absent to be depended upon. If they are present, well and good; they form valuable corroborative signs. But with repeated and persistent attacks of pain and tenderness, of sufficient severity, in the iliac region, nothing else being found to account for them, a diagnosis of pericæcal inflammation is warranted.

HOSPITAL NOTES.

HÆMATURIA.

Abstract of an Original Lecture delivered at the Hospital of the University of Pennsylvania.

By JAMES TYSON, M.D.,
PROFESSOR OF CLINICAL MEDICINE.

The patient presented was a girl of twenty years, a domestic, who enjoyed good health until five weeks ago, when she suddenly began to pass bloody urine, with no other apparent symptoms. When brought to the clinic she was anæmic, but this seemed to be rather a result than a cause. In studying a case of hæmaturia, Dr. Tyson said that the first thing to determine is, whether the hemorrhage is from the kidney or the bladder. In this instance he thought it was from the kidney, because of the intimate admixture of the blood and the urine, the absence of clots and of irritation of the bladder.

Supposing it to be from the kidney, it may be due to a variety of causes. Small hemorrhages are found in acute Bright's disease and chyluria. Malaria in this country is quite a common cause. Impacted calculus, tumors of the kidney, injuries and wounds are also frequently the cause. In tropical countries, parasites in the kidney often excite severe and exhausting hemorrhages. Finally, there occur cases of renal hæmaturia which are unaccountable.

In this case the cause could not be acute Bright's disease, because the amount of blood was too large, and there were no other symptoms of that disorder. For the same reason it could not be chyluria. It is not likely to be caused by impacted calculi, because there is no pain and no attacks of nephritic colic. Dr. Tyson thought it more likely to be malaria, but it could not be definitely settled in this case, as a direct history of exposure to malaria was absent, and the blood had not yet been examined for the malarial plasmodium of Laveran. Parasites in the kidney are scarcely to be thought of in this climate. Treatment, of course, must vary with the cause. The patient should always be put to bed. In malarial hæmaturia, quinine freely administered will generally promptly arrest it. In the absence of a definite cause, gallic acid should be the first remedy used, in doses of 15 grains every 3 hours. Dr. Tyson has had success with subsulphate of iron in ½ grain doses, which he combines with 1-30 grain of sulphate of strychnine. Among the most valuable remedies are the natural astringent mineral waters, such as Rockbridge Alum Water, the water of the Bedford, Va., alum springs, or of Wallowhatoola alum springs, also of Virginia. He related a case which, having resisted all other treatment, appeared to be relieved by electric baths.

MEDICAL PROGRESS.

Fastening Rubber Bandages without Tapes.—The Swiss correspondent of the *British Medical Journal* suggests the following convenient method of keeping rubber bandages in place on the leg, without the use of inelastic tapes, which, by retarding venous circulation, often frustrate the object for which the bandage is applied. The method in question consists in applying the bandage to within six or eight inches of the end, this free end is then thoroughly moistened with water and slipped under the last two turns of the bandage. According to this authority, if the bandage is well moistened, as described, it will more certainly remain fixed than if tied in the usual manner.

Ointment for Conjunctivitis.—*L'Union Médicale* for October 5, 1889, has the following treatment for inflammations of the eye:

Extract of belladonna .	1 drachm.
Mercurial ointment . .	2½ drachms.

This is to be employed smeared above the orbit in inflammation with great pain and in injuries of the eye. Also where pain is due to a foreign body.

Pilocarpin in Gall-stones.—Dr. Lekarskie considers pilocarpin almost a specific in the treatment of gall-stones, basing his opinion on the results of treatment in thirty cases. He administers one-eighth grain hypodermatically once or twice daily. The effect on the pruritus of jaundice is immediate, and adds greatly to the comfort of the patient.—*Bulletin Générale de Thérapeutique*, October 15, 1889.

Iodoform in Scrofulosis.—M. Besner prescribes iodoform to scrofulous children in the following formula:

℞.—Iodoform . . . . gr. jss.
Mel. despum . . . . f℥iv.—M.

Of this, a teaspoonful may be given three times daily. He prefers iodoform to the preparations of iodine, from the fact that it may be used for a longer time without interfering with digestion. Iodine in its elementary form he considers more efficient than the iodides, and prescribes the tincture in doses of one drop diluted with boiled milk.—*Revue Générale de Clinique et de Thérapeutique*, October 24, 1889.

Salicylic Acid in the Treatment of Corns.—Moisten the corn with a solution of salicylic acid, and sprinkle over the surface a layer of pure acid. Cover with a small pad of salicylated cotton and oiled silk. This dressing should be renewed every four or five days until the corn is desiccated, when it is easily removed. One or two weeks' treatment is usually sufficient.—*Revue Générale de Clinique et de Thérapeutique*, October 24, 1889.

Chronic Cystitis.—PROF. MOSETIG-MOORHOF advises the following mixture in chronic catarrh of the bladder:

℞.—Iodoform . . . . . ℥jss.
Glycerin. . . . . f℥x.
Aq. dest. . . . . f℥ijss.
Tragacanth . . . . . gr. iv.—M.

A tablespoonful of this is added to one quart of water and injected into the bladder every third day. Improvement is usually noted after three or four injections.—*Wiener medicinische Presse.*

Hypodermatic Injections of Carbolic Acid in Erysipelas.—DR. PAUL SAMTER, of Danzig, in the *Deutsche medicinische Wochenschrift*, enthusiastically advocates the treatment of erysipelas with injections of carbolic acid, believing that, if used early, it prevents suppuration and other complications. Cases uninfluenced by sufficiently large doses of the acid, he believes, are not instances of true erysipelas, however much they may resemble that disease. The drug is administered in the following formula, and freshly prepared for each case:

℞.—Acid. carbol. } . . . āā ♏ xxij.
Alcohol }
Aq. dest. . . . . f℥ijss.—M.

Of this, from one-half to one syringeful is injected into the healthy skin about an inch from the border of the erysipelatous area. Without pinching up a fold, the needle is thrust obliquely toward the disease, and the solution deposited in the deeper tissues. If not used upon the face, these injections cause but little pain. The diseased surface should be surrounded with a series of such injections from one to four inches apart. To prevent carbolic acid poisoning, Samter advices that with the above treatment a tablespoonful of a 3 per cent. solution of sulphate of sodium should be administered hourly.—*Therapeutische Monatshefte*, October, 1889.

Dangers of Parenchymatous Injections of Goitre.—At the recent Congress of German Physicians and Naturalists, DR. HEYMANN, of Berlin, reported the case of a woman in whom a goitre had diminished to one-third of its former size after injections of iodine, practised twice a week for four months. After the last injection there were great pain, vomiting, loss of consciousness, contractions, and gradually increasing loss of sensibility and movement in the upper extremities, and death followed two days after with signs of cardiac paralysis. No autopsy was obtained.

The author was of opinion that thrombosis had occurred from penetration of the iodine into a large vein, the clot extending to the external and intracranial branches of the internal jugular vein. Heymann had collected sixteen recorded cases of death after parenchymatous injections. The same result may follow from injection of other drugs, *e.g.*, perchloride of iron and ergotin, etc.—*Journal of Laryngology and Rhinology*, November, 1889.

Reduction of Temperature by a Spray of Water.—DR. PLACZEK, in Virchow's *Archiv*, advocates spraying the entire body as an efficient means of reducing temperature. In an animal with high temperature, he succeeded in reducing the same two degrees by spraying the body with one and a half pints of water at a temperature of from 53° to 59° F., and immediately after with three ounces at 95° F. The after-spraying with water of a higher temperature dilates the capillaries, and this induces a consequent loss of considerable body-heat.

Thus in a tuberculous subject whose evening temperature would at times reach 104° the author reduced the same to normal by using somewhat over one pint of water of from 59° to 66° F. The temperature was with ease kept for four hours at this standpoint and then gradually allowed to rise, but not allowed to reach its former high standing.

Compared to the ordinary method of bathing, this treatment has the advantage of simplicity and comfort, factors not to be disregarded in private practice. The patient simply remains in bed, coverings and shirt are removed, a rubber cloth laid under him, and the *modus operandi* proceeded with. As each application does not require more than twenty-five minutes, it can be repeated several times daily.—*Medical Chronicle*, October, 1889.

Treatment of Fractured Patella.—In a paper read before the Royal Academy of Medicine in Ireland, MR. MYLES, after alluding to the unsatisfactory results in treating fracture of the patella with external mechanical means, to the dangers of wiring even under antiseptics, and to the well-known objections to Malgaigne's hooks, describes his own method of treatment thus:

The limb being cleaned, the skin is drawn well up; a small puncture is then made through the skin on either side with a common bradawl; the upper fragment is cautiously drilled from side to side, the drill being constantly kept accurately parallel to the anterior surface of the fragment; through the drill hole a stout nickel-silver pin is passed, its two ends project on either side of the fragment, its centre is buried in the substance of the fragment. The lower fragment is then similarly drilled and transfixed, the skin having been previously drawn well down.

With the pins now in position a powerful grip on the fragments is secured, and it is astonishing how little force is necessary to overcome the muscular contraction. When the fragments are drawn together and fixed in proper apposition, a gauze tape can be passed under and around them in a figure of 8, as in a harelip operation, or the free ends can be securely wired together.

Corrosive lint, a posterior splint and flannel roller completes the dressing, which is not disturbed for five or six weeks.

The advantages claimed for this method are:

1. That it is effective—that is to say, it will keep the fragments in perfect apposition without the tilting incidental to mechanical appliances.

2. It is free from the danger of septic infection, as the joint is not opened.

3. It is easy and simple, requiring no costly appliances.

Comparing this method with Mr. Treves's modification of Malgaigne's hook, Mr. Myles thus summarizes the disadvantages of the latter:

1. The joint is often perforated above or below.

2. The hooks also tend to tilt forward the lower end of the upper fragments as they press the patella from the front and above.

3. They are painful and cumbersome.—*The Dublin Journal of Medical Science*, November, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, NOVEMBER 23, 1889.

THE TREATMENT OF RETENTION OF URINE DUE TO ENLARGED PROSTATE.

ENLARGEMENT of the prostate gland, with its consequent disastrous effects upon the urinary bladder, occupies, unfortunately, a prominent place in the long list of diseases that belong to old age, and, until recent years, all that surgical skill could do for it, no matter how severe might be the suffering it caused, was to deal with it in a manner purely palliative. To be sure, in a certain proportion of cases the use of the catheter has yielded results more or less satisfactory, and, of course, there always will be cases in which it will be found a valuable source of relief. On the other hand, instances will be met with in which the catheter, although it may have been for years employed with none but satisfactory effect, all at once becomes a source of irritation, or infection perhaps, and establishes a troublesome cystitis, which eventually is fatal. For such cases the surgeon should possess radical means of cure.

As a step in this direction the operation of perineal incision for drainage of the bladder, which has been a recognized procedure for at least a decade, was introduced. It holds out the promise of certain relief, but not of cure, and in spite of the good results it has yielded, it possesses the disadvantage of being but a temporary measure. Permanent cure is attainable only through an operation which effects the removal of the hypertrophied prostate, or such part of it as is obviously the cause of the patient's disability. Prostatectomy is an accomplishment of modern surgery, in fact, of very recent years, and, as is generally known, there are three methods in which it has been performed—the urethral, the perineal, and the supra-pubic. Against the first two the strong objections of uncertainity and extreme difficulty of performance must be urged, while the last is an essentially simple operation, and presents the great advantage of permitting the operator to learn through the sense of sight, as well as touch, the precise state of affairs he has to deal with.

At the meeting of the British Medical Association, held at Leeds in August last, there took place a most interesting discussion on the subject of "The Treatment of Retention of Urine from Prostatic Enlargement." It appears in the *British Medical Journal* for October 19. The discussion was opened by Mr. A. F. McGill, Surgeon to the Leeds Infirmary, who presented in a very concise manner an admirable and most instructive paper. Confining his attention entirely to those cases of enlarged prostate in which retention is chronic, requiring habitually artificial relief, the speaker made his remarks in a series of propositions, which he himself discussed, and then invited expressions of opinion from the other members of the surgical section of the Association. Mr. McGill's propositions are the following: I. That prostatic enlargements which give rise to urinary symptoms are intra-vesical and not rectal. II. That retention is caused by a valve-like action of intra-vesical prostate, the urethral orifice being closed more or less completely by the contraction of the bladder on its contents. III. That in many cases self-catheterization is the only treatment required. IV. That when the catheter treatment fails, or is unavailable, more radical measures are necessary. V. That this treatment, to be effectual, should (1) for a time thoroughly drain the bladder, and (2) permanently remove the cause of obstruction. VI. That these conditions are best fulfilled by a supra-pubic rather than a urethral or perineal operation. A table comprising twenty-four cases in which the operation had been performed at the Leeds Infirmary accompanies the paper, and from it we learn with surprise of the excellent results obtained. Considering the fact that the patients were all elderly, some very old and feeble men, the mortality of four cases in twenty-four (16.6 per

cent.) must be considered, as Mr. McGill puts it, "lower than might reasonably be expected." Granting, however, that recovery was the result in so large a majority of these cases, so far as the operation itself was concerned, the question still remains to be answered as to what was accomplished in the direction of radical cure. In reply we have from McGill the following figures, excluding from the twenty-four tabulated cases seven in which the operation was undertaken for the removal of stone and the prostatectomy was incidental: four deaths, three resulting immediately from the operation, and one from pneumonia during convalescence; two cases still under observation, and one lost sight of—fourteen in all—ten remaining in which the final result can be stated. "Of these ten, eight have continued well, but one requiring the passage of a catheter, and that only after excessive drinking." The ninth case was one in which it was found impossible to remove the prostate, owing to its extreme hardness, and in which accordingly only supra-pubic drainage was attempted. The tenth case died ten months after the operation, having, however, been relieved for a time. To have afforded permanent relief in eight out of ten cases seems to us a most creditable showing.

We cannot forego alluding to the very graceful manner in which Mr. McGill acknowledges as the first surgeon to perform supra-pubic prostatectomy Dr. Belfield, of Chicago, the date being October, 1886.

The discussion which was elicited by Mr. McGill's paper was scarcely less interesting, and the unmistakable bent of opinion was in favor of radical operation in properly selected cases of prostatic enlargement.

Let us hope that American surgeons, many of whom have already performed supra-pubic prostatectomy, will give it the fair trial that it so richly deserves. Surely, the above results invite it.

PHTHISIS VENTRICULI.

THE efforts which are made to mark the advance in knowledge of diseases by corresponding improvement in their nomenclature are by no means always successful. On the contrary, it often happens that an enlightened pathology at once discards a number of unsuccessful terms, invented to set forth the essential anatomical or clinical characters of a disease, in favor of well-worn popular designations. Terms like influenza and chorea embody no scientific conception of the pathological processes which they designate. On the other hand, they convey no false views of the nature of these diseases.

The growth of knowledge in regard to diseases of the stomach, which has been so conspicuous in the last two decades, has given rise to a number of new nosological terms, several of which have no adequate *raison d'etre*.

Meyer, who suggests the name "phthisis ventriculi" for the process characterized by progressive atrophy of the glands of the stomach, points out, in a recent number of the *Zeitschrift für klinische Medicin*, the defects of several of these terms. The term "atrophy of the stomach" is altogether inappropriate for a condition in which the organ is very frequently much enlarged, and occasionally presents, whether enlarged or not, decided thickening of its walls. "Atrophy of the glands of the gastric mucous membrane" is objectionable, seeing that the term atrophy conveys the idea of persistence of the wasting structures, while in the condition under consideration the glands themselves wholly disappear. Atrophy of the gastric mucous membrane is a designation hardly applicable to a process in which finally a mere layer of connective tissue replaces the mucous membrane.

The German "Schwund der Drüsen der Magenschleimhaut," which is about equivalent to "obliteration of the glands of the mucous membrane of the stomach," well describes a condition which is the terminal stage of chronic inflammation of this membrane. It is, however, too cumbersome for ordinary use; nor are the processes by which this condition is brought about adequately represented by such terms as "gastritis atrophicans" or "catarrhus atrophicans." As a matter of fact, phthisis begins when inflammation and catarrh have run their course. Nor are the gastritis and catarrh which lead to phthisis specific processes, since any form of chronic gastritis can under certain circumstances end in complete wasting of the mucous membrane. It is not easy to estimate the confusion to which this use of this word catarrh, in defiance of its etymology, has given rise.

In support of the term "phthisis ventriculi" Meyer calls attention to the fact that the lesions by which the secretory functions of the stomach are impaired are associated with changes in the muscularis, which also progressively impair its motor function, and with other alterations in the mucous membrane which in a corresponding manner decrease its

power of absorption. Thus the three most important functions of the stomach, secretion, movement, and absorption, are progressively abrogated by changes in its parenchyma. Such parenchymatous changes in other organs, accompanied by wasting of the whole organism, are spoken of as phthisis — for example, phthisis pulmonum. As secondary changes in the organism at large follow these wasting processes in the stomach, the author regards the name "phthisis ventriculi" as a designation eminently appropriate, especially in view of the progressive nature of the disease.

The terminal condition which is marked by complete abolition of the secreting structures is best described by Ewald's term, "gastric anadenie."

REVIEWS.

A Text-book of Animal Physiology, with Introductory Chapters on General Biology, and a Full Treatment of Reproduction. By Wesley Mills, M.A., M.D., L.R.C.P. Lond., etc. Illustrated. 8vo., pp. 700.

To anyone who knows of Dr. Mills's thorough work in scientific lines, this book seems to be just what such a student of physiology would write, and to give, as he points out in his preface, an opportunity for the grouping together of certain facts which deal with the study of animal function, and not with human physiology, about which we of course know very little. This has always been a favorite theme of the author, and he has inveighed against the use of the words "human physiology" as applied to text-books for a long time, pointing out that nearly all our knowledge of vital function is obtained from the lower animals. We think, however, that there are two sides to the question, one of which Dr. Mills has overlooked in his attack on the terms commonly employed, namely, that to the vast majority of persons animal physiology is of little interest, and that its entire value depends upon its relation to man. To prevent all fault-finding, the correct title of a physiological text-book should be, perhaps, "Animal Physiology as Applied to Man." So far as the ordinary medical student is concerned, very little embryology is necessary, and yet we find a large part of the book, comparatively speaking, is devoted to this subject, showing once more that the author has placed his stamp upon his work. Still further evidence of the direction of his studies is the consideration of the functions of many of the forms of life far removed from man.

In the article on respiration, we are sorry to note that no notice is taken of Marchwald's work on the nervous mechanism of breathing, particularly in reference to the hypothetical respiratory centres in the spinal cord, in which the author evidently has some belief.

In the article on animal movements, which has of late come to be so important a subject, the work of Mr. Muybridge, which is certainly the most valuable, has also been ignored.

These are some of the faults; let us consider some of the virtues of the book. We find that it is the best one of its character extant, dealing, as it does, in a thoroughly clear manner with every subject which it discusses, and although every part may not seem complete, as a text-book for a student it is assuredly thorough enough. Dr. Mills impresses upon nearly every page the fact that he is a teacher, and apparently recognizes the needs of students to the utmost, making his sentences clear and concise. His illustrations are nearly all of them wisely chosen, and while we think that some of the pictures of the lower forms of life, below the mammalia, might have been left out with advantage, this is not a point wherein lies a fault.

Dr. Mills has written a book which is, we fear, too good for its day. Unfortunately, necessity and desire for gain actuate so many ordinary mortals whose souls have no love for science in itself, that unless a book brings to them some practical suggestions for everyday life, they do not care for it. We doubt very much if the ordinary practitioner can gain much from its pages, and the average medical student has so many other text-books claiming his attention that we fear he will not thoroughly appreciate the one before us. The entire work is unusually well printed and bound, but is blemished by the publishers, who have inserted an illustrated catalogue of their publications which adds, with its index, sixty-three pages to the volume.

Wood's Medical and Surgical Monographs. General Orthopedics, including Surgical Operations. By August Schreiber, M.D., Surgeon-in-chief to the Surgical Division of the Augsburg Hospital. 8vo., pp. 345. New York: William Wood & Co., 1889.

This book, which forms part of the series of Wood's *Medical and Surgical Monographs*, is a valuable addition to the literature of orthopedic surgery. The frequency of deformities, and the great advances which have very recently been made in this branch of surgery, render a monograph on the subject of orthopedics and the modern orthopedic operations of value, not only to the surgeon, but to the physician, for it is the latter who in most cases has charge of the early treatment of these diseases. The first chapter is devoted to a consideration of general orthopedic treatment, mechanical appliances, and the surgical operations for the cure of deformities. In the subsequent chapters the special kinds of deformities and the conditions which produce them are considered in detail.

In the treatment of abscesses resulting from caries of the vertebræ, the author recommends the method of aspiration followed by iodoform injections. The statistics of P. Bruns, who had twenty permanent recoveries among twenty-two cases submitted to this treatment, should certainly encourage us to follow his method.

In the chapter on scoliosis due importance is given to the static form of lateral curvature, or to the curvature caused by unequal length or supporting power of the lower extremities. Dr. T. G. Morton has shown the frequency of this cause of lateral curvature in America, and Stoppel has found the same cause present in 76 out of 230 cases. The illustrations of scoliosis are good, and the discussion of the mechanical forces which produce

not only the lateral curvature, but the spiral twisting is thorough and interesting. As the author states, the conception of scoliosis, as a gradual transformation of the previously well-formed spine under mechanical influences, has at present the greatest number of adherents. We take pleasure in reading the advice as to the importance of early diagnosis and treatment in beginning scoliosis, and we heartily agree with the author when he states that "the indifference with which the anxious mother is quieted by the physician consulted for the 'high shoulder' or the 'oblique attitude' of a child with the statement that this will be 'outgrown,' and spontaneously disappear without even making a careful examination, cannot be too strongly condemned."

Chapter V. is devoted to a thorough consideration of deformities of the extremities. The operations of osteotomy for the relief of genu-varum and genu-valgum are clearly described; and the advice in regard to cases suitable for this treatment rather than for gradual reduction by mechanical appliance, is careful and conservative. The statement that the mortality after Macewen's operation for genu-valgum has been three out of 1384 operations, shows the safety of osteotomy under antiseptic methods.

The bibliography which appears at the end of each chapter is a very interesting feature. Our only criticism is that the references are chiefly to German literature: many American and English authorities being neglected.

Wood's Medical and Surgical Monographs. Vol. III., No. 3, August, 1889. The Treatment of Syphilis at the Present Time, by von Zeissl. The Treatment of Inebriety, by Stewart. Manual of Hypodermic Medication, by Bourneville and Bricon. 8vo., pp. 286.

This is one of the best numbers of this series that have so far appeared. In the first place, it is filled with just what the practical physician wants, namely, studies in the treatment of disease. The article by von Zeissl is, we think, unusually clear and to the point. The various modes of treatment are discussed in a fair and impartial manner; the results reached by each school of syphilographers are detailed, and the value of each method clearly pointed out. We do not think that we have ever read in so short a space such valuable material on this subject.

The article by Stewart on Inebriety in the Higher Classes occupies only eleven pages, and is somewhat disappointing. It attempts to deal with a difficult subject in an easy way, and fails. Most of the measures are only what common sense will dictate, and he suggests no new means of treatment.

By far the most important part of the volume is that on Hypodermic Medication, occupying as it does the greatest number of pages, and giving the reader one of the best *résumés* of this subject that has been published. We think that the publishers have been peculiarly fortunate in having given to the English-speaking practitioner such an interesting and useful work.

Many of the articles for use, mentioned, are extraordinary and never so employed, but as the text deals with everything that has, can and cannot be injected under the skin, it is proper that this should be so. The history of the subject is given thoroughly, without being too long and wearisome, and adds materially to the interest of the article. The translator, Dr. Currie, has added useful comments upon those points where he thought they were needed. The article is one which every active practitioner should read and profit by.

NEWS ITEMS.

Medico-Chirurgical Faculty of Maryland. — The semi-annual meeting of the Medical and Chirurgical Faculty of Maryland was held at Hagerstown on November 12th and 13th. The address of welcome was delivered by Dr. A. S. Mason, of Hagerstown, followed by remarks by the President, Dr. A. Friedenwald, of Baltimore. Papers were read by Drs. J. J. Chisolm, Robert W. Johnson, Edwin Michael, George H. Rohé, William B. Canfield, Joseph T. Smith, Randolph Winslow, T. A. Ashby, S. T. Earle, William Lee, J. N. Mackenzie, and George J. Preston.

Chinese Army and Navy Service.—Cable dispatches state that William N. Pethick, Vice-Consul in charge of the United States Consulate at Tien Tsin, China, has notified the Department of State of an important step taken by Li Hung Chang, Grand Secretary of State for China and Viceroy of the Province in which Tien Tsin is located. Li Hung Chang has decided to establish a medical service for the Chinese Army and Navy on Western models. That he may have the best of these to study, he has asked Mr. Pethick to solicit the help of the State Department in obtaining a complete collection of the present regulations and various official publications for several years past of the medical department of our army and navy, including the organization and management of hospitals and ambulance service, and the Surgeon-General's report on our late war. The proposed service is to be under a foreign Surgeon-General with an adequate staff of assistants. It will include hospitals and dispensaries at various places, a medical school, and native surgeons for the fleet and the military stations of North China. A start will be made, the Vice-Consul says, with a number of young men, educated in the United States several years ago by the Chinese Educational Mission, and who have studied medicine under foreign teachers since their return to China. In accordance with the suggestion of the Vice-Consul, the State Department will ask the War and Navy Departments to provide the documents requested to be transmitted to Li Hung Chang.

The New German Pharmacopœia.—In October the Reichs-Pharmacopöie Commission (Imperial Pharmacopœia Commission) met in Berlin to frame a third edition of the *Pharmacopœia Germanica*, so as to have the work completed for 1890. The scientific discoveries or inventions, and the practical experiences made known in materia medica since the publication of the second edition, will in this forthcoming one be incorporated and rendered available. At the same time it will not undertake, any more than its predecessors, to set forth all those remedial agents which individual German physicians have prescribed and apothecaries have made up. In the preparation of these remedies the most diverse rules and prescriptions have been followed, resulting in inconveniences and errors, sometimes serious to the public

and compromising to the profession. To obviate or minimize this confusion, the German Apotheker-Verein (Society of Apothecaries) has resolved to issue a supplement to the forthcoming Pharmacopœia, which shall deal with all the remedies not given in the official dispensatories, and put the prescriber *au courant* with the latest and most accredited additions to his resources, both as to chemical quality and preparation. The profits accruing to the Society from the sale of this supplement will, it announces, be devoted to a philanthropic purpose.

University of Michigan.—The Ann Arbor *Courier* of October 30, 1889, states that "the special correspondent of THE MEDICAL NEWS credits Dr. Maclean with being in this University nineteen years, when it should be fifteen years. He also credits Dr. Maclean with building up the medical department of the University, when the fact is that the medical department of the University built him up. He was 'discharged' for repeatedly opposing the plans of the Regents of the University, and not because he opposed the retaining of the clinic in the little town of Ann Arbor; and the statement that Dr. Frothingham was elected President of the State Medical Society because of his views favoring the removal of the clinic to Detroit is not true, either. The Doctor was elected to that position because he was entitled to it, having withdrawn the year before in favor of an older man, and also because of his eminence."

Death from Ether.—A death under ether is reported to have occurred at Bellevue Hospital on November 5th. The operation was for abscess in the cervical region. Ten minutes after anæsthetization was begun, asphyxia took place. The kidneys were found, at the autopsy, to be the seat of cystic degeneration.

Resolutions on Death of Dr. C. L. Weed.—At a special meeting of the Deutsche medizinische Gesellschaft of Philadelphia, held on October 17, 1889, at the house of the secretary, the undersigned committee was appointed to convey to the family of our late fellow-member, in the name of the Society, an expression of heartfelt sympathy in their present affliction. The sense of personal loss sustained by the members of the Society, encourages the committee to venture the sending of these words of regret.

Dr. Charles L. Weed was one of the founders of this Society; and its present success is largely due to his untiring energy and to the signal ability with which he contributed to its scientific advance. His attainments were unusual. His premature death broke the promise of a rapid elevation to the highest ranks of our profession. His talents claimed our admiration; his geniality won our friendship. We will cherish his memory, and deplore his loss.

GEORGE A. MUEHLECK,
JOHN S. MILLER,
THOMAS H. FENTON, *Secretary*.

At a special meeting of the Staff of the North Fourth Street Union Dispensary, held October 17, 1889, the undersigned committee was appointed to convey an expression of sincere sympathy to the family of their late co-laborer; and a resolution, indicative of the great loss experienced by them on his death, was adopted.

Dr. Charles L. Weed was chief of the eye and ear department, and his ability and energy built up a most successful clinic in that field. His loss will be keenly felt, both by his patients and colleagues, among whom he was deservedly held in high esteem.

Knowing his character and ability, and high qualities both mentally and morally, we realize most forcibly the great loss his death has been to all, and we can and do offer to his family, in the name of the staff, our most heartfelt sympathy in their affliction.

J. REED CONRAD,
JOHN S. MILLER.

Successful Cæsarean Section.—According to the *Lancet*, DR. MURDOCH CAMERON, obstetrician to the Glasgow Maternity Hospital, has recently performed his third successful Cæsarean section. The patient was rachitic, about 48 inches in height, and had been in labor two days when the operation was performed. Both mother and child were saved.

Recent Appointment.—DR. FRANCIS J. QUINLAN, of New York, was recently appointed Lecturer on Diseases of the Throat and Nose in the New York Polyclinic School and Hospital. He is connected with the Eye and Ear Hospital, and is Assistant Surgeon in the Department of Diseases of the Throat and Nose in the Vanderbilt Clinic of the College of Physicians and Surgeons.

New York Post-graduate Medical School and Hospital.—The Executive Committee of this institution have established a clinic for diseases of the rectum, to be under the care of Dr. Charles B. Kelsey, for the treatment of poor persons suffering from these diseases. Dr. Kelsey will also give clinical instruction in the Post-graduate School on this subject.

It is believed that this is the first institution in New York City to organize such a clinic, which has long been needed. The wide reputation of Dr. Kelsey, founded upon years of special work, will afford a guarantee that the cases will be skilfully treated. Dr. J. Blair Gibbs will assist Dr. Kelsey in this new departure.

The New York Academy of Medicine.—The Anniversary Meeting of the New York Academy of Medicine was held on Thursday, November 21, 1889. The address, entitled, "The Relation of Medicine to some of the Questions of the Day," was delivered by William M. Polk, M.D. This meeting was public, the laity—ladies and gentlemen—being present by invitation.

Yellow Fever at Key West.—DR. JOSEPH Y. PORTER, State Health Officer of Florida, states that about September 21st a case of yellow fever was recognized by the surgeon of the Marine-Hospital Service stationed at this port, in the person of Abraham Horn, a peddler, who was at the time convalescent.

On the 5th of October the same medical gentleman recognized two cases of yellow fever in the persons of Wolff Abraham and his wife; the wife being convalescent, the husband being still in bed.

These above-named cases were reported to Surgeon-General Hamilton as yellow fever. The fourth case was recognized by Assistant Surgeon Geddings, of the Marine-Hospital Service, and Dr. Porter, on the twelfth day of illness, the attending physician, Surgeon Murray, dissenting from this diagnosis.

The fourth and last case is now sufficiently recovered to leave his house, and as it has been three weeks since his seizure and no other cases have arisen in his family, all restrictions of egress and ingress have been removed from the premises.

Every precaution has been used to prevent the spread of the disease, and the infected bedding, and other articles liable to carry infection, that could not be subjected to moist heat have been destroyed and paid for. The premises have also been disinfected and cleaned. The city has been ordered to be cleaned, and all the foul spots disinfected, under the direction of the city health officer, who to-day reports the completion of his task.

At the time and immediately preceding the occurrence of the fever cases there had been an unusually heavy rain-fall at this place, followed by a period of intense heat of about a week. Happily this was of brief duration, and being followed by cool north winds had the effect, to his mind, of arresting any spread of the fever. For the past two weeks the weather has been unusually cool for this place at this season.—*Weekly Abstract of Sanitary Reports.*

Sickness Relief Medical Association.—A mutual benefit organization exists in England for the relief of medical men who fall sick or suffer accident. It is known as the Medical Sickness and Life Assurance Society. It addresses itself chiefly to the junior members of the profession and to those practising in the country districts. It has a capital of $140,000, and is directed chiefly by medical men who serve without pay.

The California State Board of Health.—The legal contest of Dr. J. R. Laine to recover his seat in the California State Board of health, now held by Dr. G. G. Tyrrell, has, according to the *Occidental Medical Times* for November, resulted in the favor of Dr. Laine. However, the defendant will move for a new trial, and delays without end may ensue before the latter can be compelled to surrender his position.

Faith-curing of Contagious Diseases Suppressed.—The Board of Health of Matteawan, New York, having encountered a case of diphtheria that was being neglected by some faith-curing practitioners, declared an immediate quarantine, which was maintained by the police. In this manner the faith-curists were shut out, a reputable physician put in charge of the case, and the child began to improve. Apparently its life has been saved by the expedious action of the sanitary board.

The Paris Exhibition.—American pharmacy has been worthily represented at the Paris Exhibition by Messrs. William R. Warner & Co., of Philadelphia, who were accorded the silver medal of their department (the highest award) for their pharmaceutical specialties.

Danger in the Use of the Telephone.—The frequency with which telephone lines become crossed by electric-light wires carrying strong currents seems to be constantly increasing. Dr. Albert R. Rice, of Springfield, Mass., recently found the wood-work surrounding the telephone in his office on fire, owing to this cause. It was discovered just in time to prevent the destruction of his house. The application of such an instrument to the ear would, of course, produce fatal results, and while many telephones in the large cities have attachments which are supposed to prevent such accidents, the danger is certainly one which should not be overlooked.

Isolation of Dangerous Industries.—The French government is investigating the manufacture of celluloid, which has been found too dangerous to life and property to be unrestricted. Within three years there have been three or more accidents, with loss of life, serious injuries, and destruction of property. The large quantities of gun-cotton at the celluloid works makes the business extra-hazardous, and unfit to be permitted in settled communities. The terrible explosion at a factory in New Jersey, about two years ago, was an unmistakable lesson on the importance of placing such establishments in isolated localities.

The Census of 1890.—Commissioner Porter, of the Census Bureau, has made the following statement regarding the new features that may be looked for in the coming census:

"Owing to improvements in the records of some of the States and to the active coöperation of 80,000 physicians, to whom registers have been sent, the vital statistics will be more complete than it was possible to make them in the census of 1880.

"Among the important new features is a special study of the birth- and death-rates and of the principal causes of death in twenty-four of our largest cities; a special study of the influences of race upon fecundity and mortality, and a special study of the relations of occupation to death-rates and to particular causes of death."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 12 TO NOVEMBER 18, 1889.

The following changes in the stations of medical officers serving in this Department are hereby made:

L. W. CRAMPTON, *Captain and Assistant Surgeon.*—Ordered from Fort Teyon, Colorado, to Fort Sheridan, Illinois.

W. H. CORBUSIER, *Captain and Assistant Surgeon.*—Ordered from Fort Hays, Kansas, to Fort Lewis, Colorado.

IVES, F. J., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Teyon, Colorado, to Fort Sill, Indian Territory.—Par. 3, *S. O. 167, Headquarters Department of the Missouri, Fort Leavenworth, Kansas,* November 9, 1889.

By direction of the Secretary of War, LOUIS M. MAUS, *Captain and Assistant Surgeon,* having relinquished the leave of absence on surgeon's certificate of disability, granted him in S. O. 249, October 25, 1889, from this office, will, upon being relieved from duty at Fort Porter, New York, as directed in S. O. 242, October 17, 1889, from this office, proceed without delay to Fort Stanton, New Mexico, and report in person to the commanding officer Department of Arizona.—Par. 8, *S. O. 261, Headquarters of the Army, A. G. O., Washington,* November 8, 1889.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

OVARIOTOMY AND OTHER CASES.

A Clinical Lecture
Delivered at the Rush Medical College, Chicago, Ill.

BY CHARLES T. PARKES, M.D.,
PROFESSOR OF SURGERY.

[Reported by A. J. OCHSNER, M.D., Chief of Surgical Clinic.]

GENTLEMEN: The first patient I bring before you is a woman aged forty-five years.

About four years ago she first noticed a lump in the lower portion of the abdomen, to the left of the median line. This continued to increase in size, slowly at first, but more rapidly during the past few months. Now, the abdomen is distended to the extent of a six months' pregnancy, and is somewhat more prominent on the left side.

Palpation, percussion, and vaginal examination give the usual signs of an ovarian tumor. Menstruation has been irregular lately, and absent during the past four months, during which time the tumor has increased more rapidly, giving rise to shortness of breath and considerable pain from pressure. The patient has been prepared for operation by liquid diet and the administration of laxatives during the past three days, and an enema given six hours ago. She also has had repeated hot vaginal douches to disinfect the vagina to make vaginal drainage safe should it prove desirable. She has had thorough soap and warm water baths. The field of operation has been carefully washed and a moist two per cent. carbolic acid dressing applied to the abdomen twelve hours previous to the operation.

This preparation of the skin is always made previous to operating and will not again be referred to. The abdominal incision is now made through the different layers of tissue without the use of the grooved director. Upon approaching the peritoneum the tissues on either side of the median line are seized with dissecting forceps and the tissues cut between them. This facilitates the work, as it does not ordinarily require more than one minute to enter the peritoneal cavity, there being no danger of wounding any of the viscera.

A small incision is made at first which can be enlarged if necessary by means of scissors, the finger being introduced into the cavity to prevent wounding of the viscera. Upon opening the peritoneal cavity the characteristic bluish-white surface of the ovarian cyst shows itself. The wound is enlarged to four inches; an assistant holds the abdominal walls in contact with the surface of the tumor while I puncture it with a large trocar. The issuing chocolate-colored ovarian fluid is collected in a pan and measures fourteen pints. The trocar-opening in the sac is now closed with Nélaton forceps, and the empty sac drawn out through the abdominal wound. The tumor consists of one very large and a number of small unopened cysts. The pedicle, which is short and broad, is transfixed by a needle carrying a large double silk thread and tied in halves. The ligatures are cut short at once to prevent loosening by an accidental pull upon them. The shortness of the pedicle made it necessary to cut rather too closely to the ligatures, causing some loosening of the latter and consequent oozing. Before cutting the pedicle the stump was caught on either side by a large hæmostatic forceps. The oozing is stopped by again transfixing the stump and tying in halves. The abdominal cavity is now carefully sponged out and closed with five silk sutures, including all the layers of tissue in the abdominal wall. The wound is powdered with iodoform and a dry dressing of iodoform gauze and borated cotton applied.

NOTE.—Patient recovered without unfavorable symptoms, the temperature never reaching 100°. On October 12th, when first dressed, the wound was entirely healed by first intention and all the stitches were removed. On October 26th, the patient was discharged entirely well.

SARCOMA OF GROIN.

The next case is a man, aged fifty, married, and a carpenter by occupation. His habits, previous history and family history are good.

Eighteen months ago, the patient noticed a tumor in his right inguinal region. This has enlarged constantly, and during the past four months very rapidly. It causes much inconvenience and some pain. The right leg is œdematous. The tumor is hard and apparently pulsating in every direction; this, however, being due to its proximity to, and fixation over the external iliac artery. There is no aneurismal bruit and the femoral artery can be plainly felt pulsating below Poupart's ligament.

An incision seven inches long and down to the transversalis fascia is made directly over the centre of the tumor parallel to Poupart's ligament. The tumor is thoroughly exposed by careful separation of the layers of the transversalis fascia, and is found lying upon and surrounding the external iliac vessels and covered by the iliac fascia. It is the size of a fist and has the appearance of a sarcoma. After dividing the iliac fascia over it, the tumor is easily dissected out, exposing the peritoneum and the external iliac vessels and leaving an enormous hole. The wound is sponged out carefully with dry aseptic gauze, and united with deep silk sutures. No drainage is used. Iodoform, iodoform gauze, and borated cotton constitute the dressing.

NOTE.—On October 12th, wound was entirely healed and stiches were removed. On October 21st, patient was discharged entirely well.

TUBERCULAR TESTICLE.

The third case is a man, forty-five years old, Irish, iron-furnace laborer. Fairly well nourished and of

strong frame. His scrotum is inflamed and on the left side contains a tumor consisting of an enlarged testicle and cord.

The tumor has the appearance of a tubercular testicle, and there is a sinus leading from it discharging pus. The surface having been disinfected, castration is performed, the pedicle being tied with catgut. The wound is cleansed of pus as much as possible by profuse washing with pure warm water. A drainage tube is introduced and the skin united. Iodoform, iodoform gauze, and borated cotton, as in the preceding cases, constitute the dressing.

NOTE.—On October 12th, the edges of the wound had united but were somewhat red, and there was a slight amount of purulent discharge. The stitches were removed and a moist two per cent. carbolic dressing applied and changed daily. On October 19th, wound looked well. On the 26th, patient was discharged, cured.

OSTEOMYELITIS OF TIBIA.

The next case is a schoolboy of fifteen years, badly nourished and anæmic. About six months ago he had an acute attack of what was supposed to be articular rheumatism of the left ankle-joint. There was a very painful swelling at the time, which pointed and was opened by the family physician, by eight different incisions, at different times. The sinuses that were thus formed have been curetted, but without benefit. The probe enters the lower end of the tibia through several of the sinuses, striking denuded bone and soft granulation tissue. The diagnosis is osteomyelitis.

An incision six inches long is made down to the tibia on its anterior inner surface. The shell covering the mass of granulations is freely chiselled away, a quantity of granulation tissue as large as a hen's egg and several small pieces of dead bone are removed. The osteomyelitis reaches the epiphysial line, as the largest fragment of dead bone shows the epiphysial junction.

The whole cavity and the sinuses are thoroughly scraped with the sharp spoon. The entire surface of the cavity, all the sinuses, and the skin are washed vigorously with pure warm water, and dusted with iodoform, the wound is packed with iodoform gauze, and an iodoform gauze and borated cotton dressing applied externally. The Esmarch bandage which has been applied is not removed until the dressing is completed. The leg is to be placed in an elevated position for forty-eight hours.

NOTE.—On October 12th the dressings were removed for the first time, with the exception of the packing. The wound was found perfectly aseptic. The packing was left until loosened by the growing granulations.

ORIGINAL ARTICLES.

THE SURGICAL TREATMENT OF VOLVULUS.

BY N. SENN, M.D., PH.D.,
MILWAUKEE, WISCONSIN;
ATTENDING SURGEON TO THE MILWAUKEE HOSPITAL; PROFESSOR OF THE PRINCIPLES OF SURGERY AND OF SURGICAL PATHOLOGY IN THE RUSH MEDICAL COLLEGE, CHICAGO, ILLINOIS.

VOLVULUS constitutes a well-defined and definite anatomical form of intestinal obstruction. This term is used to designate that form of impermeability of the intestinal canal which results from twisting or rotation of one or more loops of the bowel about its mesenteric axis.

Frequency of its Occurrence.—Volvulus, as compared with some other forms of intestinal obstruction, is quite rare. In 1541 cases of obstruction from different causes, collected by Leichtenstern (Ziemssen's *Cyclopedia of the Practice of Medicine*, American edition, vol. iii.), and analyzed with special reference to the anatomical cause of the obstruction, after deducting 178 due to carcinoma, 33 cases only were due to twisting of the bowel, including twists of both the sigmoid flexure and the ileum. Upon another page the same author gives the result of his examinations of 76 cases of volvulus which he has collected, and of this number the lesion was found in 45 cases in the sigmoid flexure, in 23 cases in the ileum, and in 8 cases in the jejunum and ileum combined.

Predisposing Causes.—Volvulus can only occur where the mesentery of the bowel is of abnormal length, and is, therefore, most frequently met with in the segments of the intestinal tract normally provided with a long mesentery, as the sigmoid flexure and the lower part of the ileum. That the relation of the length of the intestinal canal to the mesentery has something to do in the causation of volvulus has been well shown by Küttner ("Ueber innere Incarcerationen," *Virchow's Archiv*, B. 43, S. 478), who has ascertained from his anatomical researches that in persons who subsist almost exclusively on coarse vegetable food, as is the case with most of the peasants in Russia, the small intestine measure from twenty to twenty-seven feet in length, while in persons of German birth the length varies between seventeen and nineteen feet. The same author has also shown that volvulus is much more frequently met with in Russia than in Germany. As the mesenteric attachment to the posterior abdominal wall must be nearly the same in all individuals, as far as its extent is concerned, the occurrence of volvulus will be favored in proportion to the length of the intestinal canal. The nearer the two bars of an intestinal loop approach each other the narrower the mesentery, and, therefore, the greater the risk of rotation about its axis from causes which disturb the peristaltic movements. Sudden or gradual elongation of the intestinal canal from distention, as we observe it in cases of intestinal obstruction and peritonitis, furnishes one of the mechanical conditions upon which the production of volvulus depends, by disturbing the normal relations which exist between the length of the intestines and their fixed points of attachment. It is not uncommon to find in post-mortem records of persons who have died of peritonitis, mention of volvulus as a secondary condition, and in cases of intestinal obstruction it is by no means rare to find the same condition as a secondary occurrence on the proximal side of the primary occlusion. I have met

with volvulus in two of my abdominal sections, where this lesion could only be accounted for by attributing it to elongation of the intestines from distention. In one case it followed a strangulated hernia. The patient was a young man who had suffered for a week from a strangulated inguinal hernia. On opening the sac the strangulated loop was found to be gangrenous; the incision was therefore enlarged in an upward direction, and the bowel brought down until healthy tissue was reached. The part of the intestine leading downward was collapsed, while the portion on the proximal side was only moderately distended. As this amount of distention did not explain the general diffuse tympanites, it was deemed necessary to search for an additional cause of obstruction higher in the intestinal canal. The abdomen was opened by enlarging the incision in an upward direction. About one foot above the seat of strangulation, a mass of intestinal coils was found twisted upon their mesenteric attachments and firmly adherent. Above this secondary obstruction, the intestines were enormously distended and very much congested. In this case the distention of the intestine, commencing at the internal inguinal ring, had caused elongation of the bowel, which in turn resulted in volvulus, giving rise to a speedy aggravation of the symptoms of obstruction. That the volvulus was not of long standing was evident from the fact that the adhesions were recent, and limited to the part of the intestine implicated in the twist. In the second case the volvulus formed after perforation of a typhoid ulcer. I examined the patient three days after the perforation had occurred, and at that time the symptoms pointed rather to volvulus than perforation and peritonitis. The abdomen was opened and the volvulus readily found. A number of loops of the small intestine had undergone a complete twist around the mesenteric axis, and showed evidences of strangulation, and were at the same time enormously dilated. The diffuse septic peritonitis which was present had been caused by perforation of a typhoid ulcer a few inches above the ileo-cæcal valve. The perforation was closed by suturing, the volvulus corrected, and the abdominal cavity flushed with a weak solution of salicylic acid. The patient never rallied fully from the shock and died a few hours after the operation.

Nieberding ("Beiträge zur Darmocclusion nach Ovariotomie," *Centralblatt f. Gynäkologie*, No. 12, 1889) has recently called attention to another cause of volvulus. He has reported a case which occurred in Bumm's practice, where, after an ovariotomy, a volvulus of the small intestine occurred which proved fatal after a few days. During the operation the omentum, which was adherent to the cyst, was separated and a portion excised. The necropsy showed that the raw surface of the omental stump had formed an adhesion to a loop of the small intestine, and above the fixed point a volvulus was found. He reported another and somewhat similar case which had come under his own observation. A large cystosarcoma of the left ovary was removed, in a woman twenty-nine years of age. Before closing the wound it was noticed that the omentum was so short that the intestines could not be covered by it in the region of the incision. At the end of the second day symptoms of acute obstruction set in, the temperature remaining normal. As the symptoms increased in gravity and the ordinary treatment proved fruitless, the wound was opened and a loop of intestine was found adherent to the left margin of the incision, and after this was separated a volvulus was detected. The bowel was untwisted and its contents forced into the segment further down, beyond the seat of obstruction, the detached loop pushed beyond the reach of the abdominal wound, and the abdomen closed. The day after the operation the intestinal canal appeared to be permeable, and gas escaped per rectum, but evidences of peritonitis set in and the patient died with symptoms of collapse. From the foregoing considerations it is apparent that the following three mechanical conditions favor rotation of the intestine about its mesenteric axis:

1. Long mesentery.
2. Physiological or pathological elongation of the bowel.
3. Intestinal adhesions to the abdominal wall.

Exciting Causes.—Among the exciting causes of volvulus Küttner mentions, as the most important, unequal distribution of intestinal contents and exaggerated peristalsis. He never observed peritonitis in any of his cases, even if life was prolonged for five or six days. He asserts that the complicated forms of knotting of the intestines, which are still described in the text-books as rare but distinct forms of obstruction, are only varieties of volvulus. Grawitz (*Virchow u. Hirsch's Jahresbericht*, B. 1, 1876, S. 284) asserts that the immediate cause of volvulus is to be found in an accumulation of intestinal contents above a constricted portion of bowel; that the distended portion of intestine above the seat of constriction undergoes elongation, and that this elongated portion then rotates around its axis. Henning ("Beiträgezur Kenntniss der Pathogenese des Volvulus," Dissertation, Berlin, 1883) firmly ligated the intestines of animals, and injected water above the seat of obstruction. In the small intestine, the distended and elongated coils above the ligature always showed a tendency to rotate upon their vertebro-mesenteric axes, thus producing a volvulus. In the large intestine, on account of the shortness of the mesenteric attachment, the same experiment caused rupture of the bowel before a volvulus could be produced. These experiments

furnish positive evidence that volvulus of the large intestine cannot occur when the mechanical conditions described as predisposing causes are absent. Henning collected a number of cases of volvulus, scattered through the literature on this subject, where, in the post-mortem description of the twisted bowel, it was distinctly stated that the lumen of the intestine was narrowed by some form of acquired or congenital stenosis, which is only another proof in support of the statement that elongation of the bowel constitutes one of the most important conditions in the causation of this form of intestinal obstruction.

Spontaneous Reposition.—We have reason to believe that a violent peristalsis not infrequently produces a volvulus, but when the bowel and its mesentery are of normal length spontaneous reduction occurs as soon as the peristaltic wave has passed. Such a condition gives rise to abdominal pain and a temporary disturbance of the fecal movement. In animals, when I produced volvulus artificially by twisting an intestinal loop completely around its axis and fixing it in this position by suturing, I was never able to produce obstruction, and usually found, subsequently, that partial reposition had been effected by gradual yielding of the sutures and adhesions. The conditions are entirely different when both the intestine and the mesentery are abnormally long, under which circumstances spontaneous reposition seldom if ever takes place. In such cases the mechanical obstruction caused by the twist is soon followed by dynamic obstruction in the segment of bowel constituting the volvulus, caused by the pathological conditions arising from the strangulation. The mechanical constriction which takes place at the point of rotation produces paresis, venous engorgement, œdema, and gangrene. These secondary conditions are followed by distention of the intestine and accumulation of intestinal contents, which cannot fail to aggravate the mechanical difficulties which initiated the obstruction.

Symptoms and Diagnosis.—Primary volvulus is of sudden occurrence, and when located anywhere above the ileo-cæcal valve it is usually attended by severe pain and other symptoms of acute obstruction. Vomiting is a prominent symptom in volvulus of the small intestine, but is often entirely absent when the colon is the seat of the twist.

Poppert ("Zur Frage der chirurgischen Behandlung des Ileus," *Archiv f. klin. Chirurgie*, B. 39, S. 207) reports a case of volvulus of the sigmoid flexure, which had become twisted 180° around its mesenteric axis, where vomiting never occurred from the beginning of the attack to the fatal termination. He also refers to the statement made by Roser, that in cases of volvulus of this portion of the colon vomiting is a late symptom, or may be entirely wanting. Treves found that this symptom was absent in three out of twenty cases of volvulus which he collected.

In Poppert's case it was shown during life, by the introduction of an elastic tube through which the organ was washed out, that the stomach was empty or nearly so. In volvulus of the sigmoid flexure the pain is often referred to the umbilical region and not to the seat of the obstruction. A circumscribed area of tenderness over the surface corresponding to the circumference of the twisted loop is an early and well-marked symptom. A volvulus once fully developed gives rise to complete obstruction, the violent peristalsis above the seat of obstruction only aiding in rendering the occlusion more complete. Diffuse peritonitis is never met with in cases of volvulus unless it has developed in consequence of gangrene or perforation. Localized plastic peritonitis is, however, of frequent occurrence, commencing in the twisted mesentery and extending from here to the intestine. Such adhesions in cases where a number of loops are implicated in the volvulus, or where knotting of the intestine has taken place, frequently offer serious difficulties in effecting reposition, and after successful reposition tend to reproduce the volvulus unless provision is made by special measures against such an occurrence. The occurrence of gangrene of the twisted loop is announced by a small, rapid, feeble pulse and other symptoms indicative of septic intoxication. Professor von Wahl ("Ueber die klinische Diagnose der Darmocclusion durch Strangulation oder Achsendrehung," *Centralblatt f. Chirurgie*, No. 9, 1889) has recently called special attention to an important diagnostic sign in cases of strangulation and volvulus. Schweninger's experimental investigations have shown that meteorismus first takes place in the constricted or twisted loops of the bowel, and von Wahl has in a number of cases been able to make a positive diagnosis of volvulus by percussion, by which he located a circumscribed area of tympanites, which, on opening the abdomen, was found to correspond to the site of the twisted and dilated intestinal coil. As this circumscribed tympanites is one of the earliest symptoms, it should be sought for and its significance recognized before general tympanites sets in, as at that time a correct diagnosis is most important in enabling the surgeon to adopt timely measures for successful treatment. As volvulus occurs usually in some portion of the colon or the lower portion of the ileum its exact location can be readily determined by rectal insufflation of hydrogen gas. This diagnostic measure is of the greatest importance and value before general tympanites has set in. If the volvulus is located at the sigmoid flexure, only a small quantity of gas can be introduced, and after the distention of the colon

below the seat of obstruction the localized tympanites due to the volvulus will be found a little higher up in the abdomen, the twisted loop of the bowel having been pushed in an upward direction by the distended colon. If the cæcum is the seat of the volvulus the insufflation can be continued until the entire colon is fully distended, but the gas cannot be forced into the small intestine. The effect of the insufflation under such circumstances will be to widen the abdomen without increasing its prominence. If the volvulus is situated above the ileocæcal valve the gas will rush from the colon into the ileum with an audible blowing or gurgling sound, and the distention of the lower coils of the small intestine will cause the hypogastric region to become more prominent. In recapitulation it may be said that the most important symptoms and signs upon which a probable or positive diagnosis can be based are the following: 1. Suddenness of attack. 2. Absolute obstruction. 3. Localized area of tympanites. 4. Permeability of intestinal canal to rectal insufflation of hydrogen gas as far as he seat of obstruction.

Prognosis.—A fully developed volvulus—that is, a half to two complete twists—occurring in a portion of the intestine predisposed to such an occurrence by congenital or acquired causes, is never corrected without direct mechanical assistance, and, if left to itself, invariably results in death from intestinal obstruction, gangrene, or septic peritonitis in a short time. The acuteness of symptoms, and the immediate danger to life, increase as the volvulus approaches the upper portion of the intestinal canal. Death results either from exhaustion owing to the incessant vomiting and defective nutrition, or from the pathological changes which occur in the twisted portion of the bowel; the latter consisting in gangrene affecting the entire loop, or from circumscribed gangrenous spots at the point of greatest pressure, resulting in perforation and septic peritonitis. As the gangrene is the result of pressure or strangulation, its rapid occurrence may be expected when the twist is tight—that is, when the intestinal loop has been rotated once or twice around its mesenteric attachment. Death from any of these causes may occur in a few days, and life is seldom prolonged for more than a week.

Treatment.—As violent peristalsis is not only one of the causes of volvulus, but seriously aggravates the local and general conditions after the accident has occurred, one of the first indications of treatment should be to place the bowel as nearly as possible in a condition approaching physiological rest. No food should be introduced into the stomach, and thirst should be quenched by small pieces of ice. If the vomiting is severe, or if this symptom is absent and there is reason to believe that the stomach is not empty, washing out of the organ by means of a flexible tube is indicated, and this simple procedure is often followed by immediate and great relief. The peristalsis is quieted by the administration of some preparation of opium, and if this is not retained by the stomach morphia is administered hypodermatically. The bowel below the volvulus is evacuated by copious injections, which should be given while the patient is placed in Hegar's position. The patient is to be nourished exclusively by rectal enemata. Are there any known means by which reposition can be effected without opening the abdomen? Jonathan Hutchinson, whose views concerning the utility of laparotomy in the treatment of intestinal obstruction are, to say the least, exceedingly pessimistic, in a recent publication ("Records of Intestinal Obstruction, with Especial Reference to Symptoms and Treatment," *Archives of Surgery*, vol. i., No. 1) again calls attention to the value of his method of performing abdominal taxis in the treatment of intestinal obstruction, irrespective of a probable or positive anatomical diagnosis. His method is described as follows: "The first point in abdominal taxis is the full use of an anæsthetic, so as to obliterate all muscular resistance. Next (the bowels and bladder being supposed to be empty) the surgeon will forcibly and repeatedly knead the abdomen, pressing its contents vigorously upward, downward, and from side to side. The patient is now to be turned on his abdomen, and in this position to be held up by four strong men, and shaken backward and forward. This done, the trunk is to be held uppermost, and shaking again practised directly upward and downward; whilst in this position copious enemata are to be given. The whole proceedings are to be carried out in a *bona fide* and energetic manner. It is not to be merely the name of taxis, but the reality, and patience and persistence are to be exercised. The inversion of the body, and succussion in this position, are on no account to be omitted, for they are possibly the most important of all. I do not think that I ever spend less than half or three-quarters of an hour in the procedure."

As Mr. Hutchinson mentions no exceptions, as far as the nature of the obstruction is concerned, we have reason to believe that he advises taxis as above described in the treatment of volvulus. Taxis has a limited field of useful application in some forms of intestinal obstruction, but in the treatment of volvulus it must be looked upon not only as a useless, but also as an exceedingly dangerous, performance. It is difficult to conceive in what manner such gymnastic exercises could effect reposition, while it is easy to understand in what manner the different movements would increase the rotation. Furthermore, volvulus is rapidly followed by text-

ural changes which weaken, and, finally, destroy, the intestinal walls; and hence taxis, as advised and practised by Mr. Hutchinson, would expose the patient to the imminent risk of producing a rupture of the bowel, without promising the shadow of a hope that reposition would be accomplished. Only one mechanical measure suggests itself to me as offering any inducements in effecting the reposition of volvulus, short of laparotomy. Rectal insufflation of hydrogen gas has already been referred to as a diagnostic measure. In some cases of volvulus the rotation of the bowel around the vertebro-mesenteric axis is often less than one complete circle, and before the loop has become considerably changed by the twist a reduction might be effected by dilating and elongating the bowel below the seat of obstruction, thus bringing the same causes to bear which have produced the displacement, but in an opposite direction. This method of reduction should be practised with great care, in the manner described in my work on *Intestinal Surgery*, page 12, and is, of course, only applicable in recent cases, before the appearance of general tympanites and before the bowel has undergone serious tissuec-hanges in consequence of the strangulation. If this comparatively harmless procedure fails in accomplishing the desired object, laparotomy should be performed at once, as every hour of delay increases the danger and diminishes the prospect of a favorable issue by operative interference. Statistics show a fearful mortality of operations done for the relief of obstruction from volvulus, simply because they were performed too late. Oettingen (Dissertation, Dorpat, 1888) has collected five cases of volvulus treated by the formation of an artificial anus, with the result that all the patients died. Of the cases treated by laparotomy, six recovered and thirteen died. The cause of death in these cases was generally due, not to the operation, but to pathological changes in the bowel, caused by deferring surgical interference too long. Laparotomy, undertaken early in the treatment of this form of intestinal obstruction, will show better results in the future. If reposition of the twisted bowel is accomplished by direct measures at a time when the general tympanites is not excessive and the twisted loop has not undergone irreparable tissue-changes, the prospects of a speedy recovery are as good as after any other intra-abdominal operations which now present more encouraging statistics. Early diagnosis and early treatment by laparotomy are the requirements which will insure success in the treatment of volvulus. Treves, in his paper on "The Operative Treatment of Intestinal Obstruction" (*British Medical Journal*, August 29, 1885), claims that this form of obstruction is only aggravated by forcible rectal injections, as such a procedure will tend to tighten rather than to relax the twist. Of the operative treatment, he says that simple laparotomy is an unpromising procedure, but that in the future he will make the incision in the median line, puncture the gut, and attempt its reduction; if this fails, or the result appears unsatisfactory, he will evacuate the involved gut through an opening in the summit of the flexure, unfold the volvulus, and establish an artificial anus, using the opening first mentioned for that purpose. The advice here given I should like to modify by the following suggestions: 1. Never to puncture the gut. 2. Substitute intestinal anastomosis for the formation of an artificial anus. 3. Evacuate not only the twisted loop, but also the bowel for some distance on the proximal side. The strictest antiseptic precautions are urgently indicated in the surgical treatment of volvulus, more particularly if the operation is performed before gangrene or perforation have occurred, as in such cases the surgeon has to deal, in the majority of cases, with an aseptic peritoneal cavity. The stomach and intestine below the seat of obstruction should be thoroughly evacuated before the anæsthetic is administered.

Incision.—A median incision should always be preferred, even if it has been determined beforehand that the volvulus is located at the sigmoid flexure. The first incision is made sufficiently long to permit the introduction of the hand for the purpose of making a brief manual exploration of the abdominal cavity, with a view to determine the existence and exact location of the volvulus. If the cæcum is found distended, it is proof positive that the volvulus is located at the sigmoid flexure. A brief examination of the sigmoid region, if the volvulus is located here, will show that the bowel composing the volvulus is more distended than the remaining portion of the colon, and the twist in the mesentery can usually be felt and recognized without any difficulty. In cases of volvulus above the ileo-cæcal region, the colon will of course be found collapsed and empty.

If the probable diagnosis of volvulus has been confirmed by this manual exploration, or if, after the examination of the most important landmarks in determining the location of the obstruction, no positive conclusions can be reached, no time should be lost in enlarging the incision sufficiently to permit of ready evisceration. As the intestines are usually found greatly distended, it is of the greatest importance to support them well and to keep them covered with moist warm aseptic compresses, so as to prevent injury, especially at the points where they come in contact with the sharp margins of the abdominal incision. The twisted portion of the bowel, on account of its greater degree of distention, will be among the first loops to escape, and it is thus made easily accessible to direct treatment.

Reposition of Volvulus.—Intra-abdominal reposition of a volvulus is not a feasible procedure, hence the necessity of making a large incision and bringing the twisted bowel within reach of sight and direct manipulation for the purpose of dealing more efficiently and safely with the displacement. The danger incident to a few moments' exposure of the intestines is more than counterbalanced by the risks which attend attempts at replacement through a small wound with the abdomen often distended to its utmost by dilated intestines with congested and fragile walls. Reduction is easily accomplished in recent cases without adhesions, and it is not difficult if the adhesions are of recent date. The intestinal loop is rotated in an opposite direction from that of the twist until the unfolding is completed. As a rule, the segment of bowel of which the volvulus is composed contains but little solid or fluid matter, but is distended to its utmost by gas which has been generated within it by putrefactive or fermentative changes since the accident occurred. If there is any difficulty encountered in the unfolding of the distended loop it is advisable to empty the bowel by an incision at least an inch in length, made parallel to the intestine and on its convex side, as through such incision not only the twisted portion but the intestine above the seat of obstruction can be emptied of its contents—a matter of great importance in such cases. After the bowel has been washed out with a warm solution of salicylated water further escape of intestinal contents is prevented by an assistant compressing the wound during the time the surgeon is engaged in correcting the twist. I believe it is absolutely necessary to incise the bowel in every instance where the abdomen is opened for the purpose of reducing a volvulus. Before the incision is made, it may be necessary to place the patient on his side to enable the operator to draw the bowel beyond the rest of the intestinal coils, so that after the incision has been made the intestinal contents can escape into a receptacle without coming in contact with the prolapsed intestines. This position is to be maintained until the intestinal contents which have accumulated about the seat of obstruction can be poured out through the incision. This pouring-out process is accomplished by seizing the highest loop which it is deemed necessary to evacuate, and, by raising it, pouring the contents by the force of gravitation from loop to loop until the incision is reached. I even deem it an excellent plan not only to evacuate as much as posible of the intestinal contents, but also resort to irrigation of the bowel through the incision with a weak warm solution of salicylic acid. Such thorough evacuation of the bowel at and above the seat of obstruction accomplishes three desirable objects: 1. It facilitates the replacement of the intestines into the abdominal cavity. 2. It directly unloads the distended paretic intestine, and thus favors the return of peristaltic action. 3. It exerts a potent influence in preventing putrefactive and fermentative changes in the intestines after the operation. Before the bowel is returned the incision is closed in the usual manner by Czerny-Lembert sutures. If one or more circumscribed points of gangrene are found they should be buried by suturing over them healthy peritoneum when the bowel is returned, with a fair expectation that after removal of the strangulation the gangrene will not extend. If large portions of the intestines or the entire loop show evidences of gangrene, enterectomy has become an unavoidable evil. If, as is usually the case in such instances, the patient is in a collapsed condition, no time should be lost in the restoration of the continuity of the intestinal canal by circular enterorrhaphy, as the same object is attained in a much shorter time by closing both ends of the intestine, and making a lateral apposition by means of decalcified perforated bone disks.

Intestinal Anastomosis.—Cases may occur where it will be found impossible to unfold the volvulus without tearing the bowel, and the question arises, Is it best to resect and suture the ends of the intestine, or to leave the volvulus and establish a communication between the intestine above and below the obstruction? Mr. Hutchinson (op. cit.) reports such a case. A soldier, aged forty-six, in good health, who was in bed in the hospital, after removal of a fatty tumor, two days after operation complained of pain in the back and abdomen. He had not left the bed since the operation. The following day the pain was less; slightly nauseated; constipation; injections and laxatives produced no effect, excepting to increase the sickness. On the fifth day after the attack the retching and vomiting were persistent and distressing. On the seventh day the abdomen was distended and coils were visible. The symptoms became more and more threatening, until death occurred on the tenth day after the commencement of the attack. I will append the report of the autopsy and criticism as given by the reporter:

"*Autopsy.*—Three inches above the ileo-cæcal valve a coil of small intestine was found twice twisted round a portion of the mesentery, and the canal of the bowel was thus completely obstructed. There were no recent inflammatory changes about this part of the intestine, but from the dense and contracted condition of the bowel where twisted, it must have been for some time narrowed at this point. When I moved aside the coils of intestine which lay in front of the obstruction, more or less adherent amongst themselves by means of old and tough peritoneal bands—and when I endeavored to, and after some sorting of the parts, succeeded in unrolling the twisted canal, *I was glad not to have attempted the operation during the life of the patient, for it would have been impossible.* [Italics my own.]

"*Criticism.*—It seems not improbable that in this case

some old adhesions favored the formation of the twist. It may be alleged that an early operation would have found the unravelment not so difficult; but then it must be remembered that the early symptoms were but slightly marked. The case was not considered a serious one until seven days had passed. It is in order to illustrate the vagueness of the early symptoms that I have quoted this case."

I cannot appreciate the reasons for self-congratulation on the part of Mr. Hutchinson for not having made an attempt to save the life of this patient by surgical interference. The result might have been better, and certainly could not have been any worse. The time will come, and is not far distant, when as much blame will be attached to a surgeon who will look on as an idle spectator at the bedside of a patient whose life is in danger from intestinal obstruction, as now falls upon an obstetrician who permits a parturient woman to die undelivered. In the case above quoted I cannot see any cogent reasons why unravelment in the hands of such an able and careful surgeon as Mr. Hutchinson is known to be, would not have succeeded, if not equally well, during the life of the patient as in the post-mortem room. But supposing that unravelment would have been found impossible or impracticable, two plans of treatment were still left for the operator to pursue, and either of them might possibly have become a life-saving measure. As the bowel presented no evidences of gangrene, resection was not to be thought of, but the continuity of the intestinal canal might have been restored by intestinal anastomosis with permanent exclusion of the volvulus from the fecal circulation. Or, if the operator had no faith in this procedure, he could at least have made an artificial anus above the seat of obstruction. An intestinal anastomosis between the intestine above and below the volvulus by means of decalcified perforated bone disks can be done in a few minutes, and at once restores the continuity of the intestinal canal. If such a procedure is chosen in the treatment of an irreducible volvulus, it becomes necessary to make provision for a permanent outlet of the contents of the isolated segment of the intestine which constitutes the volvulus, as the obstruction of both ends of this portion may prove to be permanent. This can be accomplished by making a second anastomosis between the apex of the volvulus and an adjoining intestinal loop in preference to a loop below the seat of obstruction. Such a procedure will establish with but little additional risk a permanent fistulous opening between the twisted portion of the bowel and the fecal circulation, and will prevent any danger that might arise from over-distention and perforation should the obstruction caused by the volvulus remain permanent. In making intestinal anastomosis the lateral apposition with the bone-plates should be preceded by thorough evacuation and disinfection of the intestine. As a matter of precaution a continuous suture, embracing the serous and muscular coats, can be applied around the margins of the disks, thus obliterating the grooves between their margins. In order to hasten plastic adhesions the serous surfaces which are to be coaptated should be freely scarified.

Shortening of Mesentery.—After the reduction of a volvulus has been accomplished by operative measures, it is desirable to protect the patient in the future against a possible recurrence of the same accident in the same place. As an elongated mesentery plays the most important *rôle* in the production of volvulus, this can be done in a few moments with certainty and safety by shortening the mesentery. Resection of the mesentery is out of the question, as such a procedure would in all probability result in gangrene of a corresponding portion of the intestine. Shortening of the mesentery, however, can be effected by folding the mesentery upon itself in a direction parallel to the bowel and suturing the apex of the fold to the root of the mesentery. By this method the floating bowel is firmly anchored and a recurrence of the volvulus is made impossible. The indications for flushing the abdominal cavity and for establishing drainage are the same as in laparotomy for other forms of intestinal obstruction. As a contribution to the statistics of the surgical treatment of volvulus I will append the following case:

Volvulus of the sigmoid flexure; laparotomy; recovery.—The patient was a man, sixty-three years of age, carpenter by occupation, who was placed under my care at the Milwaukee Hospital by his medical attendant, Dr. Walbridge, October 13, 1889. It was ascertained that he was of good habits, good general health, well nourished, but with no tendency to obesity. With the exception of occasional attacks of constipation, which readily yielded to mild laxatives, he had never been sick. The present attack was not preceded by constipation. In the morning of October 6th, while walking around in his room, he was suddenly seized with a severe pain in the middle and lower part of the abdomen. He sought rest in the recumbent position and the pain gradually subsided. At this time the appetite was impaired, but there was no nausea or vomiting. Toward evening he felt somewhat distressed in the abdomen, a circumstance which he attributed to flatulency, as he felt relieved after loosening his clothing. The following morning he awoke free from pain, but on rising the pain returned. He remained quiet all day and suffered only an occasional attack of colicky pain. He rested well during the night, and on the third morning he was again free from pain. He ate a light breakfast and started to resume work at his shop. On his way, however, the pain returned. On reaching his destination the severity of the pain increased and he returned home. The pain yielded to rest, but the abdomen became more distended. The fourth day he was again able

to be about. As the bowels had not moved since the beginning of the attack he took a dose of rhubarb in the evening. As the cathartic did not act by the following morning he took an enema, which brought away a small quantity of fecal matter. The following two days the pain became more severe and the distention of the abdomen greater, with nausea, but no vomiting. He did not consider himself sufficiently ill to call a physician until October 12th, when Dr. Walbridge was called, who, after examination, diagnosticated some form of intestinal obstruction, and sent the patient to the hospital to be placed under surgical treatment. Examination at this time showed that the temperature was normal; pulse 90, soft, and compressible; copious eructations, but little nausea and no vomiting. According to his statement he had not had a proper movement of his bowels since the attack, and no flatus passed per rectum. Abdomen enormously distended and tympanitic over the entire surface; contour of intestinal coils visible at a number of places. It was evident that the obstruction was located low down in the colon, probably in the sigmoid flexure, and it was surmised from the history of the case and the symptoms presented, that it was caused either by a volvulus or a circular carcinoma. Laparotomy was advised, and as the patient at once gave his consent, it was performed the following day, October 13th, about noon. After he came into the hospital the nurse administered two ounces of castor oil in one dose without any appreciable effect being produced.

Operation.—As the patient was suffering at the same time from a chronic bronchial catarrh, chloroform was used in place of ether as an anæsthetic. The temperature of the room was kept at 85° to 90° F. The most careful antiseptic preparations were made, and during the operation rigid aseptic measures were carried out. The abdomen was opened by a median incision half-way between the umbilicus and pubes, and sufficiently large to permit introduction of the hand. Intra-abdominal manual exploration showed in the first place that the cæcum was greatly distended, consequently the examination was continued by exploring the sigmoid region. Below the sigmoid flexure the colon and upper portion of the rectum were found completely empty and collapsed. The sigmoid flexure could be distinctly felt, and was enormously distended and twisted around its mesenteric axis. The twist in the mesentery could be distinctly felt. No time was lost in useless attempts to effect reduction. The incision was enlarged in an upward direction to three inches above the umbilicus. As the intestines escaped they were covered with hot, moist aseptic compresses and carefully supported by two assistants. The small intestine was greatly distended and extremely vascular; the visceral peritoneum had lost its glistening appearance. The colon had become so much distended and elongated that the transverse portion, in the shape of a horse-shoe, was found displaced in a downward direction to near the pubes. The sigmoid flexure was twisted around its mesenteric axis one complete twist. The twisted portion of the mesentery was the seat of a limited plastic peritonitis which had resulted in adhesions. The part of the bowel constituting the volvulus measured at least eighteen inches in circumference, and its walls appeared to be of the thinness of parchment paper. Reposition was very easily effected by simply turning the bowel in an opposite direction to that of the twist until the normal position was restored. Peristaltic action appeared to be almost completely suspended, both in the large and small intestine. It would have been mechanically almost impossible to return the intestines into the abdominal cavity without producing serious injury, perhaps complete rupture of the bowel, hence an incision an inch in length was made into the colon, where the distention was the greatest. The incision was made parallel to the long axis of the bowel and directly opposite its mesenteric attachment. The part of the bowel which had been twisted contained, besides gas, only a very small amount of fluid fecal matter. The incision did not empty more than this part of the bowel. As a large amount of fluid feces had accumulated above the seat of obstruction, this was evacuated by the "pouring-out process," previously described, and in this manner almost the entire colon was emptied. The incised portion of the bowel was drawn well forward, and held in this position by an assistant during the entire time required for unloading the bowel, and thus soiling of the intestines and abdominal cavity was prevented. As far as could be readily done the intestine was subsequently washed out with warm salicylated water. The wound was closed with two rows of silk sutures. The mesentery of the volvulus was at least eight inches in length and was shortened more than one-half by the method described above. Replacement of the intestines was now accomplished without any difficulty, and after drying the peritoneal cavity with sponges wrung out of warm sterilized water the external incision was closed in the usual manner. No drainage. The customary antiseptic compress composed of iodoform gauze and salicylated cotton was applied and the abdominal walls well supported with adhesive strips. Outside of the adhesive strips a layer of common cotton was applied, and over this a snugly fitting binder. Duration of operation nearly an hour and a half. The patient recovered rapidly from the immediate effects of the operation. At 8 o'clock in the evening temperature was 100.5° F., pulse 110. Free movement of bowels; feces liquid, dark colored, and of a very offensive odor. Complained of no pain but a sensation of soreness in the abdomen.

October 14. Temperature 99.5° F., pulse 90. During the night had four fluid passages of the same offensive character. So far, the patient had not been allowed any food by the mouth. Thirst was relieved by giving water in small quantities and frequently repeated. In the evening the patient felt so well that during a brief absence of the nurse he got out of bed and walked around the room.

15th. Temperature and pulse normal. Imprudence on part of patient did not seem to have resulted in any harm. From this time on the patient was allowed liquid food, and after the lapse of another week was placed on the ordinary hospital diet. With the exception of a small parietal abscess

the recovery was not marked by any untoward symptoms. The patient left the hospital three weeks after the operation in perfect health.

CONCLUSIONS.

1. The predisposing causes of volvulus are either congenital or acquired, and consist in elongation of certain segments of the intestine, abnormal length of mesentery, and adhesions.

2. Irregular distribution of intestinal contents and violent peristalsis are the most important exciting causes.

3. Volvulus is most frequently met at the sigmoid flexure and the lower portion of the ileum.

4. Secondary volvulus on the proximal side of other forms of intestinal obstruction is not a rare occurrence; it is also frequently developed during an attack of peritonitis.

5. As a rule, the symptoms are more acute and intense if the volvulus is located above the ileocæcal region.

6. Vomiting in cases of volvulus of the sigmoid flexure is not a constant symptom.

7. The most important physical sign of volvulus is a circumscribed area of tympanites which corresponds to the location of the volvulus, but this sign is only of value before general tympanites has set in, and, therefore, enables the surgeon in many cases to make an early and positive diagnosis.

8. All cases of volvulus should be treated by laparotomy if reposition cannot be accomplished by rectal insufflation of hydrogen gas.

9. Reposition should not be attempted without evisceration.

10. Evacuation of intestinal contents by a free incision should be practised in every case where general distention of the intestines is present.

11. Enterectomy becomes necessary if any considerable portion of the intestinal wall has become gangrenous.

12. Irreducible volvulus should be treated by establishing intestinal anastomosis with permanent exclusion of the seat of obstruction from the active fecal circulation.

13. Recurrence of volvulus can and should be guarded against by shortening the mesentery by folding it upon itself parallel to the long axis of the bowel and suturing the apex of the fold to the root of the mesentery.

THE USE OF CREOLIN IN CYSTITIS OF THE FEMALE.

BY THEOPHILUS PARVIN, M.D.,
PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN IN THE JEFFERSON MEDICAL COLLEGE.

CYSTITIS in women, though not a frequent disease, does occur occasionally, often then causing great suffering, and may become chronic notwithstanding diligent treatment; in some few of the latter cases the affection is so severe and obstinate that the patient's condition is most pitiable.

The great majority of cases of acute cystitis that have come under my observation have been caused by the catheter, either for the reason that the instrument was not made aseptic before its use, or in its introduction septic material from the vulvar secretions or air was carried into the bladder. These patients have been women in childbed, or those upon whom abdominal section has been made, or an operation upon the external sexual organs, upon the vagina, or upon the neck of the uterus been done.

Professor Winckel, in his monograph, *Die Krankheiten der weiblichen Harnröhre und Blase*, remarks that simple hyperæmias, hemorrhages, and catarrhal conditions of the bladder permit a favorable prognosis. "As the entire inner surface of the bladder can be easily irrigated and without special pain, it is generally possible, in uncomplicated cases, to effect a cure in eight to fourteen days."

In the cure of cystitis, he regards the local treatment as the most important. He begins by washing out the bladder with warm water; afterward he employs lime-water, or mucilaginous decoctions, as flaxseed tea, frequently adding salicylic acid (1 : 1000), or employs a 3 per cent. solution of boric acid. "The injection is made by a Hegar's funnel, not held too high, to which an elastic catheter is attached by means of a rubber tube; the fluid remains in the bladder a few minutes, and then, by

lowering the funnel, is withdrawn. The quantity which can be injected depends upon the age of the person and the size of the bladder, and will vary between one-fourth, one-half, and one litre, the bladder being irrigated one to three times daily. As soon as these injections are not sufficient, I use solutions of nitrate of silver, 1–2–3 : 500, or of tannin 0.5–1 : 100, and employ them for weeks in a similar manner." I have given in full the local treatment advised by Professor Winckel, and also the method employed by him in washing out the bladder. The illustration here presented is of Hegar's funnel, an instrument that is invaluable—I had almost said essential—in

the treatment of cystitis in the female. In using it, let the funnel, tube, and catheter be filled with the solution, which should be warm, and the first held so low that no fluid will escape from the catheter before its introduction into the bladder; this precaution is taken to prevent wetting the patient's clothing, while previous filling the funnel and tube is done to prevent the introduction of air into the bladder.

Having found creolin so valuable as a local application in cervical catarrh, and a mixture so useful in leucorrhœa, and reading the statement made by Chéron in the *Revue Médico-Chirurgicale des Maladies des Femmes*, about a year since, that he had cured a urethritis by injecting into the bladder a two per cent. mixture of creolin, I was led to try the remedy in some cases of cystitis. The first patient had been suffering some months with the disease. I used a two per cent. mixture, producing no pain, and having a very satisfactory result. The second patient had acute cystitis following the use of the catheter after the removal of an ovarian tumor: the nurse was an experienced one, and very careful as to the cleanliness of the instrument, but never used an antiseptic solution for washing the catheter. The inflammation of the bladder was severe; frequent removal of the urine was necessary, and it was very offensive and contained a large quantity of purulent matter. Following the example of Chéron, and emboldened by my previous success, I washed out the bladder with a warm mixture of creolin and water, the proportions being the same as before. The irrigation was followed by violent local suffering, which lasted for several hours; the urine, however, had no offensive odor for half a day, and contained less pus. Next day I repeated the injection, but with only one and a half per cent. of creolin. The injection still caused great suffering, and it was not repeated. Nevertheless a cure rapidly followed, no medicines being used internally; in a week the urine was clear and the cystitis had vanished.

It is quite probable that the strength of the mixture had some effect in causing the rapidity of the cure. Nevertheless I would not again, at the beginning of the treatment of cystitis employ the creolin in so large a quantity, but rather a half per cent. mixture, increasing the strength from day to day as the bladder seemed more tolerant or the disease more obstinate.

The cases which I have mentioned, and two others in which I have used creolin, lead me to believe that it will prove very useful in the treatment of cystitis in the female. It probably is not necessary to irrigate the bladder with the creolin mixture oftener than once in twenty-four hours.

Those who are in the habit of using a mixture of creolin in water have observed that while the mixture is readily made, the drug rapidly diffusing itself in clouds, until a milk-colored compound results, have also noted that after a time a considerable portion of the creolin settles to the bottom of the vessel. I think it is very desirable to find some means which, while not lessening the antiseptic power of the remedy, will render it completely soluble in water, for it is quite possible that the severe suffering which sometimes follows vaginal or vesical injection of the mixture arises from some of the drug being deposited upon a peculiarly sensitive part of the mucous membrane.

NOTE ON ACCIDENTAL HEMORRHAGE.

By W. W. JAGGARD, M.D.,
Professor of Obstetrics, Chicago Medical College, and Obstetrician to Mercy Hospital.

This paper is written as a preliminary note on hemorrhage due to premature separation of the normally implanted placenta. Three typical examples of the condition have recently come under my observation, which I beg to describe with particular reference to causation and treatment.

Frozen section of an undelivered parturient eclamptic (Winter). Premature separation of the normally implanted placenta, *a*; an extravasation of blood behind the placenta, *b*.

Premature detachment of the normally implanted

placenta is so uncommon that both Boivin and La Chapelle have denied its occurrence. Out of 22,498 labors at Guy's Hospital, the anomaly was noted but three times, while in 156,100 confinements at the Rotunda in Dublin it was not observed at all. Goodell, in 1870, was able to collect only 105 cases.

CASE I. *Premature central separation of the normally implanted placenta, the effect of trauma, in a IV.-para at the eighth month. Severe internal and external hemorrhage, without rupture of the amnion. Expectant treatment, spontaneous labor eighteen hours after the injury; delivery of a stillborn child. Recovery.*—Mrs. A., thirty-four years old, American, IV.-para, well-formed, healthy woman, of medium stature, weighing about one hundred and thirty pounds. Delivered of a daughter at term, January 2, 1878; of an abortive ovum of three months, July, 1882; of a son at term, January 6, 1885. Date of commencement of last menstruation, December 6, 1886. Course of pregnancy to time of accident, normal.

The patient, a lady of unusual intelligence, has given me the following account of the probable cause of her illness: "August 7, 1887, about four o'clock in the afternoon, while driving in the park, a horse backed against the side of my Victoria, his head coming almost on my shoulder. A terrible pain immediately passed up my spine into the heart, followed by another in two or three minutes. I went home as quickly as possible, the drive occupying probably three-quarters of an hour. I felt very badly all the evening, slept poorly and could eat no breakfast. I was in great distress after breakfast, and laid down upon the sofa until ten o'clock, when hemorrhage began." The patient did not stir from the carriage-cushion, and the trauma must have consisted in jarring of the entire body from the impact of the refractory horse against the vehicle.

Dr. John E. Owens arrived about noon, and invited me to see the case in consultation. At his request I undertook its further management.

Patient was in the first stage of premature labor, pains frequent and forcible. Inspection showed considerable enlargement beyond the norm of the uterine tumor. This increase in volume was asymmetrical, and largely composed of a swelling of the size and shape of the crown of a Derby hat, limited to the right antero-lateral segment of the corpus and fundus. During the intervals between the pains the fœtal body—outlined with difficulty on account of the tense uterine walls—was found to present by the vertex in the left occipito-anterior position. Active fœtal movement imperceptible; the patient stated that she had not felt motion since the accident. Fœtal heart-beats inaudible. Digital examination revealed effacement of the vaginal portion of the cervix, dilatation of the os externum of two fingers' breadth; commencing formation of the bag of waters, and the vertex engaged within the inlet. Free bleeding from the uterus—clots and fluid blood—was present, about one-half litre of clots being removed from the vagina.

The patient's general appearance gave evidence of serious loss of blood—pallid lips, white skin, rapid, feeble pulse. She was lying flat on her back—a position assumed as much on account of dizziness as by reason of the flooding.

The localized pain, the sudden asymmetrical enlargement of the uterus, the signs of considerable internal and external hemorrhage, the precipitation of labor, coming on immediately after bodily injury, all pointed to premature detachment, probably complete, of the normally implanted placenta. The relation of the head to the lower uterine segment, determined by sweeping the finger within the cervix around the presenting part, excluded placenta prævia. During the interval between pains, the circumscribed enlargement of the right antero-lateral segment of the corpus and fundus persisted relatively hard and solid, while the remainder of the uterus became somewhat flaccid. This lump was looked upon as composed of the placenta and blood-clots, separating the organ from the walls of the uterus—an opinion confirmed later by the perfect symmetry of the uterus when emptied.

The nature of the case was so clearly marked that there was no occasion to think of rupture of the uterus, nor of extra-uterine pregnancy.

As uterine contractions were frequent and forcible, and as the external hemorrhage had diminished, it was deemed best to stand by and observe the progress of the case before interfering. The pain steadily increased in force and frequency, the head descended to the pelvic floor, the bag of waters ruptured spontaneously, discharging liquor amnii unmixed with blood, and labor terminated without assistance some six hours after its beginning. For obvious reasons, chloroform was withheld, and the delivery was uncommonly painful.

Puerperium uncomplicated, except by a persistent cephalalgia referred to anæmia, which finally disappeared under the exhibition of iron. At the time of writing, the patient is in excellent health, but she has not since become pregnant.

The fœtus, a well developed male, corresponding to the eighth month, still-born; rigor mortis marked. The afterbirth, along with three litres of blood-clots, spontaneously expelled. The maternal surface of the placenta was thickly covered with firmly adherent blood-clots of recent origin. Upon washing off these clots, the periphery was found smooth, covered with the gray layer of decidua, while the central portion was ragged and torn. The decidua was adherent to the chorion læve, normal. The aperture in the amnion, through which the fœtus passed, was small and equidistant from the borders of the placenta, indicating the high attachment of this organ.

In this case, then, a copious hemorrhage took place behind the centre of the placenta, which peeled off this organ from the uterine wall, and became external by seeking the path of least resistance between the decidua vera and chorion læve. The process must have been purely mechanical, and not in consequence of a sudden decrease in the area of

the placental site, nor of diminution of intra-uterine pressure, nor of dilatation of the lower segment of the uterus.

The urine was perfectly normal, and the careful examination of the placenta and membranes, as well as the antecedent and subsequent history of the case, furnished no evidence of the presence of decidual endometritis (J. Veit). Moreover, it is unnecessary to invoke unusual fragility of the utero-placental vascular connection in the explanation of the bleeding, seeing that a cause adequate to the effect is presented in the severe concussion, even without the adjuvant action of fright. Furthermore, the immediate sequence of the separation of the placenta upon the reception of the injury, before the beginning of labor, must be regarded as demonstrative of this causal nexus.

The cause of fœtal death was probably asphyxia, and not hemorrhage, since the integrity of the fœtal bloodvessels may be assumed (B. S. Schultze, Runge).

Case II. *Premature separation of the normally implanted placenta in consequence of hydatidiform degeneration of placenta in a II.-para at eighth month. Severe internal and external hemorrhage without rupture of the amnion. Accouchement forcé; delivery of a dead fœtus; manual removal of the placenta. Recovery.*—Mrs. B., twenty-seven years old, American, II.-para; strong, well-formed woman; tall, weighing about one hundred and forty pounds. First child, a girl, five and one-half years old. Patient could not give the date of last menstruation, but thought she was about eight months advanced in her second pregnancy.

During the night of June 15, 1888, a severe uterine hemorrhage occurred suddenly, without pain, and in the absence of any apparent cause. Dr. J. A. McGaughey was called, but before his arrival the bleeding ceased. After removing the clots that distended the vagina, and changing the bed-linen saturated with blood, Dr. McGaughey advised rest in the horizontal position, and administered a little opium. He remained in the house until morning. In a few days the patient was up and around as usual. Two weeks later Dr. McGaughey asked me to see the case, in consultation. The uterus corresponded in size to the eighth month, and the fœtus was found presenting by the vertex in the first position. Neither fœtal heart-beat nor active fœtal movement was detected. *Per vaginam* the head could be felt above the inlet (*caput balotabile*), and the placenta was plainly absent from the lower uterine segment. The vaginal portion of the cervix had been lacerated on each side during the first confinement, but showed no change suggestive of impending labor. Urine normal. The opinion was expressed that the bleeding had its origin in partial detachment of the normally situated after-birth, and the patient was advised to go to bed. Sunday night, July 1st, a severe uterine hemorrhage occurred, suddenly, painlessly, and without apparent cause, as in the first instance. Dr. McGaughey and I were summoned. The woman was not dangerously anæmic, but a free flow of blood had saturated the bed-clothing, and the vagina was filled with large clots—old and recent. The vaginal portion of the cervix was unchanged, and uterine contractions absent.

The life of the fœtus being despaired of, and the state of the woman being critical, it was determined to empty the uterus at once. The patient was placed on a table, and Dr. McGaughey gave her chloroform. The bladder being emptied, and the accessible genital tract irrigated with sterilized water, it was found that the index-finger passed with ease through the cervical canal up to the presenting part—a distance of four centimetres. Two, three, four fingers, and, finally, the cone of the half-hand, were successively introduced, until, in the course of thirty minutes, it was thought that the cervix was dilated enough to permit the passage of the child's head without much risk of still further tearing the vaginal portion. The fœtus was then turned by the feet, after Braxton Hicks's plan, the amnion ruptured and a dead fœtus extracted very gradually by the Smellie-Veit method. The liquor amnii, excessive in quantity, was unmixed with blood. During the operation, which lasted nearly one hour, free hemorrhage continued, but upon delivery of the fœtus the wound contracted and the bleeding stopped.

Upon attempting to express the placenta, uncommon difficulty was encountered, so that at the expiration of twenty minutes one hand was introduced within the cavum uteri. The placenta was found attached by its inferior border to the right side of the corpus, near the fundus, while the membranes were intimately adherent to the uterine wall lower down on the same side. The placental edge was easily separated, but it required some time and care to detach the membranes. About one litre of old and recent clots was turned out along with the after-birth.

After the evacuation of the uterus ergot was exhibited hypodermatically, and the fundus gently rubbed until the organ assumed its normal tonus.

Puerperium normal. (The husband has informed me that his wife became pregnant for the third time in June last, but miscarried at the end of the fourth month, in consequence of fright. I have been unable to obtain the ovum, or to gain exact particulars of the event.)

Fœtus female, double harelip, second and third toes of right foot webbed; showed signs of commencing maceration; weight, 822 grammes; length, 33 cm. Cord, 80 cm. in length, normal. The placenta, typical example of extensive hydatidiform degeneration, with old and recent clots intimately adherent to the maternal surface. The hand in the uterine cavity demonstrated the fact that in this case the myxoma was not of the destructive, interstitial character (R. Volkmann). Upon washing off the clots, the maternal surface was seen to be broken up, apparently by the force of the hemorrhage. The decidua, chorion, and amnion, closely united, opaque, greatly thickened, roughened, and tuberose, showing the presence of universal chronic interstitial

decidual endometritis. Weight of placental mass, 399 grammes. The aperature in amnion, through which the fœtus passed, was at the pole of the ovum opposite the placenta. This fact, taken with the actual feeling of the placenta by the hand within the cavum uteri, demonstrates the high or normal placental site.

The origin of the bleeding may have been either fœtal or maternal, or both, since the chorion frondosum as well as the decidua was the site of very marked anatomical changes, quite sufficient to explain rupture of the vascular tunics. The process of placenta separation, so far as spontaneously accomplished, must be viewed as purely mechanical as in the first case, since at the time of occurrence the placenta was normally implanted, the uterus perfectly quiescent, and the amnion intact.

Technically, the plan of treatment adopted in this case ought to be designated, *Accouchement forcé*, since it comprehended "a series of obstetric operations, following the one upon the other, with the object of complete removal of the entire ovum from the uterine cavity at a time when labor had not begun and when the cervix had not commenced to dilate" (Kilian). But the name of "forced delivery" parts with some of its harshness, and the operation itself loses much of its traditional barbarity, when the need of prompt action is urgent and when the cervix is the soft, plastic organ of a multipara. In this particular case, although labor had not commenced, still the lower uterine segment was formed, the short, soft, vaginal portion the site of a bilateral laceration, and the cervical canal easily traversed for its entire length by the index finger. The indication for immediate arrest of bleeding was clear and pressing. Moreover, the extraction of the child was performed slowly. Finally the patient made an excellent recovery, and examination of the vaginal portion some weeks later revealed no aggravation of the original tear.

CASE III. *Premature, central detachment of the normally implanted placenta, from trauma, in a primipara, at the seventh month. Severe internal and slight external hemorrhage without rupture of the amnion. Artificial induction of premature labor by intra-uterine colpeurysis, spontaneous delivery of a dead fœtus; recovery.*—Dr. Frank Cary has kindly written the following history:

Mrs. X., American, thirty years old, married two years, first pregnancy, medium stature, weight one hundred and ten pounds. Date of commencement of last menstruation December 30, 1888; quickening April 30th. Course of pregnancy up to the time of the accident normal. August 5th the patient drove all the morning: in the afternoon she took a long walk. During the walk, on suddenly elevating her foot a considerable distance to tie her shoe-string, she felt a sharp pain in the region of the abdomen. Half an hour later, on reaching home, irregular pain set in, which she did not regard as "labor pains." At this time there was a slight hemorrhage. At midnight Dr. Cary was called. He found the uterus enlarged beyond the degree in correspondence with the time of gestation, in a state of tonic contraction that persisted throughout the night. Hemorrhage from the uterus was slight and the vaginal portion of the cervix unchanged; fœtal heart-beats not audible. The patient was placed upon her back and morphine exhibited hypodermatically. At eight o'clock the next morning the external hemorrhage increased slightly in severity, and Dr. Cary asked me to see the case in consultation. The uterine tumor, symmetrically ovoid in shape, now extended to the ensiform cartilage and the lower borders of the false ribs, the uterine walls appeared tense, like a drum-head, rather than contracted, as in a tonic spasm. Fœtal heart-beats and active fœtal movements not perceptible. On account of the extreme distention of the uterus, it was impossible to palpate the placenta, or the fœtal body. Labor pains were notably absent.

Upon vaginal examination, the head was found filling out the lower uterine segment, caput mobile and about to engage within the pelvic inlet. The vaginal portion of cervix—3 cm. in length, relatively dense, os externum passable by the tip of the index finger—showed signs of beginning effacement and dilatation. Blood was oozing in a small stream through the os externum, and clots were felt by the finger-tip in the cervical canal.

The woman's blanched lips, pallid skin, feeble, frequent pulse, and tendency to syncope indicated that considerable intra-uterine hemorrhage had taken place or was occurring.

The nature of the condition seemed to be perfectly clear—intra-uterine hemorrhage from complete or partial detachment of the normally implanted after-birth. This diagnosis was based upon a number of particular facts—the history of pain localized in the abdomen following upon muscular exertion; the sudden, considerable, symmetrical enlargement of the uterus; the abrupt cessation of active fœtal movements; the disappearance of the heart-beats and the external hemorrhage. The relation of the head to the lower uterine segment, completely filling it out, and the absence of any body like the after-birth upon palpation of the convex vault of the vagina, negatived the notion of placenta prævia.

The indication for treatment was also plain—the evacuation of the uterus, and the arrest of hemorrhage by the natural mechanism of contraction and retraction. It was feared that simple puncture of the amnion, and more or less sudden diminution of intra-uterine pressure, in the case of a greatly overdistended organ with a relatively unchanged vaginal portion, might result in an increase of the internal bleeding, notwithstanding the manual compression of the uterus through the abdominal parietes and the use of ergot. Moreover, recent experience has demonstrated the feasibility, and provided the means, of the safe and rapid dilatation of the normal cervix uteri during the second half of pregnancy.

Although the urgency of the indication was ad-

mitted, it was deemed permissible to observe the case for a short time, in the hope of the spontaneous occurrence of premature labor. At the expiration of two hours, as no sign of labor pains appeared, and as the uterine tumor had grown slightly larger, it was determined to interfere.

Accordingly, the woman was placed on a table in the position for lithotomy. After emptying the bladder, the vagina and lower cervical canal were thoroughly irrigated with sterilized water. Then, after a little preliminary dilatation with the index finger, a sterilized Barnes's rubber bag, No. 2, wrapped around a Hegar's bougie and anointed with vaseline, was passed through the cervical canal until it was securely placed within the lower uterine segment, between the head above and the undilated vaginal portion of the cervix below. Tepid water was gradually injected into the water bag until the lower uterine segment was put upon the stretch. In this way, it was possible to substitute adequately the bag of water, not yet formed. Care was taken to expel bubbles of air, by allowing a little of the water to run out after each injection. By degrees, four teacupfuls of water were introduced within the bag, changing its characteristic shape into that of a globular balloon about eleven centimetres in diameter. At the same time, the tube from the bag was drawn taut so as to cause the fluid wedge to descend the cervical canal after the fashion of the normal bag of waters. Uterine contraction became perceptible in three-fourths of an hour, and the increase in general intra-uterine pressure produced a sensible effect in driving the tampon still further down into the undilated cervix. At the expiration of an hour, the lower end of the balloon appeared at the os externum, followed by larger peripheries, until the bag passed out of the effaced and fully dilated cervix into the vagina, whence, in its distended shape, it was withdrawn by gentle traction through the vulvar orifice, two hours after it had been introduced. Upon the escape of the bag from the vulva, some inconsiderable loss of blood occurred. Upon examination, the cervix was found effaced and completely dilated; the bag of waters, perfectly formed, protruding into the vagina, and the vertex presenting in the left occipito-anterior position.

Labor pains being strong and efficient, and the head securely plugging the cervical canal, the amnion was ruptured and the liquor observed to be unmixed with blood. Spontaneous delivery of dead child and placenta occurred one hour later. About three litres of large blood-clots, all of recent origin, were expelled with the placenta. No anæsthetic was used, but the patient complained of no unendurable pain until the head was about to pass the vulvar orifice. Retraction of the uterus, although normal, was reinforced by ergot and massage, as in the first two cases. Puerperium normal. At the end of two weeks, when the patient rose from her bed, Dr. Cary examined the vaginal portion of the cervix and reported a trivial fissure of the os externum, one centimetre in length, on the right side, easily within the physiological limit.

Fœtus, female, well-formed, marked rigor mortis; weight 1701 grammes; length 45 centimetres; placenta and membranes normal in structure—no anatomical evidence whatever of antecedent endometritis; weight 284 grammes. The maternal surface of the placenta presented the same anatomical picture as that described in Case No. I. That the placenta occupied its normal site is evident from the fact that the rent in the membranes through which the fœtus escaped, was at the pole of the ovum opposite to the placenta. It is fair to postulate in this case, the same source of hemorrhage, the same mechanism of placental separation, and the same mode of fœtal death as that mentioned in detail in Case No. I.

From the point of view of etiology, the first and third cases are of special moment, since they show that premature separation of the normally implanted placenta sometimes occurs as the effect of trauma, not necessarily severe, in the absence of textural changes in the decidua or fœtal envelopes. The dominant significance of inflammatory change of the decidua in the determination of this accident has been abundantly demonstrated by J. Veit, Winter, Fehling, and others; so that in the second case the chief point of interest consists in the nature of the condition, myxoma of the chorion frondosum, uncommon so late in pregnancy.

Concerning treatment, the first case shows that spontaneous labor may occur so soon after the detachment of the placenta that interference is not required in the interest of the mother. The second and third cases, respectively, illustrate the value of *accouchement forcé* in multiparæ, and of intra-uterine colpeurysis in primiparæ, when labor is not imminent and when the mother's life is threatened from loss of blood. All three cases indicate that the accident is commonly fatal to the fœtus, but that the maternal death-rate need not be large if the cases are seen in time and if the conditions are favorable for operation.

2330 Indiana Avenue.

REMARKS ON SLIGHT CONTINUED DIARRHŒA AND ASTRINGENT INJECTIONS IN ITS TREATMENT.

By WILLIAM PEPPER, M.D.,

PROVOST AND PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE AND CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

I have elsewhere spoken of slight continued diarrhœa as occasionally the cause of irregular continued fever, which is doubtless dependent upon the local catarrh producing the intestinal disturbance. In these cases the general health suffers markedly, and the general symptoms are, of course, more prominent than where such slight diarrhœa is afebrile in its course. Indeed, in many cases, the habitual looseness of the bowels is of so slight a degree, that it can scarcely be regarded as more than one symptom of intestinal dyspepsia; but a careful study of the evacuations will usually show conclusively that

in addition to the imperfectly digested matters, and the excessive amount of serum, there is, at least occasionally, a notable amount of gelatinous or stringy mucus, demonstrating the fact that, either as cause or effect, local intestinal catarrh exists. I fancy all must meet, as I often do, with cases where such slight local intestinal catarrh has existed for a considerable period, attended with progressive failure in flesh and strength and color, and yet with few or no digestive symptoms, save that daily, or with few exceptions, the evacuations are liquid. Such patients may scarcely make mention of this intestinal condition. They may come to you complaining of the failure of general health; they may even say in response to your question that the action of the bowels is very regular, so that it is only upon questioning that one learns that the daily evacuation is of a diarrhœal nature. Of course, more frequently the condition is better appreciated by the patient, and they will report that for many months they have been in the habit of being disturbed early in the morning, and even being awakened by an urgent call to stool, when the movement passed is of a liquid or semi-liquid character. This may be the only movement during the day, or there may be one or more shortly after breakfast. There is occasionally at the same time abdominal discomfort, or quite sharp colicky pains. During the remainder of the day the patient may be quite comfortable and free from any disturbance or unpleasant sensations. Appetite may not be impaired; and I have frequently had such patients consult me after a continuance of such a condition for months or even for several years, and had them state that their diet continued unchanged, and that they practically ate everything they desired. In other instances, the more observant patient will have noticed that certain articles of food or certain beverages are apt to be followed by a greater degree of subsequent disturbance. Upon the whole, however, the influence of diet is rarely recognized as being of much moment. During this time there is a slowly progressive failure in general tone and condition, easily explicable by the fact that there has been a daily loss of a certain proportion of nutritious matter, and that the long existing local irritation has exerted an injurious reflex effect upon the system. Anæmia develops to a high degree, and there is loss of strength, so that exertion causes fatigue more readily. There is undue sensitiveness to cold and damp, and if the patient has observed closely he will have detected that the degree of diarrhœa is very subject to to atmospheric influences.

The tongue is usually clean, and gastric digestion well performed. The abdomen is often full, and on ordinary palpation may appear indolent everywhere. Careful palpation with the tips of the fingers will, however, frequently show points of tenderness over the colon, especially in its descending portion. The evacuations, as already stated, vary in number, amount, and consistency. There may be days when well-formed stools are passed, or days may pass without the bowels being moved. Usually, however, there is at least one evacuation daily of distinctly less consistency than normal, and careful and repeated examination will show the presence of an undue amount of intestinal mucus. When a slight cold has been taken, the only evidence may be, not in any catarrh of the air-passages, but solely in a slight increase in the looseness, and in the appearance of a much greater amount of mucus for two or three days. It generally happens that such patients will report that they have received considerable medical treatment for the condition without being relieved, having taken a great variety of astringents, and having been placed upon a great variety of diets, but all without effecting any permanent improvement. The degree in which the general health has suffered varies greatly; sometimes the patients appear in good condition, while at other times their appearance strongly suggests grave organic trouble, or even malignant disease.

As an illustration of the more severe results of this trouble, the following may be quoted from a very large number of cases in my case-books:

Mrs. C., of Elk Co., Pa., was never very strong herself, and had been weakened by domestic griefs. She was subject to intestinal dyspepsia, and during the spells of this would sleep badly. She consulted me in 1886, and six years previously she had catarrhal fever, and since then frequent diarrhœa, and for the previous year this had been almost constant. Her stools were habitually thin. They varied from two to five a day, and were moderate in amount. There was rarely any pain, and there was no soreness on ordinary examination. Her appearance indicated grave malnutrition, and suggested deep-seated organic or malignant disease. Examination of the abdomen gave negative results, with the exception of points of tenderness along the descending colon. The urine was normal. The heart and lungs were healthy.

Examination of the rectum showed no ulceration. She had pursued many varieties of treatment, having consulted a number of physicians, and had obtained temporary relief from systems of restricted diet, or from astringent remedies, but the trouble always returned. Her gastric digestion was fair. I instructed her carefully in every detail of personal hygiene, and excluded from her diet all fruit, acids, and rich or indigestible articles. She took for breakfast finely ground grits with a chop or small piece of steak, stale bread with a small amount of butter, and a glass of milk and hot water, equal parts, slightly sweetened. For dinner she took beef or mutton roast or broiled, or chop or steak, or soft egg, boiled rice, or macaroni, or tapioca, stale bread, and, as at breakfast, a glass of cambric tea, and for dessert a little simple pudding. For supper, soft egg, stale bread and

butter, and cambric tea. Rigid care was given to her dress, to the avoidance of draughts, to the restriction of night air admitted to her chamber. A broad flannel bandage was worn around the trunk over the abdomen. Each day, after the first movement, she injected one ounce of warm water containing one or two grains of sulphate of zinc, with from five to ten drops of deodorized tincture of opium, according to the amount of looseness. She lay down for half an hour after this injection, and always retained it, and she was also directed to lie down and rest after each meal. Internally she took a powder of six grains each of bismuth subnitrate, and of Scheffer's pepsin, one hour after each meal. The injections produced an immediate good effect, and she was soon able to omit the bismuth and begin the use of emulsion of cod-liver oil, with liquor acidi phosphorici. Her improvement was very gratifying, and in the course of two months the diarrhœa was entirely under control. She was unable to bear either iron or arsenic even in the smallest quantities. But by continuing careful hygiene and diet she has regained good health, and has had no return of diarrhœa.

The point which seems especially interesting in these cases is the prompt benefit derived from small astringent and sedative injections, even when careful examination shows that there is no ulceration of the rectum. Examination of this part should always be made, but in the vast majority of cases nothing would be detected. The condition is apparently a circumscribed catarrh of the colon, especially in its descending portion. The amount of liquid I habitually use in the injections is too small to reach directly even this part. It is altogether probable that a larger part of the success in treatment is due to rigid care in details of personal hygiene and in diet. The gastric digestion is not impaired by the use of astringent or sedative remedies by the mouth, and only such remedies are given as will improve this digestion, and help nutrition. But after all allowance is made for this, the fact remains that in these cases of continued slight diarrhœa from catarrh of the lower colon, remarkable benefit will be found from the use of small mild injections such as above named. I have even had the extraordinary statement made to me by a patient who complained of slight daily looseness for years, for which he had tried change of climate, and many physicians, that the trouble was completely and permanently arrested after five or six such injections. I never use more than two ounces of liquid, or more sulphate of zinc than one and a half, or, at the most, two grains to the ounce of water, and usually less. The amount of deodorized laudanum is graduated to the degree of looseness. A second injection, later in the day, given a few minutes after one of the subsequent movements may be required in more severe cases. These remarks do not apply to more grave cases of chronic diarrhœa, nor to cases where the lesion is in the upper bowels. I refer only to the cases described in the above remarks. But observation will show that these cases are numerous, that they often prove rebellious to ordinary methods of treatment, and that the proceeding here advised is very useful.

CLINICAL MEMORANDA.

SURGICAL.

A Case of Cystitis, Pyelitis, and Perinephritis.—My excuse for reporting the following solitary case is the unusual train of symptoms, the particularly happy result following the lumbar incision, and that it may perhaps throw light on some obscure case with which a fellow practitioner is wrestling:

Mrs. F., æt. twenty-six years, became pregnant with her first child in August, 1885. She was the subject of an unusual amount of vomiting, and through the entire nine months apparently vomited everything she swallowed. Certainly she had constant vomiting, ended only by her accouchement.

There were no other annoying conditions; urination was frequent, but not more so than is usual, and there was no incontinence or dysuria.

Labor came on during the evening of April 19, 1886. Pains rapidly increased in force. The head was delayed when partially rotated, and forceps were used to end the labor. The forceps were on the head certainly less than fifteen minutes. There was a slight tear in the perineum which was immediately stitched. The urine was drawn with a clean silver catheter about noon the following day.

The catheterization gave rise to an unusual amount of pain, and *pus* was withdrawn with the urine. A soft-rubber catheter was used at the next catheterization, but gave about as much pain as the silver one; pus being withdrawn this time also.

The pain caused by the use of the catheter was so great that it was not employed again, but when the urine was passed voluntarily the dysuria was frightful. Micturition became frequent, and was dreaded by the suffering patient.

The case was viewed as one of puerperal cystitis, but the usual remedies were absolutely without effect.

The patient was in her room for four weeks, and a greater part of the time entirely quiet. As soon as any movement occurred urine was voided with frightful pain and tenesmus. When the sufferer went about her household duties she was forced to use a napkin, for walking, rising from a sitting posture, or jolting in a carriage, caused an uncontrollable desire to urinate, each time accompanied with the terrible pain.

Systematic washing of the bladder was undertaken, but with no better results than with the administration of internal remedies. The only relief obtained was from the injection into the bladder of a solution of cocaine, twenty grains to the ounce. About half a drachm of the solution was used at each injection. The patient was taught to use the syringe, and in that way could get some hours of comfort. Sometimes the application of a pledget of absorbent cotton soaked in the cocaine solution and applied to the urethral outlet would quiet the bladder. As soon as the effects of the cocaine wore away, how-

ever, the pain returned, so the bladder was almost constantly under the influence of the drug.

During the autumn of 1886, about six months after the labor, the patient was suddenly seized with severe pain in the region of the right kidney. The pain was so intense that it caused syncope, but was speedily relieved by a hypodermatic of morphia. This pain occurred at varying intervals until the end of the trouble.

In the spring of 1887 she again became pregnant, to be delivered in January, 1888. It may be remarked that marital intercourse was always excessively painful. The second child presented by the breech, and the labor was short and without accident. After this the pain increased to such an extent, and such large doses of cocaine were necessary to control it, that it was decided to stretch the urethra.

Dr. William Taylor performed the operation in April, 1888. The bladder was carefully examined, was found much thickened, bleeding profusely on being touched with the finger, but no growth was discovered.

Forty-eight hours after the operation the patient was seized with a chill, and great pain and tenderness over the right kidney. There was no dulness in this region, and the pain and tenderness gradually disappeared.

The effects of the operation were gratifying. There still remained a great amount of burning and there was dribbling, but the almost unbearable tenesmus disappeared and did not again return. The amount of ardor urinæ was so great, however, that cocaine continued to be used, though in greatly lessened amounts.

During the following months pure blood, in small quantities, was passed without much pain. The urine was repeatedly examined. Pus was always found in large quantities and some blood, *but never any tube-casts.*

The case dragged along, sometimes better, sometimes worse, until December 29, 1888. On that day the patient was again seized with a chill, and pain and tenderness over the right kidney. The next day her temperature was 102°. There were still pain and tenderness; the amount of the urine was diminished to less than a pint in twenty-four hours. It was almost free from pus and still without tube-casts.

At this juncture, Dr. Ross Bunting saw the patient with me, and continued in attendance until her recovery.

A diagnosis of occlusion of the ureter was made. The pain still continued, tenderness increased, and the temperature gradually rose to 103°; at which point it remained almost constantly.

Professor William Osler was called in, and made a careful examination, but failed to find any fulness or increased dulness in the region of the kidney. The septic condition remained, and the patient failed steadily.

Professor Osler saw her frequently, but we were unable, from physical signs, to determine positively the presence of pus. At the end of the third week, however, there was increased dulness and the edge of the kidney could be felt in the flank.

Professor Agnew saw the case at this juncture, and, with the assistance of Professor J. William White, made an incision on the right side, between the eleventh and twelfth ribs. A large amount of laudable pus was evacuated, and the edge of the quadratus muscles was found eroded. The kidney could be felt and seen anteriorly, and, as it appeared in good condition, was not removed. No stone was discovered.

The day after the operation the temperature was normal, and continued so. The drainage tube remained in position four weeks, and, as at that time there was no discharge, the tube was removed—its track healing in a few days. Immediately after the operation the dysuria disappeared. There was never any urine discharged from the lumbar incision.

After getting up, the patient rapidly gained flesh, and had no unpleasant symptoms, and to-day is in perfect health; not having had a particle of pain with micturition since the day of the operation. Her urine is normal in quantity and quality; micturition is performed normally.

There can be no doubt that the case was originally a cystitis of severe type, that during the Fall a mild pyelitis developed, with an acute exacerbation after the urethra was stretched, finally occlusion of the ureter, retention, increased inflammatory trouble in the distended pelvis, and perinephritis either by the rupture of the pelvis in the post-nephritic space, or simply by inflammation by contiguity.

The use of cocaine in this case is worthy of especial mention. It was, as stated, the only drug that gave the least relief, which, though temporary, was the only comfort the patient obtained. The amount used was large. At times there were constitutional effects; always if the dose exceeded one grain or one grain and a half. On two occasions, after an exceptionally large dose had been administered by myself, there were alarming symptoms of collapse. The patient is entirely free from the cocaine-habit.

M. H. FUSSELL, M.D.,
One of the Physicians to the Medical Dispensary of the University of Pennsylvania.
189 GREEN LANE, MANAYUNK.

Memoranda of Several Cases of Hernia.—The following brief notes of hernial cases have considerable value from a statistical point of view, and are therefore recorded. The cases all occurred in the surgical wards of the Philadelphia Hospital during the term of Dr. A. W. Ransley, the writer being at the time resident surgeon.

J. S., white, male, æt. forty-seven years, was admitted August 7, 1886, with a strangulated left inguinal hernia. The patient stated that the strangulation had taken place a few hours before, but at time of admission there had as yet been no positive evidences of true strangulation. Examination showed a congenital absence of the testicles from the scrotum, and on either side the gland could be felt in the canal at the external opening. On either side, above the testicle, was a hernia of the intraparietal variety. That of the left side lay above and along Poupart's ligament, extending almost to the anterior-superior spine of the ilium, and was large, hard, and painful. Efforts at reduction were practised without success until the following morning, when it was deemed necessary to perform herniotomy. The incision extended over the mass for three and a half inches. The sac was firm and distended with bloody serum, and the intestines dark, but firm. After the strangulating band at the internal ring had been divided, the intestine was returned to the abdominal cavity, the wound dressed carefully, and subsequently the patient made a good recovery.

The co-existence of both non-descended testicles and these two herniæ is unique, and suggestive of the possibility of the accidental conversion of the ordinary type

of inguinal hernia into one of the intraparietal form by imperfectly performed radical operations ending in the closure of the external ring only, or by such procedures as invagination of the testicles.

The following case is of interest because of the age of the patient and the mode of reduction:

B. K., a white male, aged eighty-six years. When admitted he was suffering from a large strangulated left scrotal hernia. The mass was quite firm, large, painful, and tender—the pains passing upward from the tumor to the umbilicus. The point of strangulation was at the external ring, the constriction being evident from the surface, a marked tumescence on either side of the band. Efforts at reduction having failed, an incision was about to be made, when it was suggested that an endeavor to overcome the constriction be made from without after the manner of Sentin. The finger gradually but firmly passed into the mass near the ring, presently was able to detect the margin, and within a few moments to hook its end beneath the edge of the ring. Slow, gradual, and firm traction upon the margin in a few minutes caused a sudden marked relaxation, and the hernial mass was easily reduced. A few days of absolute rest with low diet completed the case favorably.

A third case, also of interest from the age of the patient, is as follows:

A. R., a white female, aged eighty-eight years. The hernia was of the umbilical variety, and at the time of admission the history pointed to strangulation having taken place forty-eight hours before. Taxis having failed, an incision was made at once over the mass and the strangulated knuckle of gut returned to the abdominal cavity without opening the sac, the strangulation having been caused by the gut being sharply folded over the margin of the ring in escaping from the abdomen. After a slow, uneven convalescence, the case finally made a full recovery.

ALLEN J. SMITH, M.D.

332 S. SEVENTEENTH ST., PHILA.

OBSTETRICAL.

Ante- and Post-partum Hemorrhage in the Mother. Hemorrhage from Penis of the Child on the Third Day.—On February 15, 1889, at about 1.30 o'clock A.M., I was called to attend Mrs. C. P. R. in her fourth confinement. She was of about medium size, apparently healthy, aged twenty-five. The three previous pregnancies were normal and labors easy. The first half of the last (fourth) was almost entirely devoid of symptoms. During the second half there arose some slight nervous disturbances. Just before labor pains began she arose from bed, and on returning, a large amount of blood passed for two or three minutes, followed by uterine contractions and cessation of bleeding. There was also some blood found in several places on the floor, showing that she began to flow while out of bed. On examination the os was found slightly dilated. Labor pains occurred at frequent intervals until near morning, when they ceased. After the effects of the night's sickness passed off the patient was around the house as usual. Three days later another gush of blood came on in the night, and without warning, to be again followed by labor pains for a short time. On the following morning a third hemorrhage took place; this time followed by true labor pains, which proved effectual at about 8 P.M. During the second stage of labor I gave several five-drop doses of ergot to increase the pains, which were growing weak and ineffectual. This soon revived the flagging powers of the uterus and caused the expulsion of the child. After the birth of the child contractions of the uterus ceased and bleeding began. I thereupon gave a dose of ergot and proceeded to deliver the placenta. This took perhaps, fifteen or twenty minutes, bleeding continuing until removal was accomplished. After the hemorrhage ceased the patient was extremely weak and presented some symptoms of syncope, such as nausea and temporary loss of sight—which, however, soon passed away after the administration of stimulants. No more bleeding occurred, the patient gradually improved and made a good recovery as regards hemorrhage.

On the tenth day after delivery she had a chill and fever, accompanied by severe neuralgic pains in the lower portion of the abdomen; but quinine, opium, and calomel soon checked the malarial disease.

The baby was a large male child—to all appearances well developed and strong. During the first two days after birth he slept and nursed well. The third night he was restless. At about nine or ten o'clock in the morning of the third day, while the nurse was bathing him, he had a copious discharge of blood from the penis. It was ejected with such force that it struck the head and shoulders of the nurse. She grasped the penis and compressed it, apparently checking the bleeding. Being immediately summoned, I found the child fretful, but not bleeding. On examination of the penis phimosis was discovered. The preputial orifice would just admit an ordinary silver probe. But where did the blood come from? and what the remedy? were the questions. I believed that the contracted prepuce had become partially occluded, and that the consequent straining on micturition, combined with some capillary defect, had caused a hemorrhage into the bladder, and finally a discharge of blood through the urethra. That being the case, circumcision would be the remedy. Accordingly, in the afternoon, assisted by Dr. A. D. Lowell, I operated. Just before the operation the infant had another discharge of blood. We found nothing abnormal about the prepuce, nor was there any more bleeding than is usual in such operations. After dressing it in the ordinary manner we left at about four o'clock. At seven in the evening I returned and found the dressings completely saturated with blood. My supposition then was that I had a bleeder to deal with, and, of course, despaired of saving his life. On removing the dressings the blood was seen oozing from the cut surface, with no hemorrhage from the urethra. Styptics were without avail, so I removed a stitch from the right side, and on separating the skin and mucous membrane, found a spot about the size of a dime, from which the blood oozed like water from a sponge. I pinched up a fold of the bleeding surface with forceps, and applied a ligature. This immediately checked the bleeding, which never returned. The mystery was now solved: the blood had come from this area of defective capillaries, and bleeding was more free after circumcision than before, because pressure was removed. The child lost a large amount of blood and, of course, was very weak, but he made an uninterrupted recovery.

REMARKS.—I have never before met with such a case of hemorrhage in an infant, nor seen a similar case re-

ported. During the first and second days of the child's life—as afterward stated by the nurse—his urine caused a peculiar orange-colored stain, which was undoubtedly due to the admixture of blood.

The spot of defective capillaries was on the right side of the penis, about a half or three-fourths of an inch from the end of the prepuce. The bleeding before circumcision would necessarily be slow; and as the tissues became gorged with blood it would naturally press toward the end of the penis, where, meeting with some resistance, the blood would accumulate and, finally, be discharged by the forcible straining. This process would consume some time, hence the two intervening days without decided hemorrhage.

ROGERS PARK, ILL., Oct. 4, 1889.

HOSPITAL NOTES.

THE LATEST LISTERIAN METHOD IN THE DRESSING OF WOUNDS.

Abstract of a Clinical Lecture
Delivered at the University Hospital, November 20, 1889.

BY J. WILLIAM WHITE, M.D.,
PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

AFTER operating upon a case of adenoma of the neck, removing the tumor, explaining the reason for the operation, and the method employed, Dr. White continued as follows:

Although this operation is now nominally completed, the most important part, in my judgment, remains to be performed, viz., the placing of the wound in the best possible condition for rapid healing. The aim of the surgeon, after every operative wound, is, of course, to secure union by first intention.

Any persistent form of irritation is a source of suppuration in wounds, and the different antiseptics which have been employed have not been free from the charge of contributing to the occurrence of excessive inflammation by their own irritant action. The typical antiseptic must, therefore, be as nearly as possible devoid of irritating properties. It must he germicidal—that is, it must possess the property of destroying the micro-organisms. It must have an inhibitory power—that is, it must prevent the development of such organisms. It must be stable—that is, it must not disappear by volatilization from the dressing after they are made, or after they are applied to the wound.

In the old Listerian method carbolic acid was the antiseptic employed; but this had the objection of volatility as well as great slowness of action as a germicide. Corrosive sublimate, which succeeded it, was stable and acted with rapidity, but was exceedingly irritating, and, in addition, was precipitated by the albumin contained in the serum of the blood. This precipitate, it was discovered by Sir Joseph Lister, possessed powerful antiseptic properties, with much less power of producing irritation; and he, therefore, devised a form of antiseptic dressing, which he called "the sero-sublimate gauze," which consisted of gauze charged with a solution of corrosive sublimate in the serum of the blood. This, however, was difficult to manufacture, and produced a harsh and non-absorbent material which was mechanically objectionable. It was succeeded, in his hands, by the combination of chloride of ammonium and bichloride of mercury, known as sal-alembroth, which, while much less irritating, was so exceedingly soluble in the blood serum that whenever the discharges from wounds were copious it was washed out of the dressings, leaving them without antiseptic property. For these reasons Lister in time discarded this material and employed for a considerable period a gauze containing three or four per cent., by weight, of the biniodide of mercury. This was less soluble, non-volatile, powerfully antiseptic, but, again, extremely irritating, so that the least contact with the skin produced an intense erythema, even going on to vesication.

Lister was thus led to look further for the ideal antiseptic, and he has now found it, he believes, in the preparation which I here show you, which is a double cyanide of zinc and mercury. In the last number of *The British Medical Journal* (November 9, 1889), which has just reached this country, the various facts to which I have merely alluded, are set forth at length by Lister, and his paper, besides being an important scientific contribution, supplies interesting evidence of the remarkable patience, perseverance, and attention to detail which have invariably characterized the work of this great surgeon.

I am enabled to show you the material itself, the double cyanide, and the specimens of gauze which you see here impregnated with it and ready for use, through the kindness of Sir Joseph Lister himself, who was good enough during my visit to London, last summer, to give me confidentially the various formulæ which he was using, and to supply me with the materials from his own manufacturers of gauze and of chemicals. He did this, as I have said, *confidentially*, on account of the fact that, while he was experimenting with other dressings, notably the sal-alembroth, the announcement had been made by others that he was using them, and they were extensively employed, at a time when he was quite unprepared for publication upon the subject. I have, therefore, been unable, either in teaching or writing, to make use of my acquaintance with this method until to-day, although I have been employing the cyanide gauze in my private practice; but I now intend to introduce it systematically into my hospital work, believing from my observations in the wards of King's College Hospital last summer, from the evidence furnished by Lister's work, and from my own experience, that it is the best antiseptic yet discovered. Its most evident advantages may be briefly enumerated:

In the first place, it is non-volatile; next, it is almost entirely unirritating; thirdly, it is insoluble in water, and only soluble in 3000 parts of blood serum; and, finally, while it possesses but little germicidal value, its inhibitory power is so high that a solution of 1:1200 is sufficient to keep animal fluids permanently free from putrefaction. This combination of qualities, as you will now readily understand, is possessed by none other of the antiseptics which have been mentioned; and its deficiency in germicidal power is easily remedied by including in the manufacture of the gauze dressings which are impregnated with this material a small percentage (1 in 4000) of sublimate—enough to be germicidal, but too weak to be markedly irritating.

The gauze which I now show you comes in pieces of

six yards each, and, according to the method explained to me by Lister, should be prepared as follows—the proportions which I give being those required for the impregnation of twenty pieces of gauze, each of that length: A mixture of the zinc and mercury salt and of water is made in the proportion of 800 grains of the former to 28 pints of the latter. The gauze is drawn through this mixture slowly, the apparatus used by Lister consisting of a wooden trough in the shape of an inverted pyramid, with a bar a short distance from the bottom, under which the gauze must pass, in that way securing its complete submergence. As it is drawn through it is pressed slightly against the edge of the trough, so as to squeeze out the excess of liquid, and is then dipped in a bath composed of starch, 400 grs., boiling water, 3 pints, mixed together, diluted by the addition of 11 pints of cold water, and still further by adding 15 pints of a 1 to 2000 sublimate solution. The reason for this last, or starch bath, is that the double cyanide, if allowed to dry in the gauze without the admixture of starch, will fly out as an impalpable powder whenever the gauze is handled, whereas with the starch it makes a mixture which, while not a chemical compound, seems to be a very intimate association of the cyanide with the starch, the latter holding it in the meshes of the gauze. The bichloride is added, as I have already said, for the sake of its germicidal action. The gauze, when taken out of this bath, is laid for a few moments between the folds of a perfectly clean sheet, which absorbs the excessive moisture, and is then folded and ready for immediate use. Or it may be dried and used after moistening with the 1 : 4000 sublimate solution.

Another method, which is recommended by Lister in the above-mentioned paper, will probably prove still more simple. A strong solution of starch is mixed with the double cyanide powder, and after this a quantity of the sulphate of potash, which is an inert powder, and is used in this connection just as it is in Dover's powder, for the sake of the mechanical effect produced by its gritty particles.

Take, for example—if it is desired to impregnate twenty pieces of gauze, each six yards in length—eight hundred grains of the double cyanide. Stir it into a strong solution of starch, made with warm water until it is almost pasty in consistence. Add two or three tablespoonfuls of sulphate of potash; allow the mixture to dry; powder and diffuse it in several gallons of a 1 : 4000 solution of bichloride, enough being employed to permit of the thorough immersion of all the gauze.

The excess of sulphate of potash is practically gotten rid of in this watery solution, but if it were not it would do no harm, as it is, as I said, inert. The gauze should then be carefully drawn through this mixture, which is stirred up; the material is deposited in the meshes, and should be dried between a folded sheet, if it is needed for immediate use, or over a line in a clean room free from dust. If the latter plan is adopted, it should be moistened again with 1 : 4000 bichloride just before using.

The dressing of a wound, then, according to the present Listerian method, would consist in the application immediately over the line of the wound of from six to eight layers of this gauze, out of which the bichloride has been washed by wringing it out once or twice in a solution of 1 to 20 carbolic acid. This leaves the gauze impregnated merely with the absolutely unirritating double cyanide, the carbolic acid soon disappearing by reason of its volatility. Above this are placed successive layers of the moist gauze, and outside of this, if it is necessary to use still other dressing for purposes of pressure or otherwise, the ordinary absorbent bichloride cotton may be employed.

We have then a dressing which would seem to combine all the essentials of a perfect antiseptic, and it is to be hoped that the results obtained from the use of this material will be those which, on *a priori* grounds, we have a right to anticipate. My own results thus far have been most encouraging, but I have not yet had time to use the dressing in a sufficiently large number of cases to make publication desirable.

As an illustration at once of the intense interest and of the scrupulous care which Sir Joseph Lister brings to all his antiseptic work, I feel sure that I may without impropriety mention the fact that all the gauze which he has thus been employing for more than a year past has been made by himself and Lady Lister, in the evenings, in his office; this both for the sake of avoiding premature publication of his methods, and for the purpose of obtaining an absolutely reliable and unvarying article.

I value very highly the opportunity which he has so kindly given me to use this material (of which I have not, until now, publicly availed myself since my return in the autumn), and the permission which he also gave to make its merits known and to impart a knowledge of them to you when he had himself reached a point at which, in his judgment, its introduction to the profession at large was warranted. I shall publish a record of my own experiences with the dressing later in the winter.

MEDICAL PROGRESS.

Deodorizing Injection in Uterine Cancer.—In *L'Union Médicale*, Dr. Cheron recommends the following injection as efficient in destroying the fetid odor of uterine cancers:

℞.—Acid. salicylic.	. . . .	gr. ij.
Sodium salicylate	. . . .	gr. xl.
Tinct. eucalyp.	. . . .	f℥jss.
Vinegar	. . . . .	f℥jss.—M.

This is to be added to one or two pints of water and used as a douche every few hours.

Iodoform in Endometritis.—Jacobs uses the following emulsion in the treatment of endometritis:

℞.—Iodoform	. . . . .	℥v.
Glycerin.	. . . . .	℥vj.
Aquæ	. . . . .	f℥jss.
Tragacanth	. . . . .	gr. jss.—M.

From one-half to one drachm of this is injected into the cavity of the wound two or three times a week.—*Therapeutische Monatshefte*, October, 1889.

Wash for Post-nasal Catarrh.—

Powdered chloride of ammonium	.	1 ounce.
Common salt	. . . . .	2 ounces.

A teaspoonful of this in a tumbler of hot water is to be snuffed up the nose twice a day, particularly in those cases where there is deafness.—*L'Union Médicale*, October 29, 1889.

The Salicylate of Mercury in Syphilis.—DR. HAHN, of Bonn, claims excellent results in the treatment of syphilis with the hypodermatic injections of the salicylate of mercury. He uses it suspended in paraffine oil, according to the following formula of Weisser:

℞.—Hydrarg. salicyl. . . . gr. xxij.
Paraffine oil . . . . fʒiijss.—M.

As the salt is deposited, the bottle containing the mixture must be thoroughly shaken before using. The needle should be kept in paraffine oil, and carefully cleaned before and after the injection. On beginning this treatment he injected two minims of the mixture every eighth day; but as this seemed too large an amount, he reduced it to one minim every fourth day. The injections were made deeply into the glutei. Thirty-eight patients were treated, and Dr. Hahn's conclusions are that (1) all manifestations of the disease are favorably modified, and that in the earlier stages one or two injections cause improvement; (2) it is more efficient than injections of calomel in oil; (3) it produces no local irritation nor symptoms of mercurial poisoning, if not used in larger amounts than indicated above. As yet no observations are forthcoming on the influence of the drug in preventing relapses.—*Therapeutische Monatshefte*, October, 1889.

Prescriptions for the Administration of Chloralamid.—In the *Therapeutische Monatshefte* for October, 1889, DR. A. LANGGARD gives the following formula:

℞.—Chloralamid . . . . gr. xl.
Acid. mur. dil. . . . . ♏ v.
Syrup. simplex. . . . . fʒijss.
Aq. dest. . . . . fʒij.—M.

This may be taken at one dose.

Used as an enema:

℞.—Chloralamid . . . . gr. xl.
Acid. mur. dil. . . . . ♏ij.
Alcohol. . . . . ♏xv.
Aq. dest. . . . . fʒiijss.—M.

Treatment of Influenza.—HENRI HUCHARD, in the treatment of influenza, recommends quinine sulphate and aconite to allay the periodic and febrile elements so frequent in the disease, and the extract of cinchona to combat the adynamic symptoms. He prescribes them in the following formula:

℞.—Quin. sulph. }
Extr. cinchonæ } . . . āā gr. xxx.
Extr. aconiti . . . . gr. jss.—M.

Ft. pil. 20. Three of these should be given daily.

When neuralgia is a prominent symptom hydrobromate of quinine and aconite are useful. When the febrile and neuralgic forms are united, it is often better to resort to antipyrin, in doses of thirty to forty grains daily. When gastro-intestinal catarrh is a complication, an aperient is required, and an emetic employed at the outset often gives relief. In consideration of the adynamic tendency of the disease, ipecac is the best emetic. When bronchitis predominates the following is a useful formula:

℞.—Pulv. ipecac. et opii }
Pulv. scillæ } . . āā gr. xxx.
Quin. sulph. } —M.

Ft. pulv. 20. Four or five to be taken daily.

Adynamia should be treated by alcoholic drinks and cinchona. If the adynamic symptoms are marked, give hypodermatic injections of caffeine. Tannin is sometimes of use in diminishing the secretion of mucus, and controlling headache, neuralgia and myalgia, and cerebral excitement. It does not cause digestive disturbance, as it is accused of doing, but often increases the appetite. Tannin should be given in doses of five to ten grains three times daily. With children, who usually will not swallow it, it should be given as an enema. Powdered benzoin is useful combined with tannin, after this formula:

℞.—Tannic acid . . . . gr. xxxvj.
Powdered benzoin . . . gr. vijss.—M.

In 5 powders.

Or quinine may be combined with tannin thus:

℞.—Tannic acid . . . . gr. xxxvj.
Hydrobromate of quinine . gr. xv.—M.

In 5 powders.

Although gastric symptoms are not usually a contra-indication to the use of tannin in influenza, there are some cases where frequent vomiting, intense epigastric pains, and fever require other treatment. Effervescing water, iced milk with Vichy water, salicylate of bismuth, sinapisms, will all be sometimes found useful.—*Revue Générale de Clinique et de Thérapeutique*, October 17, 1889.

Tincture of Euphrasia in Acute Coryza.—DR. G. M. GARLAND, in the *Boston Medical and Surgical Journal*, Nov. 7, 1889, strongly recommends the tincture of euphrasia in the treatment of ordinary colds. He finds that if given in the early stages the coryza is usually aborted, but that in advanced stages its effects are much less marked. The dose for an adult is ten drops every two or three hours. In infants and children the drug should be given in smaller doses well diluted; and as the taste is pleasant, its administration is not difficult.

Non-tubercular and Non-cardiac Hæmoptysis.—In the past fifteen years SIR ANDREW CLARK has seen many cases of hæmoptysis in elderly persons, due neither to tubercular disease of the lungs nor to cardiac disease, as demonstrated in a few cases by the autopsy. His observations on this hitherto undescribed symptom lead him to the following conclusions:

1. That there occurs in elderly persons who are free from ordinary diseases of the heart and lungs a form of hæmoptysis arising from minute structural alterations in the terminal bloodvessels of the lung.

2. That these vascular alterations occur in persons of the arthritic diathesis, resemble the vascular alterations found in osteo-arthritic articulations, and are themselves of a rheumatic nature.

3. That although sometimes leading to a fatal issue, this variety of hæmoptysis usually subsides without the supervention of any coarse anatomical lesion of the heart or of the lungs.

4. That the hemorrhage is aggravated or maintained by the administration of large doses of astringents, by the application of ice-bags to the chest, and by the unrestricted indulgence in liquids to allay the thirst which the astringents create.

5. That the treatment which appears at present to be the most successful, consists in restricted diet and quiet, in the moderate use of liquids, and the quieting of cough; in calomel and salines; in the use of alkalies with iodide of potassium; and in frequently renewed counter-irritation.—*British Medical Journal*, October 26, 1889.

Trephining for Epilepsy.—An interesting and instructive case of traumatic epilepsy cured by trephining is reported in the *British Medical Journal* of October 26, 1889, by Drs. Williamson and Jones. The patient was a young man who had received a lacerated wound on the left Rolandic area, two years previously. He was insensible for a short time after the injury. A week later the wound was complicated by erysipelas, and about the same time he had his first epileptiform seizure. Sixteen fits occurred the same day. He remained unconscious for a few days, and his right leg and arm were paralyzed for three weeks. He spoke slowly, and at first incoherently, but this defect passed off in a week. The paralysis of the limbs finally disappeared, commencing in the leg. The wound in the head soon healed, but had on more than one occasion discharged a little pus. The last occasion was in February, 1888. When he first came under observation there was a small triangular depression over the Rolandic area on the left side, marking the position of the old injury. On November 3d he went to bed at 1.30, and was seized with convulsions, which constantly recurred, and from which the patient did not recover consciousness until after the operation. The fits were short in duration, but recurred every ten minutes. They began with groaning and slight movements of right limbs; then tremors of right limbs; then tetanic rigidity of right limbs, accompanied by jerking of the head round to the right side, the mouth being also drawn to the right. So soon as the rigidity of the limbs and jerking of the head subsided, the right eye commenced to blink violently. In the afternoon the blinking was followed by rapid nystagmus; but in the evening, before the operation, no nystagmus was noticed. The head around the scar was shaved and washed with terebinth, and a subcutaneous injection of morphine and ether administered. A semicircular incision was made down to the periosteum over the scar, the convexity of the curve being upward. A flap of periosteum was then deflected, and the whole mass reflected, exposing the old depression. A three-quarters inch trephine was then used below the site of the cicatrix. The circle removed had attached to its internal surface a triangular piece of bone penetrating into the brain at right angles to the cranium to a depth of three-quarters of an inch. The trephine was introduced at the junction of the middle with the lower third of the Rolandic fissure, the largest diameter being opposite the ascending frontal convolution. The measurements were conducted after the method of Thane and Hare. A probe with a bent point was then placed into the trephine space and a little anterior to it; the inner plate felt bare. In consequence, another trephine hole was made a quarter of an inch anterior to the first, and the intervening bridge of bone removed by saw and forceps. This procedure yielded a small piece of necrosed bone. The wound was treated during operation with perchloride of mercury; all bleeding vessels were tied, the cut surfaces dusted with equal parts of iodoform and boric acid, a catgut drain introduced, and the whole covered with antiseptic wool dressings. Owing to the adherent condition of the dura mater to the skull, it was thought more prudent not to attempt any bone-grafts. During the operation, previous to the removal of the first button of bone, the patient had two fits. After its removal there were no more fits, their place being taken by attacks of restlessness. For the following five months there were no spasms, though a small sinus remained at the wound, which discharged slightly. At the end of about five months the fits returned with their former severity, and, on reopening the wound, a small spicule of necrosed bone was found and removed. Since then there has been no return of the fits.

Chloralamid.—Additional evidence of the value of this new hypnotic is furnished by Dr. D. R. Patterson, in the *Lancet* of October 26, 1889, who has used the drug in fourteen cases of sleeplessness from various causes. The usual dose was fifteen to forty-five grains dissolved in water, a few drops of alcohol materially aiding the solubility.

In a case of simple insomnia in an old woman, thirty grains produced twice, a long refreshing sleep. The third night fifteen grains were administered, which were also followed by eight hours of sleep.

Its influence on the insomnia associated with phthisis is quite satisfactory. A night's rest of from six to seven hours frequently resulted from doses varying from fifteen to forty grains. In a girl of eighteen, who had slept but indifferently, thirty grains induced, after thirty-five minutes, nine hours of unbroken sleep, from which she awoke with a clear head. In two out of the three cases of phthisis in which it was tried, there was present, besides moderate insomnia, copious night-sweating. The effect in checking this most troublesome and exhausting symptom was marked in both cases. Thus, in a man of forty years of age, who had profuse night-sweats and indifferent sleep, thirty grains shortly after his admission gave him the first dry night he had had for some time, besides affording him sleep. On the following evening the drug was omitted. He slept very lightly, and was quite wet in the morning. The administration of forty grains of chloralamid the evening after gave him an unbroken sleep of nine hours, and he awoke perfectly dry.

The results obtained in two cases of heart disease were encouraging, and would compare favorably with those of any other hypnotic. Doses of thirty grains in a man suffering from aneurism of the aorta gave fair rest, easing the pain and relieving the cough. There were no disagreeable accompanying effects, the patient bearing the drug well. In a case of emphysema and dilated right heart with orthopnœa, thirty grains had little or no influence; forty-five grains induced slight wandering and a feeling of intoxication, which did not, however, last long.

The restlessness and delirium of enteric fever were treated by the drug in two cases. In a strongly built man who had been ill for some time, doses of thirty grains and forty-five grains produced feelings of sickness and dryness of the mouth on awakening. The amount of sleep obtained, however, was very satisfactory. In a case in an early stage smaller amounts (fifteen to thirty grains) materially quieted the delirium and procured a tranquil night. In neither of these two cases was there any influence on the pulse.

In a case of Bright's disease, in which the sleep was seriously disturbed by almost constant headache, for which several remedies had been tried, forty-five grains led, after the space of thirty minutes, to a sleep of eight and a half hours.

Notwithstanding these results, Dr. Patterson doubts if chloralamid will replace chloral, though the freedom from injurious effects gives it a strong claim upon our attention.

The Mixed Method of Anæsthesia.—DR. AUBERT, of Lyons, is a strong advocate of the so-called mixed anæsthesia, and about thirty minutes before operating injects 15 drops of the following solution:

Muriate of morphine . . .	four grains.
Sulphate of atropine . . .	one-half grain.
Distilled water	one ounce.

According to Dr. Aubert, the advantages of this method are:

1. Safety of patient.
2. The great rapidity with which unconsciousness is obtained.
3. The absolute calm of the patient.
4. The facility of awakening.
5. The avoidance of complications or the sequela, malaise and vomiting. Professors Gayet and Leon Tupin have both employed this method of anæsthesia. Dr. Gayet recommends it particularly in ocular surgery, for the great calm that is obtained with it.—*Gazette Médicale*, October 9, 1889.

The Digestibility of Boiled Milk.—Though the importance of sterilizing milk for bottle-fed infants in cities has been proven beyond a doubt, the process seems to have some disadvantages. In a recent number of the *Zeitschrift für physiologische Chemie*, DR. RANDNITZ publishes some striking experiments on the subject. He shows by analysis of the milk ingested, and of the feces and urine, that much less nitrogenous material is abstracted from boiled than from unboiled milk. If 15.6 grammes of nitrogen in the form of unboiled milk were given to dogs for three days, analysis showed that 9.4 per cent. was stored in the tissues of the animal. On the other hand, with the same amount of nitrogen in boiled milk, but 5.7 per cent. was assimilated. If these results are confirmed it is evident that an infant must need a larger quantity of sterilized than of raw milk.—*British Medical Journal*, October 19, 1889.

Treatment of Phlegmasia Alba Dolens.—In *L'Union Médicale* of October 19, 1889, the following routine treatment of this troublesome state is given: The patient must be placed absolutely on the back; the diseased limb being treated by forcible extension, and the application of a liniment made up of olive oil, morphine, and chloroform. After this has been applied, the leg should be wrapped up in cotton batting and kept at a uniform temperature, and frequent movement and examination of the parts are to be avoided. To combat the pain, chloral and other narcotics are to be used internally, and hypodermatic injections of morphine and laxatives are to be given. After the pain diminishes, alkaline diuretics are to be used to favor the absorption of the œdema, and, if necessary, the skin may be punctured to relieve the swelling. The patient should be confined to bed for thirty days until all evidences of trouble have ceased and the œdema entirely passed away.

The Effects of Naphthalin on the Eyes.—KOLINSKI (*Vratch.*, No. 22, 1889), after a series of experiments upon rabbits, dogs, guinea-pigs, and mice, concludes that:

1. Naphthalin produces diseases not only in the eyes but also in the internal organs.
2. The principal pathological condition caused in the eyes is hemorrhage and its secondary effects.
3. The hemorrhage is usually in the choroid, and causes separation of the retina and disease of the vitreous body.
4. Opacity of the lens, caused by toxic doses of naphthalin is secondary to disease of the vascular membrane of the retina.
5. Naphthalin cataract develops in the same manner as do other soft cataracts.
6. After very large doses, the development of the cataract and the swelling of the lens are extremely rapid.
7. The appearance of an irregular astigmatism at the beginning of a cataract, is explained by an excess of liquor of Morgagni between the lens and its capsule.
8. The crystals that are found in the eye, after toxic doses of naphthalin, are composed of acid phosphate of lime and are deposited in the tissues deprived of their vascularity.
9. These crystals only form in chronic naphthalin poisoning.
10. The opacity of the crystalline continues to develop, even if the administration of naphthalin is stopped; and although the cataract is reabsorbed in time, the crystalline never becomes quite transparent.
11. The changes in the vitreous, retina, and vascular membrane never quite disappear.—*Bulletin Général de Thérapeutique*, October 15, 1889.

Methyl Chloride as a Local Anæsthetic.—DR. ERNST FEIBES, in a recent number of the *Berliner klinische Wochenschrift*, draws attention to the extensive and successful use in the Paris hospitals of methyl chloride as a local anæsthetic. Methyl chloride (CH_3Cl) is a colorless, easily liquefied gas, with an odor resembling that of ether and chloroform. The readiness with which the gas liquefies adapts it for convenient use, as it can be stored in a siphon, or in a bottle composed of non-conducting material. It may be applied to the skin directly from the siphon, or as a spray, but this method is objectionable, owing to the anæsthetized area not being in most cases sufficiently circumscribed. A better method is to saturate a cotton tampon, the size of the area which it is desired to anæsthetize, and apply by means of a wooden holder. After a few moments' contact the skin becomes pale, anæmic, and greatly diminished in sensitiveness. If the tampon is then removed reaction quickly follows, the part becoming congested; but if the application is continued a few seconds longer the skin assumes a white, dried, parchment-like appearance, which is the proper time for operation. Care must be taken not to continue the contact too long, else superficial necrosis may result. The methyl chloride anæsthesia is used not only in minor surgical operations, such as circumcision and opening of abscesses, but in the treatment of neuralgia and muscular rheumatism.—*British Medical Journal*, October 19, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

TRANSMISSION OF SYPHILIS BY CONTAMINATED INSTRUMENTS.

AT the meeting of the Académie de Médecine of Paris on November 5th, an abstract of which appears in the *Gazette Hebdomadaire de Médecine et de Chirurgie*, for November 8th, M. LANCEREAUX reported two cases in which syphilis had been communicated by the employment of contaminated instruments. In the first patient the infection took place through the agency of an Eustachian catheter which had been previously used for syphilitic individuals, and had not been thoroughly cleansed and disinfected; and in the second the instruments of a dentist conveyed the virus to the mouth of a lady undergoing preparation for the application of a set of false teeth.

Unfortunate as they are, these two cases are by no means the first of the kind recorded in medical literature, as everyone familiar with that part of it pertaining to syphilis well knows. The Eustachian catheter enjoys a most unenviable notoriety amongst the recognized sources of mediate contagion of syphilis, and certain dental procedures, such as transplantation of teeth, etc., have been held to answer for the mischief on more than one occasion.

Recognizing as fertile sources of syphilitic contagion the mouth, the throat, and the nasal cavities —each and all of them so commonly presenting contagious lesions of the disease—it is incumbent upon all who deal with the affections of these parts, and upon dentists as well, that they should appreciate the risk they run of inoculating their healthy patients by instruments employed in the treatment of syphilitics, and should take the most minute precautions to avert such calamities. Of what are these precautions to consist? One, which is obvious, is that an instrument used for treating or making applications to a syphilitic should never again be used upon anyone else except another syphilitic; this, of course, is a certain safeguard, but may not, unfortunately, be invariably applicable. Another consists in thoroughly cleansing, and sterilizing by means of antiseptic solutions, each instrument every time it is used, with just the same care and precision which surgeons exercise with their instruments. M. Lancereaux demands that dentists should be compelled to employ "only instruments rigorously clean, and as it would be impossible for them to have special instruments for each of their patients, one should see that there are at the establishment of every dentist disinfectant solutions, and, above all, that they make use of them." This stringent rule is also, he says, to be applied to hairdressers.

A question not inaptly suggested by M. Magitot, in discussing M. Lancereaux's remarks, is whether it would be safe to trust in non-professional hands considerable quantities of antiseptics, notably the most trustworthy one, bichloride of mercury. We can see no reason why dentists should not be as capable of exercising the care necessary in handling these poisonous substances as physicians, if the instruction they receive in chemistry and materia medica counts for anything at all, and if a clear comprehension of the principles of antiseptic methods is exacted of them before graduation.

A more important consideration than this, is whether or not a dentist should be expected to be able to recognize syphilitic lesions in the mouth when he sees them. To this we unhesitatingly answer that he should. Encounter them he must, for syphilis is a widespread disease, and its lesions in the mouth are among the most frequent, and at times the most intractable of its manifestations. With any reasonable amount of information upon the subject, he would, in the majority of cases, find no difficulty in recognizing these lesions, and would be at once on his guard against contaminating his instruments, or, having used them, would spare no pains to render them harmless before again calling them into service.

As to specialists in diseases of the ear and throat, their general knowledge of medicine, and the frequent opportunities afforded them of seeing and dealing with syphilitic lesions, teach them clearly the dangers surrounding their work. And yet we find that, as stated above, one of their instruments, the Eustachian catheter, has been guilty in a number of instances of carrying the virus from these lesions and inoculating healthy individuals. The necessity of exercising the most scrupulous care to employ only thoroughly cleansed and sterilized instruments in this branch of practice, cannot be too strongly insisted upon, and its observance will contribute to reducing to a minimum the possibility of a repetition of the unfortunate calamities which M. Lancereaux reports.

REVIEWS.

THE PRINCIPLES AND PRACTICE OF SURGERY. By JOHN ASHHURST, JR., M.D. Fifth Edition, pp. 1144. Philadelphia: Lea Brothers & Co., 1889.

THE previous editions of this book are so well and favorably known that we shall, in this review, refer only to some of the chief additions which have been made. The general arrangement of the volume has not been altered, and the number of illustrations has been advantageously increased by the addition of a large number of original cuts.

There is much more space devoted to the antiseptic treatment of wounds than in the previous edition, and the author acknowledges that he has been obliged to change the opinion which he formerly held in regard to the value of antisepsis. This change has been caused by the results of two years' experience with the antiseptic method, in the University, Pennsylvania, and Children's Hospitals. We coincide fully with the author "that when used with judgment, and . . . when diluted with common sense, it (antisepsis) is capable of affording very valuable aid to the surgeon." The antiseptic method employed by Dr. Ashhurst is that now in use in most of the Philadelphia hospitals. The part to be operated on is shaved, scrubbed with turpentine, soapsuds, and a solution of bichloride of mercury, 1 : 2000. The instruments are placed in carbolized water; the sponges in a solution of bichloride of mercury, and catgut ligatures are used. Neither the spray nor irrigation of the wound during operation is employed. When the operation is completed the wound is douched with a bichloride of mercury solution (1 : 2000). Rubber drainage tubes are used, and a dressing of protective and sublimate gauze.

With regard to trephining for epilepsy the author reiterates the opinion, expressed in the previous edition, that the operation is usually unadvisable; and that the results of the brilliant operations performed under the guide of "cerebral localization" have thus far not proved as practically useful as was at first anticipated. This is an opinion with which, we think, most surgeons will agree.

The chapter on Diseases of the Eye has been thoroughly revised by Dr. G. E. de Schweinitz, and presents many valuable features. The same may be said of the chapter on the Ear, revised by Dr. B. A. Randall.

The subject of laryngeal intubation is discussed, and there are presented cuts of Dr. O'Dwyer's instruments for intubation. The author considers intubation valuable as an additional resource in cases of laryngeal or tracheal obstruction; but, if circumstances permit, he prefers to introduce the canula through an incision below the seat of obstruction.

The chapter on Wounds of the Abdomen has been considerably enlarged, and several statistical tables of laparotomy for rupture, and stab and gunshot injury of abdominal viscera, have been added. The statistics of the Pennsylvania Hospital, collected by Dr. W. D. Green, show a mortality of forty-five per cent. in cases of penetrating wound of the abdomen which were treated by the expectant or non-operative plan; while the general statistical tables of laparotomy for punctured, incised, and gunshot wounds of the abdomen show a mortality of fifty per cent.

We entirely agree with the author that some of the deaths after abdominal section are attributable to recklessness on the part of the surgeon in unnecessarily prolonging the operation and in disregarding the dangers of shock from exposure and chilling of the viscera. Dr. Ashhurst considers "that if executed with skill and care, laparotomy, at least in well-selected cases of penetrating wound of the abdomen, is a proper mode of treatment."

Notwithstanding the very large number of operations done during the last few years for the radical cure of hernia, Dr. Ashhurst holds the same opinion expressed in the previous edition, "that the most favorable view to be taken of any operation which has been as yet proposed for the radical cure of hernia, is, that while not necessarily followed by grave consequences, it is not unattended with risk, and by no means certain to effect the object designed."

We feel confident that this last edition of Dr. Ashhurst's *Principles and Practice of Surgery* will be received by the medical profession with favor, and will be found to furnish a condensed, comprehensive, and conservative representation of modern surgery.

CORRESPONDENCE.

CHICAGO.

To the Editor of THE MEDICAL NEWS,

SIR: The signs of the times point to Chicago's increasing importance as a centre of medical learning and influence. First, there are our medical schools. Rush Medical College, the medical department of Lake Forest University, leads, with 500 matriculates; Chicago Medical College, the medical department of Northwestern University, follows with 215 medical and 23 dental students, and a compulsory three years' course. Dr. Josef Zeisler, formerly one of Kaposi's assistants, has been recently elected lecturer on dermatology and syphilis in this institution. At the College of Physicians and Surgeons, 150 students are registered. Late faculty changes in this school are: Dr. Henry P. Newman to the Chair of Obstetrics, vice Dr. C. W. Earle, resigned;

Dr. R. W. Jones, Therapeutics; Dr. C. C. P. Silva, Diseases of Children. About 50 practitioners are enrolled on the lists of the Chicago Polyclinic and the Post-graduate School. As yet the Woman's Medical College has not reported. Then there are about 650 students in attendance upon the homœopathic and eclectic schools. All told, in this city of a million inhabitants, over 1600 individuals are known to be actively engaged in the study of medicine. Students come chiefly from the West, Northwest, and Southwest, very few from the East. Occasionally some of them stray to the Atlantic seaboard. Commonly they are disappointed candidates for graduation, and, be it remarked, the same men usually return happy after a phenomenally brief sojourn. Passing mention ought to be made of the immense amount of surgical material at the disposal of the various clinics—not a remarkable fact, when one recalls the twenty-five important railroads that centre in Chicago. The prestige of Brainard's fame still lingers round our medical halls, and it is proposed at no distant date to erect a fitting monument to the memory of a man, whom Senn[1] has justly characterized as a clear thinker of original power, as a bold and skilful operator, as a successful practitioner, and as a patriotic citizen.

But the event of pregnant significance in the medical history of this city and of the Northwest occurred last September. It consisted in the incorporation of the "Medical Library Association of Chicago." It is proposed to collect $50,000 from the local profession by the establishment of one-hundred-dollar governing and three-hundred-dollar life memberships, with ten dollars annual dues. When this amount is deposited, the directors will appeal to the public, with confident hope of attention and response. Already an amount, over $10,000, is in the bank, and the work has scarcely begun. The office-holders of the directors for the year 1889–90, are Drs. N. S. Davis, Sr., president; Edward M. Lee, vice-president; Ephraim Ingals, treasurer; Bayard Holmes, secretary.

The urgent need of an adequate reference medical library in Chicago is apparent, as, at present, the only important collection of medical literature within the valley of the Mississippi is located at Milwaukee, and this is a private institution. To the credit of its owner, however, it must be said that he has been kind to his less fortunate professional brethren, in allowing them to consult his books.

Chicago is, or will be in the near future, magnificently supplied with libraries, full of books on every subject except medicine and the allied sciences. The "Newberry Library," on the North Side, has a fund of nearly $3,000,000, but it is designed as a reference library, without respect to medicine. The trustees of this fund admit the pressing want of a medical library and faithfully promise to consider carefully the formal petition of the profession, twenty-five to fifty years from date. In this collection "Americana" will be fully represented, also "Theologica," but there is no place for books on animal structure and function! The "John Crerar Library," with funds amounting to $2,500,000, to be located on the South Side, must contribute such a collection of literature as will fulfil the following conditions: "I desire," writes the testator, "that books and periodicals be selected with a view to create and sustain a healthy moral and Christian sentiment in the community, and that all nastiness and immorality be excluded. I do not mean by this that there shall not be anything but hymn books and sermons, but I mean that dirty French novels and all sceptical trash and works of questionable moral tone shall never be found in the library."

The "Chicago Public Library" has already demonstrated the wish to rid itself of the incubus of a medical department by offering, without conditions, the few medical books now on its shelves, to the new "Medical Library Association of Chicago."

Under these conditions, will any one attempt to deny the wisdom of the plan here outlined? Every legally qualified practitioner, irrespective of therapeutical views, has been invited to join, and the majority have signified their willingness. It is surprising to behold the unity of the profession in this enterprise. Men of opinions diverse and irreconcilable, of bitterest personal antagonisms, work shoulder to shoulder in harmony, all intent upon the common end. Indeed, the "Medical Library Association of Chicago" seems to offer a sufficient solution of the code problem.

But the Chicago public must not be condemned too severely for its apathy and apparent disregard of the higher interest of the medical profession. The doctors are loyal to their city, and they anticipate polite attention and prompt response from the people, when they, themselves, have done their duty. Matthew Arnold said that "Chicago was too beastly prosperous." This is a malicious slander that we repudiate. After all the palaces, temples, monuments, and mausoleums now under way have reached completion, and after the termination of the World's Fair in 1892, Chicago will turn her attention to still higher culture, and when she does, in the language of the west, "she will make things hum." "She will just hump herself and hustle."

The princely generosity of the late John Crerar, whose will was proved on the 14th instant, deserves more than passing mention. Among the bequests the following are of special interest to medical men: Chicago Orphan Asylum, $50,000; Chicago Nursery and Half-Orphans' Asylum, $50,000; Chicago Presbyterian Hospital, $25,000; St. Luke's Free Hospital, $25,000; Chicago Relief and Air Society, $50,000; Illinois Training School for Nurses, $50,000; Old People's Home, $50,000; Chicago Home of the Friendless, $50,000.

The thirteenth annual meeting of the American Academy of Medicine was held at the Leland Hotel on November 13th and 14th. Dr. Leartus Connor presided. He read an excellent paper on "The American Academy of Medicine; its Signs of Promise and Obstacles, its Field of Labor, and some Suggestions looking to an Increase of its Efficiency." Dr. Samuel J. Jones was elected President for the ensuing year.

At the annual meeting of the Chicago Gynecological Society, held October 17, 1889, the following office-bearers were chosen: President, J. H. Etheridge; First Vice-President, Philip Adolphus; Second Vice-President, Franklin H. Martin; Secretary, Edward Warren Sawyer; Treasurer, F. E. Waxham; Editor, J. C. Hoag; Pathologist, Bayard Holmes. Dr. Charles T. Parkes, the retiring President, in his address, referred to the treatment of spina bifida, and reported three cases recently ob-

[1] Introductory Address, Rush Medical College, September, 1889.

served. The first example of the condition occurred in a small, marasmic, bottle-fed baby, four weeks old. The tumor was situated in the lower lumbar region, three inches in diameter, pedicle one and a half inches wide. When the fluid had been reduced, a longitudinal incision was made through the covering of the tumor, layer after layer being taken up, at the same time carefully dissecting off and dropping into the spinal canal a ridge made up of terminal nerves. Union of the cut surface by *étage* suture of three strata. Strict antisepsis. Cure within ten days, although followed by slight partial paralysis for two weeks. The second case was an example of myelomeningocele in the upper lumbar region of a boy, seven weeks old. The tumor was pedunculated, four inches in diameter, with an ulcerated surface. Same operation as in the first case, but fewer nerve-elements were found in the walls of the sac. The patient was cured. In the third case a weak, delicate baby, of four months, presented an ulcerated meningocele in the mid-dorsal region. The laminæ of two vertebræ were defective, and upon reduction of the fluid the opening into the spinal canal could be felt. The same operation was performed as in the first two cases, with the exception of the final suture. In this case, one suture was passed close to the base of the tumor through the skin. In the other case the skin was avoided. The child did well until the seventh day, when septicæmic symptoms appeared, and the child died soon afterward of septic meningitis. Dr. Parkes thought the source of infection was the stitch passed through the skin.

The Society then adjourned to a banquet at the Grand Pacific Hotel, tendered by the retiring president, Dr. Parkes.

Diphtheria of a malignant type is uncommonly prevalent, the number of deaths from it for the week ending October 26, numbering twenty-four; the week following showing a considerable increase. The disease does not appear to be epidemic, but seems to be due to local causes, defective sewerage in particular. Chicago's other scourge, typhoid fever, is always present. The Health Commissioner has no return of the total number of cases of this disease, but the death-rate is high. The occurrence of typhoid fever in Chicago is not at all remarkable when one reflects upon the water supply. The sewerage of the city passes directly into the lake, and within a few hours a portion, in the form of drinking-water, is pumped back again from the "crib," about two miles out. In the dim and distant future, we hope to have a "crib" four miles out in the lake, and expect to turn the sewerage of the city into the Mississippi.

DETROIT.

To the Editor of THE MEDICAL NEWS,

SIR: For many years Detroit has been regarded as a medical centre, having one or more medical schools as well as being the seat of publication of several medical journals. The natural advantages possessed by this city, together with business enterprises and the fact of being upon the highway of commerce and travel between the east and west, have rapidly increased the population until now it numbers a quarter of a million. With this growth has also been a demand for hospitals, and now there exist several thoroughly equipped institutions, all enjoying a large patronage.

St. Mary's Hospital, on St. Antoine St., is a large brick structure under the supervision of the Sisters of Charity. Here the students of the Detroit College of Medicine receive the greater part of their clinical instruction, the attending staff of the hospital being connected with the College.

In connection with St. Mary's Hospital is the dispensary where the out-door patients are treated daily and furnish material for a complete out-door clinic.

It is the purpose of the Sisters to add another wing to the hospital which shall contain fifty more beds, and also a fine, large, thoroughly-equipped operating amphitheatre.

Clinical instruction is also given at Harper Hospital, situated at the head of Martin Place, in the northeastern portion of the city. This building accommodates the Children's Free Hospital—an institution comparatively recently organized but doing much good work and fulfilling a long-felt want.

The Farrand Training School for Nurses is a prominent feature in connection with Harper Hospital and is very successful.

A subject of much interest to the medical profession, viz., the hot-air treatment in phthisis—is being thoroughly tried by Dr. Shurly in a ward of Harper Hospital set apart and thoroughly equipped for that purpose. The publication of his results will be of great interest.

In addition to the ambulance at the hospital, Harper Hospital has established an ambulance station in the centre of the town, on St. Antoine St.

Two blocks north of Harper Hospital, on the same street, is Grace Hospital, endowed and built within a year by Senator McMillan, Mr. A. Chaffee, and the late Mr. J. S. Newberry. It is a handsome building of stone and brick. This institution is under the guidance of a homœopathic staff, has a training school for nurses, an ambulance, and an out-door free dispensary.

The homœopathic fraternity is well represented here as regards numbers, and have a medical society which meets about once a month. Of late its most important business seems to have been dealing with dissensions occurring in the attending staff of Grace Hospital, which, so far, they have been unable to settle with peace and harmony.

St. Luke's Hospital is a handsome brick structure surrounded by extensive lawns and driveways, located on Fort St. West, in the western part of the city, near Fort Wayne.

The Emergency Hospital and Michigan College of Medicine occupy a brick structure on Porter St., near Michigan Avenue, in a central portion of the city.

The United States Marine Hospital, under the supervision of Surgeon Stower, is a large brick edifice surrounded by beautiful grounds, on the corner of Jefferson Avenue and Mt. Elliott, in the eastern part of the city. An out-door dispensary at the down-town office on Griswold street affords relief to many cases.

With the beginning of the present collegiate year the trustees of the Detroit College of Medicine turned over to its faculty the handsome stone and brick building just completed for college purposes, situated near their former college building on St. Antoine Street. This is a building which should fill with pride the bosoms of any medical faculty, being a handsome brick structure with stone trimmings and facings, and fitted within with due regards

for the necessities of a thoroughly equipped medical college. The entrance is an imposing and graceful archway of dressed and carved stone and leads into a splendid and spacious hallway finished in antique oak. Without more minute description I may briefly say the museum, laboratories, lecture room, dissecting room, etc., are all models of their kind. Ventilation and the disposition of waste materials from dissecting room have been carefully provided for by the adoption of the Smead System.

There are four regular medical Societies—the largest being the Detroit Medical and Library Association, whose thirteenth annual meeting was reported in these columns a few weeks ago. This society, which formerly met twice a month, since its last annual meeting meets once a week. Contrary to the expectations of some of the members, the amount of work disposed of at the meetings, if anything, exceeds that of the former arrangement.

The Wayne County Medical Society and the Detroit Academy of Medicine are flourishing societies—the former holding meetings twice a month and the latter once a week.

The Detroit Gynecological Society devotes itself to that specialty.

Among the medical journals owned or published here are *The Index Medicus*, *The American Lancet*, *The Therapeutic Gazette*, *The Pharmaceutical Era*, and *The Medical Age*.

ST. LOUIS.

(*From our Special Correspondent.*)

To the Editor of THE MEDICAL NEWS,

SIR: Medical journalism in St. Louis has undergone a number of changes during the past year. The *Courier of Medicine*, which for ten years held a leading place, not only among the medical journals of St. Louis, but of the entire West, was discontinued at the close of the year. This was a special loss to the members of the Medico-Chirurgical Society, because by an arrangement between that society and the association which founded the *Courier* all the exchanges of the journal and all books received for review were deposited in the society library for the joint use of the members of both organizations, and in the course of ten years quite a useful collection of periodicals and books had accumulated and was becoming each year more valuable. Now, of course, the only additions to the library are those secured by special donation from the members and those which are purchased from the funds of the society. About a dozen of the leading home and foreign journals are now regularly kept on file in the society hall for the use of its members, among them, of course, THE MEDICAL NEWS.

Returning to the subject of medical journalism in St. Louis, I may mention that the faculty of the "Post-graduate School of Medicine" have started a monthly medical journal, *The St. Louis Polyclinic*, of some thirty-six pages, designed especially to keep the interests of the school before the attention of the profession in the West.

A medical quarterly has also been started by an enterprising business firm and edited by a physician in the northern part of the State. The journal is called *The Medical Advance*. Though I have seen but one number, I do not think that as a quarterly it has any prospect of success.

Besides these ventures there is a promise of another at the opening of the new year. It is to be called *The Medical Mirror*, and will be edited and published by Dr. I. N. Love, who, until the present year, has been for several years connected with the editorial staff of *The Weekly Medical Review*. Dr. Love seems to have unlimited confidence in the financial success of the new enterprise, for he has subscribed $1000 toward the guarantee fund for the World's Fair in 1892, in the name of *The Medical Mirror*.

I am credibly informed that the faculty of the Beaumont Medical College have bought a lot for their new building on the corner of Pine and Jefferson Avenues, and will proceed at once to erect a suitable and handsome structure with the expectation of occupying it at the next session.

At the meeting of the Medico-Chirurgical Society last Tuesday evening, the subject of changing the location of the society hall was discussed.

For several years the Medico-Chirurgical Society has occupied a handsome hall on the second floor of a building owned by the Post-graduate School of Medicine. It is a central location, and the room is readily accessible, quiet and convenient, and the rent, twenty-five dollars per month, is a mere bagatelle. It has been found, however, that some of the members object to having the hall for society meetings, and reading-room in a college building, and it has been thought by some that the meetings would be better attended and hence more profitable, if they were held elsewhere. After due consideration it was voted to make no change in the location at present.

In closing I would mention that the medical profession here is subscribing liberally to the guarantee fund for the World's Fair which it is hoped will be held in St. Louis in 1892.

NEWS ITEMS.

Is Colorado's Climate Changing?—The inhabitants of Denver are asking what is the meaning of the unusual snow-fall and humidity of the past month. The newspapers of that city have expressed the opinion that their climate is about to undergo a change, in consequence of surface changes of "building up" and improving the State. The present moist season has been especially disappointing to Eastern people, who have journeyed to Denver to escape the humidity of our seaboard winters.

From a letter recently received, a few sentences are quoted: "Snow has fallen each night and morning, but the sun conquers by midday, making walking almost impossible. As a usual thing, the inhabitants expect about ten days of inclement weather during winter and spring, and have not looked upon the paving of streets and crossings as at all necessary. But they are now aroused to remedy this condition. The snow-fall is said by some to be already greater than the total for three ordinary winters." The total fall at the Denver station, in October, was 2.11 inches, and is the only October since 1871, when 1.49 inches have been exceeded, with the single exception of that of 1877, when 2.15 inches were registered: there have been but nine cloudless days in the same month, while nineteen were partly cloudy. The mean temperature has been somewhat

above that of the past decade. Fog—a condition hitherto almost unknown in Colorado—occurred during five mornings in October.

Poorhouse at Wilmington, N. C.—The following report in the Bulletin of the State Board of Health of North Carolina, by Dr. F.W. Potter, of Wilmington, N. C., in regard to a local poorhouse, is worthy of note: While the condition of the poorhouse is pretty good, so far as whitewash and neatness externally are concerned, conditions exist which it is hoped will be corrected as soon as brought to the attention of the commissioners. Reference is had especially to the *pen*, which is known as "the stockade." It is a yard about thirty or forty feet square, having on one side a row of *dens* and on another a row of *kennels*. The yard is inclosed by a close fence about twelve feet high, so that those who have their *homes* within its walls have only their whitewashed surfaces and the blue expanse of heaven for their eyes to rest on, except, possibly, the tops of some neighboring pines. In this pen are kept the work-house prisoners, when not at work (in fact, I believe this constitutes the county work-house), and such unfortunate inmates of the poorhouse as are considered of unsound mind. Also, occasionally, for punishment, those who do not obey the mandates of the "keeper." In one of the "dens" above alluded to a poor wretch has been kept for five or six weeks—a young negro woman—who some time since scaled the walls and walked to Goldboro, a distance of eighty-four miles. She is insane without doubt, but there was certainly "method in *her* madness" when she attempted to find more comfortable quarters. No light reaches her except when some timid attendant forces open the door just wide enough to slip in her victuals and immediately closes it. Whether her clothing is ever changed I know not, but infer not. The "*kennels*" are hardly worthy the name, for a humane dog-fancier would doubtless provide more comfortable quarters for his pets. One of them was almost too small to accommodate the frame which was nailed to one side to receive the dirty bag of straw on which a sick man slept, and a dirty excrement bucket which stood by it. The inmates of these places will surely suffer during the cold weather of the coming winter, unless something is done shortly to prevent it, for these places are very open and exposed to the north winds. I will not take any more space in the Bulletin except to protest against the present method of providing for the poor. The contract for taking care of them is put out to the lowest bidder, and it is human nature for a man to make all he can out of a contract.

An Eccentric Physician's Will.—A physician's last will and testament, of an extraordinary character, is about to be contested at Buda-Pesth. It is that of the late Dr. Goldberger, who left a fortune of $250,000 to accumulate until, in the course of years, it shall have reached the sum of $1,000,000,000, when it shall begin to be used as a fund for the abolition of poverty everywhere. The trustees appointed under the will having declined to serve, and claimants for the estate have arisen at Madrid, London, and in this country.

A Head-nurse Dies by an Ether Explosion.—At the private hospital, in New York City, conducted by Dr. W. Tod Helmuth, of the Homœopathic College, a valued nurse lost her life by an explosion of sulphuric ether. She was in the act of pouring ether from one bottle to another, and is supposed to have been too near to a gaslight. Fatal burns were the result of the accident, followed by death, about forty-eight hours later, on the 21st inst.

Death of Dr. Robert G. Cabell.—Dr. Robert Gamble Cabell, a member of a Virginian family notable in the medical annals of that State, died at Richmond, November 17th, aged eighty-one years. He was the father of Surgeon Arthur Cabell of the U. S. Navy. He had himself been a surgeon during the late war, in the Confederate service.

An Anatomical Chair Filled at the University of Aberdeen.—The University of Aberdeen has, after much delay, found a new Professor of Anatomy. Dr. Robert W. Reid, of St. Thomas's Hospital, London, in the place of Dr. Struthers, resigned. Dr. Reid is an old Aberdeen man, and formerly, for a short period, the anatomical demonstrator at his *alma mater*. The *Montreal Medical Journal* speaks of him as a great favorite with the Canadian medical students who have attended upon his instructions at the St. Thomas's School, for they have found him "a kind friend, a sound anatomist, and a good teacher."

Anniversary of the New York Academy of Medicine.—The New York Academy of Medicine observed its forty-third anniversary on the evening of November 21st, in its new building, No. 12 West Thirty-first Street. In opening the meeting, the President, Dr. Loomis, called attention to the need of $20,000 in additional subscriptions to complete the Academy's new building. He said that $150,000 had already been subscribed, that the Academy hoped to add $70,000 to the building fund by the sale of the present building, and that the new building when done would be the best equipped of its kind in the country. The anniversary address was delivered by Dr. William M. Polk, on "The Relation of Medicine to Some of the Questions of the Day."

Diphtheria at Carbondale.—There have been some disquieting reports in the public press regarding the epidemic prevalence of diphtheria at Carbondale, Pa. There is medical evidence to show that the news agencies by which the sensational despatches were sent out were misled, and the number of cases and fatal results increased a hundred per cent. beyond the true status. At a recent date there had been one hundred cases, with forty deaths.

Leprosy in Minnesota.—According to the *Weekly Abstract of Sanitary Reports*, there are at present seven cases of leprosy in Minnesota, none of which has the disease in a very severe form. Two of the lepers have children, all of whom are perfectly healthy.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

OSTEOMYELITIS OF HUMERUS AND OTHER CASES.

A Clinical Lecture
Delivered at the Rush Medical College, Chicago, Ill.

BY CHARLES T. PARKES, M.D.,
PROFESSOR OF SURGERY.

[Reported by A. J. OCHSNER, M.D., Chief of Surgical Clinic.]

THE first patient is a little girl of three years. Six months ago the upper part of the arm became much swollen and the shoulder stiff. She had high fever. In a few weeks this swelling pointed and broke on the posterior surface of the arm about three inches below the shoulder-joint. A probe can be carried along the sinus, which has remained, a distance of two and one-half inches in the direction of the joint. The joint is now movable and apparently free from pain. Although no dead bone can be detected, it nevertheless seems certain, from the history and from the persistence of the sinus, that a portion of the upper extremity of the humerus has been destroyed, probably by osteomyelitis, possibly by tuberculosis.

The treatment advised is incision and removal of the diseased portion of bone. While waiting for the operation, systematic feeding and other hygienic measures are recommended to place the child in as good a general condition as possible.

NOTE.—At the operation at a succeeding clinic it was found that osteomyelitis existed; the surface being so thoroughly covered with granulations that no denuded bone could be felt with the probe, neither could there have been any grating upon moving the joint.

I next bring before you an anæmic, nervous boy, eight years old. Three months ago he had a severe attack of pneumonia, and following this a swelling of the upper portion of the right arm. The attending physician, detecting fluctuation, opened an abscess five inches from the upper end of the arm on its outer aspect. A sinus has persisted at this point. Denuded bone is detected by the probe. The bone is enlarged to one and one-half times its normal size. There is also a marked enlargement opposite the lower epiphysial line. The unusual swelling and hardness at the extremities of the shaft suggest that it will be found that the disease has destroyed the entire diaphysis. It will probably become an immense sequestrum. Diagnosis, osteomyelitis.

The general condition of the boy has improved very slowly since the beginning of convalescence from pneumonia until the last week or two. It was deemed best to postpone an operation for removal of the diseased bone until the patient has more thoroughly recovered from the effects of his pneumonia. Good diet, outdoor exercise, tonics, and iron are recommended, and the patient advised to return in a few weeks.

LATERAL CURVATURE OF SPINE.

The next patient is a boy, aged five years. He has an awkward gait and carries one shoulder and one hip higher than the other. The chest is flattened on the right side. The abdomen very prominent. On reddening the skin over the spinous processes of the vertebræ by friction, lateral curvature of the spine is apparent. The patient's mother is instructed in certain gymnastics to be performed each day by the child, which are calculated to develop the muscles of the back. Upon returning to the clinic further exercises will be taught.

The parents are directed to give the patient good plain food—beef, mutton, milk, butter, and cod-liver oil—and to give him an abundance of sunlight and fresh air. The patient is to report once in two weeks for examination and further instruction.

GANGLION OF EXTERNAL HAMSTRING TENDON.

This case is a man, aged twenty-four years, who some weeks ago struck his knee against the corner of a box. Since that time he has felt pain on the external surface of the leg a little below the knee. At present there is a fluctuating swelling above the insertion of the external hamstring tendon. The diagnosis is, ganglion of the external hamstring tendon. The treatment should be tapping and the application of a plaster dressing with a pad over the location of the ganglion.

NECROSIS OF SACRO-ILIAC JOINT.

This case is a well-nourished, apparently healthy young woman, aged twenty years. For six years she had a swelling in the region of the sacro-iliac joint, which opened and left a sinus in the gluteo-femoral fold three inches below the great trochanter. One year ago she had some trouble in the right hip-joint, but this has entirely subsided. The joint is freely movable without giving rise to pain. The sinus extends in the direction of the sacro-iliac joint; it can be followed, by means of a probe, for a distance of five inches, but no diseased bone can be felt, although it undoubtedly exists.

The patient is so slightly inconvenienced that the radical steps necessary to insure a permanent cure, namely, laying open the sinus, exposing and removing the diseased bone—do not seem warranted. The patient is advised to return in case of further trouble or inconvenience.

WOUNDS OF ULNAR AND MEDIAN NERVES.

The next patient is a Canadian farmer, strong and healthy, and aged forty-two years. A year and a half ago, he fell into a window severely cutting his wrist with the broken glass. Since the wound has healed, the nervous supply of the little, ring, and middle fingers has

been lacking, evidently resulting from section of ulnar and branches of the median nerve. The treatment advised is to cut down upon the ulnar nerve through the scar, to dissect up the severed ends, and unite them by means of catgut sutures. In a number of similar operations performed in this clinic during the past year, very satisfactory results have been attained.

SARCOMA OF LOWER JAW.

The next patient, a man of forty-nine years, noticed one year ago, a tumor involving the alveolar process of the middle and left part of the lower jaw. The tumor is as large as a hen's egg, and implicates the surrounding tissues. The lymphatic glands of the neck are not involved. The bone is considerably enlarged. The diagnosis is sarcoma, and an early removal is advised. It will be necessary to resect the jaw opposite the ramus on the left side and opposite the bicuspid on the right.

NOTE.—The above diagnosis was confirmed, microscopically, after the operation, which took place at the following clinic.

ANAL FISSURE AND HEMORRHOIDS.

This case is a woman, aged twenty-five years, who has, as you see, an anæmic, suffering appearance. For several months she has suffered very severe pain during and after defecation. Local examination shows an anal fissure, and both internal and external hemorrhoids. Dilatation of the sphincter is advised, and removal of hemorrhoids by means of clamp and Paquelin cautery.

NECROSIS OF TIBIA.

The next patient is a man of fifty-five years, who one year ago sustained a compound fracture of the tibia and fibula of the right leg three inches from their lower extremities. After two months of proper treatment by his family physician, he was able to walk on the limb, but soon after it began to swell, and the wounds, which had previously healed, reopened and discharged pus. On exploring the sinuses with the probe, denuded bone is detected. The limb is six inches in diameter a few inches above the seat of fracture, and the skin has a smooth, red, inflamed, œdematous appearance. The patient complains of a burning sensation. The limb is to be placed in an elevated position, and large hot fomentations of saturated solution of boric acid in water are to be applied to the entire surface. At a future clinic the sinuses are to be laid open, and the diseased bone is to be removed. All the granulations surrounding the dead bone and lining the sinuses will then be thoroughly curetted and washed out, and the cavity changed into a perfectly clean aseptic wound. It is much better to do all of this after the present extreme hyperæmia and œdema have been removed by position and fomentations.

EXOSTOSIS OF TIBIA.

This boy of eleven years comes before us with a history of having a few months ago noticed a hard immovable tumor as large as a hickory nut on the inner surface of the tibia, opposite the upper epiphysial line. There is no definite history of traumatism. If there has been any increase in the size of the tumor since it was first noticed, this has been very slow. There is neither pain nor inconvenience, nor noticeable deformity. The diagnosis is epiphysial exostosis. Non-interference is advised, unless other symptoms should occur. The patient being rather badly nourished and somewhat anæmic, good food, fresh air, and plenty of exercise are recommended; also, a tonic.

COXITIS.

The next patient is a very thin, anæmic, cachectic girl, aged five years. Removing the clothing we have the characteristic appearance of a child suffering from rachitis affecting particularly the spine and the chest. There is an extreme lateral curvature of the spine. The ribs are indented laterally and enlarged at their sternal ends, giving the patient a prominent sternum. Her respiration is abdominal. During the last two months she has begun to limp on her left leg, and to complain of some pain in her left knee. Now the leg is held in a flexed condition, and the toes are inverted. She wakes up at night screaming with severe pain. Placing her on her back on the table, and making flexion and extension with the thigh, the pelvis moves with the thigh, showing that there is muscular fixation. Diagnosis, coxitis. The general condition of the patient being so bad, no radical operation can be advised. In all cases of tuberculosis of joints in which a removal of the diseased portion is not advisable, the best treatment is to secure absolute rest. In this case, we will apply a silicate of sodium cast, which is very light, and strong enough to immobilize the joint; we will also advise the use of good food, sunlight, and fresh air.

SUBLUXATION OF HUMERUS.

The next patient is a man who sustained an injury to his shoulder by falling from a tree. The trauma caused a rupture of the attachment of the deltoid muscle and the anterior ligaments of the joint. There is a forward and downward partial dislocation of the head of the humerus. Patient can move his arm by changing the position of the scapula. All the parts seem to have been driven forward about an inch. The treatment advised is passive motion and massage.

RE-DRESSING OF ABDOMINAL SECTION.

Of the next two cases, the first is brought in for redressing and the second for further observation. A week ago, this patient had one cystic and one apparently normal ovary removed for the relief of epilepsy coming on at the time of the menstrual period. Patient returns for the first dressing. She looks well, and has been comfortable, the temperature never reaching 100°. The wound is perfectly united, and the stitches are removed.

SPECIFIC ULCER OF TONGUE.

The next patient came to the clinic six weeks ago, with a large angry malignant ulcer under the tongue and enlarged submaxillary lymphatic glands. There were sharp edges on the teeth on the affected side. No history of syphilis could be elicited. In order to remove the possibility of error in diagnosis, the patient received antisyphilitic treatment and a mouth-wash of saturated solution of boric acid in water, and was directed to have the teeth extracted. Now, the ulcer is almost completely healed, and the glands are no longer enlarged, showing that it was, in fact, a specific ulcer and not epithelioma.

ORIGINAL ARTICLES.

THE ABUSE OF UTERINE TREATMENT THROUGH MISTAKEN DIAGNOSIS.

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

WHILE the treatment of uterine diseases received a great impulse from the writings of Simpson in England, of Kiwisch and Scanzoni in Germany, and of Huguier and Recamier in France, it is to Bennet that we chiefly owe the common use of local applications and the popularization of the speculum. The former gynecologists wrote about the more strictly surgical diseases of women, which were, and will ever be, relegated to specialists. But Bennet as early as 1843 in French, and 1845 in English, published his work on *Inflammation of the Uterus*, of which the last edition was issued in 1861. In it he contended that inflammation of the cervical canal is the main factor in female diseases; that from it come ulceration, displacement, leucorrhœa, menstrual derangement, and ovarian disorder; and that the inflammation, being limited to the cervical canal, can readily be dislodged by strong caustics. Written with dogmatic zeal, advising a definite treatment to a reachable and a seeable object—a treatment which the humblest yeoman of the profession could carry out—few books of modern times have exerted so great and so widespread an influence. That riddle of the Sphinx—the cause of woman's ill-health—had been read and interpreted! The profession was taken fairly by storm; the effect was as electric as the appeal of Maria Theresa to Hungarian nobles. From Arctic to Antarctic oceans, from the Mississippi to the Volga, countless speculums of varied form leaped from their bags and flashed in sunlight boreal, tropical, and meridional. Cauteries actual or potential, applied to actual or potential uterine sores, became the order, in fact, the ruling passion of the day. In the general enthusiasm it was soon forgotten that every mucous membrane secretes, and that it must of course give evidence of its own secretion, just as every nose contains its mucus. Hence, every examined womb, being found to contain mucus, was, as it were, invalided—that is to say, it was put on the speculum list. Naturally, then, not a womb being found healthy from the speculum standpoint, this much-abused organ was charged with being the cause of almost all the ills that female flesh is heir to, and it was treated—that is to say, maltreated—for every imaginable disorder that could not be referred offhand to some other organ. Bennet, the medical Frankenstein, had evoked a monster which could not be curbed, and for five and thirty years the speculum ran riot.

But in this age of unrestful progress, at every turn of the hour-glass of time, some cherished creed, some accepted dogma, is proved a heresy, and Bennet's cervical theory fared but little better. A wholesome reaction set in. As experience grew, it was found that pelvic inflammations and strictures of the cervical canal came from this treatment. This discovery led to the abandonment of the more heroic caustics. Then, again, it gradually dawned upon truth-seekers that far more than inflammation, passive congestion of the womb and of its annexes, together with resulting structural changes, that uterine displacements and injuries, and that ovarian and tubal lesions played important *rôles* in the female economy. In keeping with this knowledge is the far more rational and beneficial treatment of the present day.

Still, granting that the treatment of actual, visible, and tangible uterine disease leaves little for improvement, the whole truth has not been reached—for truth evolves slowly and does not, like Aaron's rod, bud and blossom in a night. The ball-and-chain of tradition still drags at the heel of this branch of science, and the medical mind, in close touch here with the lay mind, tends to give the reproductive organs undue importance—to attribute, in fact, altogether too much to their influence. By a very large number of practitioners, even by specialists working in other fields of medicine, these organs are too often wrongfully made the scape-goat for headaches and nape-aches, for spine-aches and back-aches, for weakness of vision, for aural disturbances, for sore-throat and weak lungs, for irritable heart, and also for a host of so-called uterine symptoms. Yet these very symptoms may be due wholly to nerve-exhaustion, or malnutrition of nerve-centres, and not to reflex action, or to direct action, from some real or some supposed uterine disorder. I say this advisedly, because I too have thus erred, and because hardly a day passes without my seeing cases of supposed uterine disease which have been so treated for months—even for years—when the whole trouble, or the most of it, lies—not in the reproductive organs, but—in the nerve-ganglia. This abuse of uterine treatment, through a mistaken diagnosis, is, in my opinion, the great medical error of the day.

Once I was asked by a medical friend to see an exceedingly bad and acute case of pruritus vulvæ. Very naturally attributing it to uterine disease, he discovered a small cervical tear, and I was called to decide the question of repairing it. I, too, was, at first, led astray, but the suddenness of the seizure and the lack of consistency in the behavior of the symptoms, put me on my guard, and we soon found out the cause to be an acute attack of jealousy.

To this day a lady rallies me upon a wild-goose chase which I made after a uterine cause for her neurasthenic symptoms. Carefully overhauling her pelvic

organs I discovered nothing but a torn perineum, and attributing to that lesion all her ills, which were legion, I restored it, making at the same time the rash but honest promise of her complete restoration to health. The rent was a bad one and needed repair, but it had existed for years without doing harm, and it had nothing to do with her symptoms, although they were largely uterine in expression, notably a bearing-down feeling. They became, in fact, worse after the operation than before, and it was only after recognizing the nerve element of her disease, that I was enabled to do her any good. Many such mistakes, of attributing too much to the reproductive apparatus, have I seen in the practice of other physicians; but my own blunders in the same direction have made me feel very charitable toward them. Out of many examples let me give a few:

Not many years ago I was asked by one of our best and most conscientious physicians, himself a gynecologist and a medical teacher, to see a very delicate and refined lady. She had passed through most of the trials which beset a clergyman's wife, and had borne two children, the younger one ten years before. Having for many years enjoyed fairly good health, she lately had suffered a great bereavement, and she was now prostrated by nerve-exhaustion. Her symptoms were markedly of a uterine character. These were pain in the back, an irritable bladder, a pelvic bearing-down, an inability to walk, aches in the left groin, menorrhagia and leucorrhœa. These uterine symptoms had led my friend astray, and finding an insignificant cervical tear, he attributed to it all his patient's ill-health, and, against my advice, operated upon it. The wound healed perfectly, excepting in one suture track on one side of the cervix, where a small fistula remained. His patient becoming none the better, but rather the worse, he laid the blame on this fistula, and tried to close it. Not succeeding, he again called me in. Now, this small fistula had no more to do with the lady's general ill-health than the earring holes in her ears, and her disease was clearly a neurosis. Yet I could not bring my friend to my way of thinking—the uterine symptoms were too much for him, and he tinkered away at the fistula until it finally healed up, but the lady became no better. Finally, he adopted my theory of neurosis, put his patient upon an appropriate treatment, cured her, and then had the manliness to thank me for my advice. My friend is now, alas! no more, else I would not have told this story; and I have done so simply to show how hard it is for a bright and progressive mind, even for a gynecologist and a medical teacher at that, to free himself from the bias of tradition.

By breaking down the nervous system, the brain-cramming, the intellectual rivalry, the buckram proprieties, and the unwholesome confinement of our boarding-schools and public schools, breed a host of sickly girls, who swarm in every class of society. Manifold diseases, both functional and structural, date from the recitation room. They are mostly of a uterine complexion, for at that time of life the sexual sphere dominates, and the brunt of the nervous and of the vascular disturbances which form the essence of nerve-exhaustion, falls on the most exacting organs—the reproductive. Hence these suffer from neuralgic pains or from congestion and the lesions coming from prolonged congestion. Yet physicians, misled by the urgency and the number of the so-called uterine symptoms, mistake the effect, or more often the counterfeited effect, for the cause, and give a local treatment when it should be a constitutional one.

So common is it for girls in boarding-schools to suffer either from amenorrhœa or from irregular menstruation, as to create a general impression in the community that in these schools some drug is secretly given in the food in order to lessen the laundry work. In one school of great repute so many girls missed their monthly periods that the family physician of several of them wrote to me, asking whether it were possible, as his patients averred, "that as their clothes were laundried in the building, something was given in their food or their drink to produce the effect, for the purpose of saving the laundress the disagreeable task of washing the napkins." My reply was, that if laundresses were acquainted with a drug that could arrest menstruation, they knew more than the profession; and that his patients had lost their monthly periods, not from secret drugs, but from loss of health due to an unwholesome system of education.

Another physician, the worthy chairman of a school-board in a young city, became awakened to the fact that a great proportion of the girls in the public schools were failing in health from backache, wakefulness, weariness, and disordered menstruation. Full of philanthropic and architectural zeal, and with the uterine idea firmly implanted in his head, he wrote to me, asking whether the long flights of stairs in the school-houses were not to blame for these female ailments. I replied in words to the effect that were a higher culture literal, being perched upon the top of some Eiffel's tower, like Simeon Stylites upon his pillar, and were girls obliged to climb up to it, the muscular effort would no doubt put them out of breath, and repeated intellectual excursions in the same direction might in the end cause—not uterine diseases, but—the heart diseases of athletes and of Alpine climbers. I further contended that stair-climbing *per se* could rarely produce uterine disorders, and that the girls in his school

were suffering—not from uterine disease, but—from the nerve-counterfeits of uterine disease, viz., from the reflexes of a nerve-exhaustion resulting from an unhealthy, and therefore faulty, system of education. My arguments evidently failed to convince this honest gentleman, for the correspondence abruptly ended at this point, and I have a shrewd suspicion that he carried out his architectural plans. Should any of my readers journey westward, and see in some growing city a girls' school-house fashioned like a covered rope-walk or a skating-rink, depend upon it, it will turn out to be the philanthropic but mistaken evolution of my correspondent. The traveller would no doubt find education very effectively taught on the only floor—the ground floor—of this building; but doubtless, also, he would see as many pale faces, and would discover on inquiry no fewer backaches, spine-aches, womb-aches,and menstrual disturbances, than when the recitation rooms were on the third or the fourth floor.

In a parous neurasthenic woman, a leucorrhœa, a slight prolapse of the womb, a small tear of the cervix, or an insignificant rent of the perineum, each plays the part of the will-o'-the-wisp to allure the physician away from the bottom factor. To these trifling lesions —because they are visible, palpable, and ponderable, and because he has, by education and by tradition, a uterine bias—he attributes all his patient's troubles; whereas a greater and a subtler force, the invisible, impalpable, and imponderable nervous system, may be the sole delinquent. She may be a bereaved mother, a grieving widow, or a neglected wife, and all her uterine symptoms, yes, every one of them, may be the outcome of her sorrows, and not of her local lesions.

Often the victim of this misdirected treatment is a young unmarried girl, whose nerves have been upset by some secret grief, perhaps a cross in love, or by ambitious over-study. Misleading symptoms now set in, which I cannot better describe than by a quotation from one of my own articles on the subject (*Lessons in Gynecology*, third edition, p. 523):

"She loses her appetite, lies awake at night, and grows pale and weak. She has cold feet and blue finger-nails, and perhaps complains of infra-mammary and ovarian pains. Headache and backache, spine-ache, and an oppressive sense of exhaustion distress her. Her monthly periods, hitherto without suffering, now begin to annoy her more and more, until they become extremely painful, and at these times dark circles appear under her eyes. Her linen is stained by a leucorrhœa, and bladder troubles soon set in. She is wearied beyond measure by the slightest mental or physical exertion; the short visit of a friend upsets her for the rest of the day; 'a grasshopper is a burden' to her, and she finally becomes very nervous or hysterical. Now, very unfortunately, the idea attached to this group of symptoms is that the womb is at fault. A moral rape is, therefore, committed by a digital or a speculum examination, and two supposed lesions will be found —first, as a matter of course, the natural virginal anteflexion; and, secondly, a slight uterine catarrh. These are at once seized upon as the prime factors, and she is accordingly subjected to a painful, an unnerving, and a humiliating treatment for the false flexion and the sham endometritis. Unimproved, she drags herself from one consulting-room to another, until finally, in despair, she settles down to a sofa in a darkened room, and becomes either the spoiled pet or the vampire of the family."

That this is not an over-wrought picture, every one of my readers will attest. For what physician has not had the original as a patient, and cursed his stars for the possession?

At the present time there are in my private hospital seven ladies who are rapidly recovering from general nerve-exhaustion and from its sham uterine symptoms. They will get well without any local treatment whatever. Yet all were pronounced by their physicians to be cases of uterine disease, and had been so treated for months, and even for years, without benefit. One of them was urged by an excellent authority to submit to the removal of her ovaries; another, to have her slightly torn cervix sewn up; a third, to have a trifling rent in the perineum repaired. Whilst the fourth, a young girl whose nerves have given way from hard study, had a perfectly healthy and a perfectly poised womb, propped up by an anteflexion pessary, treated every other day, for weeks, by an application, and deluged twice a day with gallons of hot water.

Many of us have laughed at the quaint but kind doctor in one of Bulwer's novels, who prescribes a special pellet for each emotion, and calms a passion by its appropriate parvule. But are we, the physicians of the nineteenth century, a century of infinite progress, are we, I say, a whit the wiser? We who seek to cure the nerve-reflexes of grief, of love, of neglect and of jealousy, not by harmless infinitesimals, but by the removal of the ovaries, and by operations upon the cervix and the perineum; or try to salve brain-wounds and heart-pangs by anteflexion pessaries, by uterine applications and by vaginal douches of a temperature of 110°? Can the rankest materialism be pushed further than this?

Fortunately for the reputation of my professional brothers, and fortunately for my own—for I, the heavy Mentor of this homily, have also sinned and in like manner—this grave error of diagnosis is not without excuse. The symptoms of nerve-prostration so greatly resemble those of even coarse uterine lesions that the nerve-mimicries can very readily be mistaken for signals of actual organic disease. Nor, indeed, are they always distinguishable the one from the other, for the marvellous kinship be-

tween mind and matter is a tangled skein, not yet unravelled by dead-house or by laboratory.

What, then, are these symptoms? Their name is legion, but the most common ones are, strangely enough, those which lay and professional tradition, with singular consent, have labelled as the symptoms *par excellence* of womb disease. They are, in the order of their frequency, great weariness, more or less of nervousness and of wakefulness; inability to walk any distance and a bearing-down feeling; headache, nape-ache and backache; cold feet, an irritable bladder, spinal tenderness and pain in one ovary, usually the left, or in both ovaries. The sense of exhaustion is a remarkable one: the woman is always tired; she passes the day tired, she goes to bed tired, and she wakes up tired, often, indeed, more tired than when she fell asleep. She sighs a great deal, and her arms and legs tremble or "fall asleep" so frequently that she fears palsy or paralysis.

Other symptoms not quite so common are the cerebral ones: such as low spirits, bad dreams, nightmares and night-terrors; explosive sounds in the head, a loss of memory, suicidal thoughts, the fear of impending insanity, the dread of being left alone or of being in a crowd. Some patients are unable to protrude the tongue, or they may have weakness of vision, or a morbid keenness of smell or of taste. Others are kept away from church on account of spinal thrills and locking of the jaws, whenever they hear the lower or the tremulous notes of the organ.

The uterine reflexes are: uterine, pelvic and ovarian aches; pendulum pains swinging from one groin to the other, jerking muscles which cannot keep still, a trembling or a quivering in the abdomen, or a feeling that it needs support, which is often given by pressure with the hands. The intestines display their interest in the general neurosis, by flatulence, by noisy borborygmi, and by the belching of wind in large volumes. They usually keep bound, but sometimes they are loose, or the two conditions alternate. One very common symptom is great exhaustion after a movement of the bowels, and these movements are often caused at unseasonable hours by any simple excitement, such as the ring of the door-bell or the call of a friend.

Dyspeptic symptoms are rarely absent, sometimes they are very marked, while the tongue looks perfectly clean, even when nausea, vomiting, or diarrhœa are present.

Some nervous women are annoyed by clammy hands and feet, or by profuse sweats, which often are not general, but either local or unilateral. Thus I have seen one-half of the face always wet, while the other half kept dry. One of my patients perspired so profusely from the tips of her fingers, that they were constantly dripping and she could not wear gloves. Once I saw a hysterical nose distilling a clear serum, which for weeks dribbled away, almost in a stream. The annoyance was great, yet no treatment whatever did the slightest good; but one day it vanished as mysteriously as it came. Many nervous women are frightened by muscular cramps, or by tinglings, by loss of sensation, or by numbness in the extremities, which are deemed the precursors of paralysis. Nor does the skin escape the general sympathy. It becomes dry, harsh and scurfy, and pigmentary deposits appear under the eyes, around the nipples, and on the chin and forehead. Blondes are likely to get a mottled complexion, and brunettes may become disfigured by brown patches. Sometimes the whole complexion changes to a darker hue. In one instance this was so marked, that both the family physician and the consultant diagnosticated a case of nerve-bronzing to be one of Addison's disease.

Another very remarkable, and often very misleading, symptom is an aneurismal pulsation of the aorta in the epigastrium. Repeatedly have patients been sent to me with the diagnosis of aortic aneurism, when their sole disease was nerve-exhaustion. Lastly, abnormalities in the sexual feeling are not wanting. In the majority, all desire is quenched, or intercourse is painful; in some the sexual feeling is increased; in yet others, it is urgent, but it cannot be gratified; in a few, the dreams are erotic.

From this wealth, from this positive exuberance of symptoms, one would suppose that the diagnosis could not offer any difficulty whatever; but this is far from being the case. The laws governing woman's complex organism cannot be codified; nor can we correctly label the lesions of cerebration proper or of innervation in general. Then the instinct of causality in man leads him to forget that things seen may come from things unseen, and to attribute preferably to the seeable and to the touchable like phenomena, which may come from the unseeable and the untouchable. Naturally, then, we are likely to be misled: First, by symptoms which by common consent are deemed peculiar to uterine disease; secondly, by the co-existence of actual uterine disease, to which we attach undue and overshadowing importance. Apart from these reasons there is yet another one: the human mind, bewildered by a multiplicity of details, does not catch the meaning of their aggregate. So Goethe's traveller missed the forest by reason of the wilderness of trees around him, and the hero of our own national caricature "could not see the town, there were so many houses."

From a large experience I humbly offer to the reader the following watch-words as broad helps to diagnosis. In the first place, always bear in mind

what another has pithily said, that "woman has some organs outside of the pelvis." *Secondly*. Each neurotic case will usually have a tale of fret or grief, of cark and care, of wear and tear. *Thirdly*. Scant or delayed or suppressed menstruation is far more frequently the result of nerve-exhaustion than of uterine disease. *Fourthly*. Anteflexion *per se* is not a pathological condition. It is so when associated with sterility or with painful menstruation, and only then does it need treatment. *Fifthly*. An irritable bladder is more often a nerve symptom than a uterine one. *Sixthly*. In a large number of cases of supposed or of actual uterine disease which display marked gastric disturbance, if the tongue be clean, the essential disease will be found to be neurotic; and it must be treated so. *Seventhly*. Almost every supposed uterine case, characterized by excess of sensibility and by scantness of will-power, is essentially a neurosis. *Eighthly*. In the vast majority of cases in which the woman takes to her bed and stays there indefinitely, from some supposed uterine lesion, she is bed-ridden from her brain and not from her womb. I will go further, and assert that this will be the rule, even when the womb itself is displaced, or it is disordered by a disease or by a lesion that is not in itself exacting or dangerous to life. *Finally*. Uterine symptoms are not *always* present in cases of uterine disease. Nor when present, and even urgent, do they *necessarily* come from uterine disease, for they may be merely nerve-counterfeits of uterine disease.

SOME PRACTICAL POINTS IN THE TREATMENT OF SYPHILIS.

BY R. W. TAYLOR, M.D.,

PROFESSOR OF DERMATOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; SURGEON TO THE CHARITY HOSPITAL, NEW YORK.

AN attentive study of the history of the therapeutics of syphilis for the past twenty years clearly shows that the object of most observers has been to attain such modification and perfection in the methods of using mercury that we may obtain all its beneficial effects, and avoid all annoying and disquieting complications and deleterious results. The experience of more than three hundred years had plainly shown that this agent alone had the most marked and salutary effect in the treatment and cure of syphilis, and it gradually dawned on the medical mind that the great disadvantages and drawbacks encountered in its employment were due to imperfection and crudeness in methods of use, and to an incomplete—I may say imperfect—knowledge of the natural history of the disease. The tangible results of this awakening are now widely seen in the teaching of to-day, in the attenuation of the dosage, and in the systematic and more lengthened course of treatment.

It is impossible to overestimate the great advance made in the treatment of this disease in the establishment of the fact that comparatively small doses of mercury given over long periods of time were more radically curative, and less, if at all, fraught with the disadvantages and dangers of the old-time heroic dosage, and of the three to six months' course.

The next notable step in advance in the therapeutics of syphilis is seen in the widespread search for modification and perfection of the old methods of using mercury, and in the building up of a new method, namely, by hypodermatic injections. The objects hoped to be obtained from each and all of these methods were the use of a minimum quantity of the drug, accuracy and precision of the dosage, rapidity of action, greater potentiality, a more permanent effect—all combined, if possible, with simplicity and convenience of administration.

The natural outcome of a more thorough knowledge of the disease, and of more enlightened and perfected methods of treatment, was the hope of its abortion or annihilation. This hope has given rise to two methods of treatment for aborting syphilis, the one local, the other general. The first method is that of excision of the chancre, combined, in some cases, with the extirpation of the lymphatic ganglia in immediate anatomical connection; and the second is the abortive treatment by means of active mercurial dosage during the primary period of the disease.

The prevention of syphilis by excision of the chancre has been attempted by many observers, and some have claimed success, and although the treatment seems plausible, it is not looked upon with favor by the majority of syphilographers. I have tried it quite extensively over a long period of time, with painstaking attention to all details, and have been convinced of its failure, even in cases seemingly very suitable to its scope. I have never seen syphilis prevented nor its course rendered less mild, though I think I have seen the evolution of the secondary stage somewhat delayed.

The abortive treatment of primary syphilis by means of early and active cauterization, a very old method, has also been tried and found wanting. A more suitably favorable instance of its employment than was offered by the case—now classical—of Berkeley Hill can scarcely be imagined, yet it failed utterly of prevention. We must, therefore, dismiss from our armamentarium those heroic procedures as prophylactic measures, and employ them only in conditions of necessity and exigency.

The abortive treatment of syphilis by mercury introduced in various ways into the economy has within a few years been recommended by several observers, and its consideration naturally brings up the question of the time at which to begin general

treatment of the disease. I think that I state the matter correctly when I say that the majority of authorities to-day are in favor of beginning general mercurial treatment at the commencement of the secondary period of the disease. I should not, therefore, discuss the question here but for the quite recent utterances of so eminent an authority as Mr. Jonathan Hutchinson, and of my friend, Dr. E. B. Bronson. Mr. Hutchinson thinks that mercurial treatment should be begun as early as possible in the primary stage (that is, as soon as the diagnosis of syphilis is made), and that it should be continued in a quite active manner for at least six months. He claims, and with great propriety, that mercury causes the absorption of the indurated nodule; that it suppresses the febrile condition incident to the early secondary stage, causes the disappearance of the eruption, and, in fact, aborts the secondary stage entirely. He concedes, however, that even after this treatment the patient is liable to tertiary manifestations. Dr. Bronson in his interesting paper offers the suggestion, based, as he says, on theoretical grounds, that we may cause the rapid disappearance of the initial lesion, and the probable abortion or prevention of the secondary stage, by hypodermatic injections around and under the nodule on the penis, into the substance of the inguinal lymphatic ganglia, and into the territory of integument "whose lymphatic vessels tend in their course to the ganglia which are the seat of the disease." With all deference to the opinion of Mr. Hutchinson, I must express my earnest conviction that the aim which he hopes for will be better and more surely attained by waiting until the evolution of the secondary stage than by beginning treatment at any time during the primary period. It must, however, be conceded that it sometimes happens that the necessity for mercurial treatment is imperatively indicated in the primary stage. These exigencies of practice I have succinctly formulated in the section on the treatment of syphilis in my *Atlas of Venereal and Skin Diseases*.[1]

In my judgment no good is produced, as a rule, by the internal use of mercury in the primary stage, for at that period it tends to render the course of the disease less orderly; very often leaves the existence of syphilis in a state of doubt; it does not prevent or lessen the severity of secondary manifestations, and, though it may retard them, it really often renders them more severe. Whether syphilis is essentially caused by a microbe we are, as yet, far from certain, but we know quite clearly its ultimate pathological processes. It is a chronic, infectious disease, manifesting itself in the development of a low grade of granulation tissue which tends to reproduction in greater or less degree in any and all of the tissues and organs of the body. I think it can be stated, without fear of contradiction, that the malign influence of syphilis upon the human organism is directly due to the infiltrations of this tissue, to the irritative and inflammatory conditions incident to the hyperæmia which accompanies their proliferation, and last, but far from least, to the secondary destructive and atrophic changes which take place in the healthy tissues in the various metamorphoses of these specific new growths. Clinical and pathological observations have shown that mercury possesses a specific power over this low order of infectious tissue, and it is very probable that its real action is in the production of its fatty degeneration and subsequent absorption.

In my judgment syphilis is not mature until the date of secondary manifestations, when the newly formed, young, round, infecting cells are proliferated in vast quantities and are thrown into the general circulation, and by it carried throughout the body. When this has occurred, I think syphilis may be said to be "ripe;" then, and not till then, we have something tangible to treat. At this time, mercury introduced into the organism can exert its marvellous powers in destroying this, then, young, nascent, infectious material, and in causing its absorption.

The foregoing clinico-pathological facts have influenced me in my opinion that it is the wisest policy, as a rule, to wait until the onset of the secondary stage before we begin a mercurial course. Further than this, my opinion has been strengthened during more than twenty years by the observation of the progress and ultimate result of cases in which it has been necessary to begin treatment in the primary period for the reasons outlined in the footnote. In some instances, by means of a prolonged treatment, a cure has been effected, but in many a disorderly

[1] Conditions in which it may be necessary or advisable to begin mercury in the primary period:

1. Where the initial lesion, from its size, depth, or extent, causes much pain and discomfort, or interferes with the function of parts, or, from activity of ulceration, threatens to destroy them (glans, clitoris, urethra, fingers, eyes, nose, lips, tongue, tonsils, breast, and anus).

2. In certain of those cases where, from its situation, the chancre may lead to infection of others—such as the fingers of surgeons and midwives, nipples on wet-nurses, chancres of the tongues of infants, and on the lips of young, careless, and thoughtless persons.

3. When the enlargement of the lymphatic ganglia is excessive and causes inconvenience and impairment of locomotion, or movement of the arms, or produces much discomfort and disfigurement (neck, submaxillary region, elbows, and groins).

4. In all cases where chancres are complicated with a pyogenic (perhaps microbian) infection, attended with pain, fever, and perhaps typhoidal symptoms (chiefly on the fingers, but also, though rarely, on the nipple and mamma, and sometimes on the penis).

5. In all cases where married or sexual relations render the early disappearance of the chancre imperative.

6. Where the extreme anxiety and unreasonable impatience of the bearer render it imperatively necessary.

7. In those somewhat exceptional cases in which severe cephalalgia, neuralgia, pains in bones, joints, and fasciæ, are precocious.

course, attended with severe and extensive manifestations, often with much cachexia and even with tertiary lesions, has been observed. As a prophylactic measure, or an abortive treatment, therefore, it is my opinion that medication begun in the primary stage of syphilis is a failure.

Dr. Bronson's suggestion I regard as very ingenious and, on its face, plausible, but I do not believe that it is capable of such thoroughly practical application as to produce the result hoped for. While I believe that in the primary period of syphilis the cell infection is limited to the part contaminated, and to the immediately contiguous territory, with more or less involvement of the lymphatic vessels and ganglia in the vicinity and at a distance, and that the blood-vessels are also the seat of specific cell changes, I do not think that with the methods now at our command we can stamp out the disease and prevent its extension and the infection of the whole economy. The limited space of territory, its extreme delicacy, and its peculiar proneness to inflammation will not admit, in my judgment, of such activity and frequency of mercurial injection as would be required to annihilate the myriads of new, rapidly forming cells. Then, again, I think that such a quantity of the mercurial salt would be required in the procedure that a general toxic effect would be produced.

All these considerations lead me to the conclusion that, with our present therapeutic limitations, we are unable to abort syphilis thoroughly in its primary stage.

Though we are unable to abort it, we are, in favorable cases—and they are legion—able to cure it. By "cure" I mean that the early lesions are made to disappear and leave no sequelæ, that the ganglia seemingly return to their normal condition, that the health of the patient seems wholly undisturbed, and may so remain, that he has no late manifestations, that upon marriage he or she may procreate healthy children, and that thereafter they present no specific lesion or affection. The means of attaining this great boon we will consider a little later on.

The three systems of treating syphilis now in vogue are as follows: The expectant, or symptomatic; the continuous, or so-called tonic treatment; and the treatment by interrupted courses.

The expectant treatment is a very easy-going one, and is fraught with danger and disaster to the unhappy person who is subjected to it. The tenets of its advocates are that we should wait until symptoms and manifestations appear, and that then we should cause their disappearance by mercury, and then wait again until another outbreak occurs. It has always seemed to me that this treatment is based upon a hopeless view of the possibility of the cure of syphilis, and upon a fear that an active use of mercury will be productive of harm. It is an unscientific and dangerous treatment, and it is well for humanity that it is growing into disrepute and disuse.

Of the continuous treatment of syphilis by mercury I can scarcely speak with more commendation than I do of the expectant treatment. I think that what I have already said in my *Atlas* in this regard fully covers the ground, so I will transcribe it here:

"A condition of tolerance is induced by the continuous ingestion of mercury, and after a time it ceases wholly to be a therapeutic agent and often to have any effect, and certainly none which is beneficial. Further, in syphilitics (I will not say what it does in dogs, rabbits, or other objects of experimentations) it very commonly produces a condition of anæmia and debility (often even when the body is fat, but flabby), and perhaps a low grade of gastro-intestinal irritation. I constantly see patients, who come of their own accord or are sent by their physicians, who have been treated continuously and without any intermission for one, two, or more years with mercury, and who still have some syphilitic lesion which refuses to disappear—perhaps dermal, osseous or articular, or even cerebro-spinal or visceral. These patients, and very often their physicians, cannot understand why it is that a treatment so constant and energetic and, in most cases, so conscientiously administered, should be productive of such unsatisfactory results. The answer to the question is clear and simple. They had used mercury long after it had ceased to be a therapeutic agent, long after it had lost its influence over the syphilitic diathesis, and, strange to say, some had escaped without serious injury, but in others the chances of cure had been materially jeopardized or rendered more remote. I have seen, during a period of many years of careful observation, so much annoyance, so much trouble, misery, and even disaster result from this method of treatment that I feel that I must raise my voice against it as being irrational and even mischievous—a perversion of one of the greatest therapeutic blessings which we possess."

My experience in hospital and private practice has convinced me that the system of treating syphilis by interrupted but carefully regulated courses of mercury alone at first, and of mercury and iodide of potassium later on, is the one most preferable, most satisfactory and practicable to both physician and patient, and the one by means of which we may almost positively promise a cure to any one with ordinary health who will systematically submit to and follow it up. All systems of treatment depend on the following methods of administration of mercury: Ingestion by the mouth, endermic medication by inunctions of ointments or soaps and fumigations, and by hypodermatic injections. All these methods have their advantages, and it is a pity that the proposers of some of them, particularly of the various forms of hypodermatic mercurial injections, do not recognize their limitations, but claim for them more extended use than their merits warrant. In what follows regarding the essentials of a treatment by interrupted courses, I shall attempt to show that the best results, which, of course, means cures, are obtained by a judicious use of any or all of these

means, as the conditions or necessities of the case demand.

In this facility and ability of selecting the proper method at the right time, and of the suitable agent for the particular lesion or affection, in my judgment, resides the art of treating and curing syphilis.

The systematic treatment of the disease presupposes a careful hygiene and an orderly and well-rounded life during its continuance.

The first question which then confronts the physician is the choice of a remedy, and though there are numerous preparations of mercury, to-day the green iodide is the one most in favor. In addition to it, I think we can place the tannate of mercury (hydrarg. tannic-oxydal) as being of particular advantage in many cases. The older authors used gray powder, blue-mass, and calomel, when they desired a prompt mercurial action, and, as they termed it, "just to touch the gums." As I will show later on, we possess methods of procedure which result more efficaciously than those agents, and which are not attended with their constant drawbacks, namely, sudden and severe ptyalism and gastro-intestinal irritation. It is rather too early to define the scope of salicylate of mercury, and of the remaining salts, once used by stomach ingestion, it is not necessary to speak here.

For all practical purposes, therefore, the proto-iodide and the tannate of mercury are sufficient. In my experience the bichloride taken by the mouth is a very uncertain remedy, of scarcely any value in small doses, and capable of great harm in large ones. Its value, however, by the hypodermatic method cannot be overestimated.

This brings us to the question of the dose. I feel fully convinced that in the reaction from large doses of mercury, formerly used, we have oftentimes gone to an injurious extreme, and that many authors recommend such small doses that the system readily becomes accustomed to them, and that they often have little or no effect whatever. I am not in the least a believer in the arbitrary division which has been made of mercurial agents into "tonic" doses and full doses, or of the criteria by which they are judged, and I have found that even among intelligent men these artificial divisions are misleading rather than productive of precision.

Every case of syphilis is a law unto itself as regards the quantity of mercury which will be required to cure it; therefore, all that teachers can do is to state approximately the dose usually required, and the conditions under which it should be lowered or increased.

The tolerance of mercury in the system is very largely dependent upon the condition of the stomach, the pharynx, and of the mouth, and he who can keep these in as near perfect order as possible is the man who can, in the vast majority of cases, give mercury in such quantities that the eradication of syphilis may result. Those observers who have formulated the doses of mercury they regard as proper by their effect on the gums, and stomach, and bowels, have, I firmly believe, in very many instances based their theorem upon serious error, for the reason that very often temporary hyperæmia and exudative swelling exist in these tissues, due to local causes, which if removed would allow the introduction of mercury into the stomach, or by other methods, in the necessary quantity. Therefore, our duty in every case is to see that the mouth and gastro-intestinal tube are in perfect condition, and that all sources of irritation are prevented or removed. When this is done there will be few cases which are refractory to the use of the drug.

It is well to begin with a pill or tablet containing one-fourth or one-fifth of a grain of the proto-iodide of mercury for persons of ordinary build, but for very large and robust subjects one-third or one-half a grain may be given. This dose may be taken three times a day, and then, if the symptoms do not yield (assuming that there is much constitutional reaction), if the lesions do not show signs of involution, and if the ganglia do not perceptibly subside, a fourth and even a fifth dose may be given within the twenty-four hours. The dose of the tannate of mercury is from one-half to one grain.

I am firmly convinced, from my reading and my experience and conversations with physicians, that since the adoption of the long mercurial courses, an easy-going, happy-go-lucky feeling has taken hold of many of them in their treatment of syphilitics. They are told in some of the books, and at some colleges, that syphilis can be cured, but that a treatment of two to three years is necessary. This teaching, to my mind, has engendered a feeling of false confidence and a tendency to superficial routine. It is true that we can cure syphilis, and that mercury is our weapon, but that happy result can only be accomplished by constant care and watchfulness on our part, by feeling our way, by pushing our remedy and keeping it well in hand so as to get all of the good there is in it, and to avoid all drawbacks and harm which may arise if they are not looked out for. Therefore, I say, we must not be blinded or hampered by finely spun theories, but push on, conserving our patient's health and nutrition, with an eye always on one object, namely, the destruction, as rapidly as possible, of the young, rapidly proliferating cells of this active infecting disease, and their removal as quickly as possible from the parenchyma of organs and tissues before they shall have had time to induce those subtle, but often dangerous, structural changes which bring in their wake functional disturbances, deformities, invalidism, and perhaps

death. In my judgment, the early secondary period is the crucial one in the life of the syphilitic, and upon the activity and suitability of the treatment at this time his future immunity largely depends. It seems to me very probable that much of the late rebelliousness and malignity of syphilis is due to the fact that the newly formed infecting granulation cells and the concomitant subacute inflammation induce in tissues and organs, particularly delicate ones, structural and nutritive changes which predispose them to subsequent low grades of inflammation and cell increase, beside a repetition of the essential syphilitic processes.

There is nothing extraordinary in the pursuance of an early active mercurial course. It requires of the surgeon a fair knowledge of the disease, a moderate amount of moral courage, never-ceasing watchfulness and care of his patient. It is well that the first mercurial course of this treatment should be both active and rather prolonged. Therefore, we should endeavor to keep the patient under the influence of the mercurial treatment for at least three months, and, if possible, four or five, and even six, if necessary. In most cases, at the end of three months, during which the remedy should be taken quite steadily, the patient's condition will be found to be so reassuring that a stoppage of the dose may be allowed for one, two or even three weeks. In favorable cases, and by far the greater number, patients will affirm that they feel as well as they ever did, and in private practice it is rare at this time to see any but the mildest and most trifling lesions, such as spots on the tongues of smokers or drinkers, or scaly patches in those subject to simple skin affections.

The next course may last but two or two and a half months, when perhaps about four weeks of freedom from drug-taking may be granted. Then the medicine may be used again, and in the course prescribed. During the second year I am accustomed to combine iodide of potassium with the mercurial salt, using either the bichloride or the biniodide. During this second year, all things being favorable, the intervals may be lengthened, though a full dose of the combined drugs should be given when treatment is being followed. The morale of the patient is always much improved by these periods of liberty.

It must be understood that syphilis in private practice is wholly different from that of our dispensaries and hospitals, that in the former perfect cures are obtainable, whereas in the latter we really practise a series of patchings-up, as we may say. It is most gratifying to hear, as I and, of course, other surgeons do, patients express their wonderment at the seeming benignancy of syphilis, the contemplation of which at first filled them with apprehension, and even horror.

With this general outline of the system of interrupted treatments, I shall now proceed to show how in certain cases the various methods of treatment may be utilized to the great benefit of the patient.

Many years ago I was very much impressed with the fact of the very rapid disappearance of syphilitic lesions, particularly of the secondary period, around and in the vicinity of the sites upon which hypodermatic mercurial injections had been made. I then learned that the early lesions, when recent, were then very readily dissipated, and that their retrogression was slower in proportion to their duration and to lateness of appearance. The observations then made convinced me that the local and regional effects of mercury were also possible, and that these results were an important factor in the general scheme of treatment. I shall now proceed to show, in a general manner, the indications for these local mercurial treatments, and the means we have for their practice.

There is one fact that the surgeon should always keep in mind in the treatment of syphilis, namely, that all syphilitic lesions, even the most minute, are to be feared as possible sources of continuous or intermittent reinfection of the system. The morbid cells contained in these lesions are capable of great, even infinite, multiplication, and the so-called syphilitic relapses are due to the continual recurrence of these cell proliferations, which occur from morbid foci left over at an earlier date. While all deposits of syphilitic new growth in any part or tissue are of much danger in their ultimate results, those which occur in the lymphatic ganglia, in the lymphatic vessels, and around bloodvessels are especially so by reason of the activity of growth of these organs, of their very ready transposition to all parts of the body by means of the lymph and blood circulation. Many cases of syphilis do badly, in my judgment, for the reason that mercury by the mouth does not invariably act radically upon the lesions when they have become a little old. If in these cases the remedy is brought into more intimate local contact with these new growths or, as the many call them, infecting foci, an incalculable gain is the result. Therefore, I claim that the art of the surgeon in treating syphilis is shown when (the exigencies of the case demanding it) he is not at the end of his therapeutic resources when he has made his patient swallow a pill in orthodox fashion, but has such practical familiarity with all the other methods of using mercury that he can adapt them to the peculiarities and varying necessities of the case.

Taking the average of cases as we find them, the most successful results are obtained by men who are not routinists. Great as are the value and power of mercurial treatment by stomach ingestion, in very many instances it is for longer or shorter periods found wanting, and then the temporary adoption of

other methods will often produce the effect we desire.

My readers are familiar, or can readily become so, with the technique of mercurial inunctions and hypodermatic injections, and it is probable that they know the conditions which must guide them when prescribing mercurial fumigations; therefore I shall not use space to give these details, which are accessible to all.

I shall now further elaborate my general scheme of the systematic treatment of syphilis by interrupted courses by stating, in a general way, the condition in which mercurial inunctions and fumigations, and hypodermatic injections may be employed, according to special indications, to exigencies of various gravity, and by reason, perhaps, of utility.

Mercurial inunctions are used by some surgeons, particularly abroad, as routine method of treatment, but this is not largely the case in this country. I prefer them as an adjuvant reserve and emergency resource, since by this course I think we get the best results.

The early rashes of syphilis are best treated, in my judgment, by mercurial inunctions, both during their active and chronic stages. Thus, if the erythematous syphilide is exceptionally severe and persistent, it is well to leave off internal pill dosage and use mercurial inunctions, according to the usual plan and the indications presented by the case. When the eruption has disappeared the pills are resumed again, and the ointment discontinued, unless perhaps some small patches require its continued use.

Then, again, early in the secondary stage, we can often greatly assist the cure by direct mercurial action upon the enlarged lymphatic ganglia, particularly when they are abnormally hyperplastic. It is a valuable, even a golden, rule never to be content with the action of mercurial pills, unless we see a decidedly rapid subsidence of the lymphatic ganglia. Failing to produce this effect is evidence that our remedy is not carried in sufficient quantity by means of the circulation, and that local medication is necessary. Upon the inguinal regions we can always produce a decided effect by mercurial inunctions, and the same may be done with the ganglia of the arm in chancres of the fingers; with those of the neck when the chancres are upon the head, lips, or within the mouth. Unusually large infiltrated syphilitic ganglia, wherever situated, are signs of evil omen, and, as a very general rule, it may be said that they require an active regional treatment. In like manner, hyperplastic lymphatic vessels and hyperplastic bloodvessels must be locally and actively treated. It may be well to state that the inunctions should be made over the ganglia and upon the region supplied by their lymphatic radicles.

It is my custom in hospital practice to order the inunction treatment for all those cases of early papular syphilides, and direct that the applications shall be made directly to the parts upon which the lesions are present. Thus, taking the head and neck one day, and one or two arms the next, and the other portions of the body in anatomical succession, thus going on day after day; if there are no contrary indications, the whole rash is brought under a local mercurial treatment, and, at the same time, the general system is affected by the absorption of the drug into the circulation. When the rash has disappeared internal treatment may be employed, usually, however, after a suitable interval of freedom from medicine-taking.

In like manner later-occurring and usually more special localized eruptions of all varieties may be treated, the aim in all instances being to produce a decidedly regional mercurial effect at the same time that systemic absorption is produced.

It has long been my custom to order mercurial inunction with all local precautions upon the neck and under the jaws, even upon the temple and occiput, in appropriate cases of early and late syphilitic meningeal and cerebral disease. In the cephalalgias of the early and late periods, in the neuralgias of the cranial nerves, and in syphilitic neuralgias in general, I am a firm believer in the efficacy of a well-ordered, carefully applied regional treatment. In looking over my notes I find that in cases of optic neuritis, neuro-retinitis, retinitis, choroiditis, and iritis, much benefit and even cure have been brought about by these local inunctions. In some instances of great gravity the effect has been noted as gratifying and even marvellous. It is always well in these urgent cases of syphilis of the head generally, particularly of the brain and eyes, to administer simultaneously iodide of potassium in free and increasing doses. When mercury is then being rubbed into the neck, we must carefully, very frequently, watch the gums, mouth, and throat, and use all local and hygienic measures to keep them in a state of health, for the occurrence of ptyalism and gingivitis may necessitate the discontinuance of the inunctions, and we may lose our control of the disease.

Many of the earlier pustular eruptions of syphilis are really papules surmounted with a small cap of pus, and for them mercurial inunctions are especially adapted. Where, however, the pus production of syphilitic skin lesions is great these applications are liable to produce dermatitis. I think we are sufficiently advanced in the study of bacteriology as applied to syphilis to affirm that the pus producing lesions of that disease, and chiefly those seated on mucous membranes and the skin, are due to pyogenic microbes. In many instances these microbes

produce pustular eruptions upon the skins of syphilitics for the reason that the latter are prone to fall into inflammation on even slight irritation. In other words, the vulnerable skins of syphilitics offer a favorable soil for these pus-producing microörganisms. In my opinion many cases of the ecthymaform, the rupial, and the superficial serpiginous syphilides are due to this microbian complication. Then, again, these same minute organisms induce purulent foci in syphilitic new growths, papular and tubercular. These cases are striking instances of a general systemic infection, complicated by local pyogenic infections. My experience teaches me that in cases of syphilides with much pustulation and encrustation the common antiseptic remedies are better, certainly for a time, than mercurial inunctions, which will prove beneficial for the resulting thickenings of the skin.

It is also important to remember throughout the course of syphilis that any simple inflammatory conditions of the skin or mucous membranes should be promptly treated and dissipated, since they may become engrafted with the syphilitic impress or new growths.

Besides being treated with careful antisepsis, the initial nodule should be covered with mercurial ointment or calomel. In like manner mucous patches and condylomata in both sexes should be cleansed and dusted with calomel.

The hypodermatic method of treating syphilis is, within certain well-marked limitations, one of much practical value, and to it we accord a subordinate place in our armamentarium. Its advocates have failed in their hopes of its very general use, and its substitution for the older methods, because they claimed for it a wider sphere of usefulness than its merits will really entitle it to. Then, again, the profession has been bewildered by the great variety of salts of mercury, both old and new, and those thought to be pharmaceutically improved and modified, which have been vaunted as the perfection of specific medication. Each prominent advocate has exploited his own favorite preparation as being better than all the rest, and the bulk of the profession, being in a quandary, have marvelled, and used none of them.

There can be no question that by the hypodermatic method of using mercurial salts we may use a minimum dose, we may insure precision and accuracy in the amount of the drug, and that we may obtain rapidity and perhaps rather greater potentiality of effect, with much less liability to mouth and intestinal drawbacks, in a simple and convenient manner. But weighing against these advantages we have counterbalancing facts in the widespread repugnance of patients to the treatment, the pain and soreness, the formation of indurated nodules and plaques, the occasional occurrence (even with the greatest care) of abscesses, and when the insoluble salts are used, the danger of embolism. Still, as I have said, the method is useful at certain times, when used with intelligent and careful technique.

My experience has taught me that the soluble salts of mercury are the ones to be employed as being more manageable, equally effective, and that, except in very rare instances where calomel may be used, injections of insoluble salts of mercury should not be employed. In my judgment, a pure watery solution of the bichloride of mercury is the best all-around preparation for hypodermatic injection in every possible respect. Of this, two solutions may be kept on hand; the first, in which one-twelfth of a grain of the drug is dissolved in ten drops of water, and other, containing one-eighth of a grain in the same quantity of the menstruum, both of which may be taken as standard doses. The weaker solution is the one with which to begin treatment for adults, and the stronger one can be used if the case requires a larger dose. For women and children a less quantity should be injected. Full details of the method of using hypodermatic injections of mercurial salts in syphilis will be found in my textbook. It will often be found that these injections will cause the rapid subsidence of specific lymphatic swellings, when made in their vicinity and in some cases into their substance. Localized and regional eruptions can be made rapidly to retrogress and disappear by their use. This rapidity of action is often very necessary when the lesions are on such exposed parts as the face, forehead, neck, hands, and wrists. The injections may be made very close to the seat of the eruption, in very urgent cases, on the forehead, scalp, and nucha, and also upon the neck and near the hands on the flexor surfaces. If great care is taken they will give rise to no trouble, even on very delicate parts.

The cephalalgias of syphilis and the various neuroses may very often be promptly relieved by injections made as near the seat of the trouble as possible or practicable. In many of these instances there is more or less gastric intolerance from various acute or chronic causes, and then, by means of the injections, we may push on vigorously with the specific treatment.

Where the early eruptions are very extensive and copious, I prefer the mercurial inunctions, but even in these cases hypodermatic injections may be used with efficacy.

In some instances, happily rare, mercury taken by the stomach acts as a general depressant, and the nutrition is much impaired. I have many times seen these grave drawbacks and seeming contraindications promptly dispelled by the use of the injections of the bichloride of mercury. In such

cases it is well to begin with quite a small dose and then work upward as fast as we can.

In ocular troubles, both mild and serious in their course, these injections may be used with benefit, but owing to their gravity I am disposed to rely more commonly on mercurial inunctions. It is in these threatening cases of grave intra-ocular trouble that we sometimes see marvellous results follow the employment of regional injections of calomel.

Osseous, bursal, fascial, and articular lesions of syphilis, particularly the earlier ones, are often much benefited by sublimate injections. In such cases, however, it is well to administer synchronously iodide of potassium in full and increasing doses. For this class of osseous and fibrous tissue lesions, however, we must never forget the known efficacy of mercurial inunctions.

There are many other conditions in which sublimate injections may be employed as a method of utility and emergency, which will become apparent to the surgeon after he has familiarized himself with their value and approximative scope.

Mercurial fumigations are of great value and are capable of wide use, though with proper limitations. They are, in the main, useful in cases of stubborn localized and even general eruptions, and particularly in the chronic scaly stage of early and late eruptions, and also in almost all cases of pustular ulcerative and serpiginous syphilides. They must be used with caution, and the patient should be carefully watched while undergoing their influence.

The foregoing facts and considerations, I think, will clearly show that the treatment of syphilis is far from being a matter of routine or a mere problem of dose-arithmetic, as many seem to think. To be thorough and successful, it must be based on broad principles and upon an accurate and full knowledge of the disease. The physician should be well versed in general medicine, as well as in syphilis, and in its management he should be zealous, watchful of all conditions and complications which may arise, and ever ready for such modifications and expedients in treatment as the case may demand. Thus equipped, it is within the power of any physician to make himself the master of syphilis in the greater number of cases and to be able to promise his patient ultimate freedom from his disease.

40 WEST TWENTY-FIRST STREET, N. Y.

THE OIL OF EUCALYPTUS IN SOME FORMS OF MALARIA.

BY J. H. MUSSER, M.D.,
ASSISTANT PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA; PHYSICIAN TO THE PHILADELPHIA AND PRESBYTERIAN HOSPITALS.

THREE years ago the writer called attention to the value of the oil of eucalyptus in some malarial affections in a paper presented to the Philadelphia County Medical Society. It would not be referred to again, save that it was quoted extensively, and, as the writer now holds a different opinion regarding the value of the drug than he held at that time, it is only proper that a record should be made of his recent experience with it. This experience is considerably opposed to the conclusions in the former article, and is, as the writer believes, more accurate.

When the paper mentioned was published, we were not familiar with the organisms which are found in the blood of patients suffering from malaria, so well described first by Laveran, and since then by Councilman, Osler, Van Dyke Carter, and others. The recognition of the bodies in the blood, and the effects of treatment of the malarial patients upon them, make any conclusions regarding the value of the drug in acute malaria tolerably exact. Naturally, therefore, the writer was induced to study a number of cases with the object of finding the effect on the organisms when eucalyptus was administered to the patient. The studies were made, of course, with other drugs, among which was quinine, and, regarding it, the well-known conclusion that the organisms, or the bodies, disappear quickly after the administration of the drug, was upheld. It was different, however, with regard to the oil of eucalyptus. The drug was administered to some fifteen cases, and the blood carefully studied, just prior to the administration of the drug, and during it. In one case only were the organisms found to disappear entirely while the oil of eucalyptus was used. In other cases the drug had to be discontinued and quinine given in its place, in order to control the paroxysms and clear up the blood. Careful temperature records were made of all the patients, and the charts show that the drug was of no use in true acute intermitting fever.

Reference to the article previously published shows that at the time the writer's studies therein summarized were made, he concluded that the oil of eucalyptus was of decided value in about 33⅓ per cent. of all cases of intermitting malarial fever. This is in direct variance with the more exact scientific studies that have been made, and is worthy of a possible explanation. It was found, for instance, in a large number of cases of intermittents admitted to the wards of the Philadelphia Hospital, that without the use of any drugs, and without any particular form of diet, but simply from change alone or removal from the infected locality —a truth which is well known — the intermittent paroxysms grew less and less in severity and duration, and after intervals of from three to ten days would disappear entirely. In other words, under favorable circumstances the disease is self-limited. This is a probable explanation for a large number of the cases of intermittent fever that were pre-

viously referred to. A second explanation for the favorable effects of the oil in the first class of cases may be because of the mental impression which the visit to the hospital and the exhibition or the use of a new drug made upon the patient. The subject knew well that quinine was always given in intermittent fever, and without one word from the physician could well see that he was treated in some other way. The self-limitation of the disease, the mere fact of taking medicine, with the added fact, possibly, of taking a new drug, were sufficient to produce a strong mental impression, whereby the course of the disease was changed, or even checked entirely—an effect well known, and particularly noted in the old records regarding the natural history of malarial fever.

The results of these exact studies have not been encouraging, it is true, and yet the writer firmly believes that the oil of eucalyptus is of particular service in cases that might be called habit-chills. It is quite certain that one sees persons with intermittent fever in which, while in a measure controlled by quinine, yet, even after full saturation by this drug, the chills continue. Over and over again such has been the writer's experience, and others have called his attention to the occurrence of similar cases in their practice. Dr. Girvin recently told the writer of a case of intermittent fever in an old man which did not yield to the anti-periodic doses that were proper, but which continued with the same degree of regularity and severity as before the administration of the drug. The patient was seventy-five years of age; he could not state where he contracted his malaria; he did not reside in a malarious district; he improved within three days after the administration of the eucalyptus; the chills lessened in severity, and in a short time the paroxysms ceased entirely. The writer recently had a middle-aged lady under his care, who contracted malarial fever in New York State. Large doses of quinine and arsenic were given without result, even after removal from the locality. When the oil of eucalyptus was given she began to improve, and ten days after its administration was entirely free from chills and fever. Unfortunately, no cases of this character have been studied with regard to the condition of the blood, although the writer believes organisms could not have been found in it, and that the chills recurred from habit.

While here and there isolated cases of this character may be found in which the drug has proved of value, undoubtedly one does see a great number of cases with malarial symptoms that are benefited by the oil of eucalyptus. In the paper previously referred to, the writer quoted eighteen cases of vague intermittent malarial affections, of which fourteen were positively benefited by the drug in question. A large experience since then convinces him that it is of service in cases of neuralgia occurring in persons who live in a malarial district, and in headaches, generally congestive, not due to functional or organic disease in other portions of the body. Then the large class of cases who suffer from paroxysms, either daily or every other day, characterized by headache, languor, a general aching with sensations of heat and flushings, and even for an hour or more of fever or feverishness, with or without antecedent chilliness, are actually cured by the oil of eucalyptus. They are generally most stubborn, and do not yield to quinine. They appear to be, at least in the cases the writer has studied, due to malaria or to paludal intoxication, not sufficient to cause persistent blood-change, or in which one or two crops of growths of the organism alone took place, and then the organism ceased to exist and the symptoms were the results of their growth and possibly death. It is true, the blood has never been studied. Certainly careful examination of the body does not show the presence of any disease, either catarrhal or suppurative in character, which might cause the paroxysms. In this class of cases just referred to, and which the writer has seen benefited, the ofttime gastro-intestinal catarrh of some forms of malaria was absent. And it is well to exclude such cases, for no doubt they often yield symptoms very much like the milder forms of malaria.

Still a third class of cases have come to the writer's notice which are also benefited by the oil of eucalyptus. It is that large class that do not get well after quinine has been used, and used successfully, to control the paroxysms of intermitting fever. After the paroxysms have been controlled, symptoms continue, intermitting in character, which do not leave, in spite of the continuance of the drug in large or small quantities. Thus, in the writer's personal experience after the control of an intermittent, the patient suffered from daily paroxysms of headache with flushings, with an awful sense of heat and burning, and with the most intense lassitude and general aching. Notwithstanding full cinchonism was kept up for days, a paroxysm usually occurred in the middle of the day, and the desire for food was lost entirely during its continuance, which was for three or four hours. The continuance of quinine, the discontinuance, the use of it in smaller doses, failed entirely to give any relief, and only after the oil of eucalyptus was taken three times daily, six to seven drops at a dose, were the uncomfortable symptoms controlled. It is well known that arsenic is of service to complete the cure of a case of malarial fever, of whatsoever form, which has been controlled by quinine. The writer believes that in the same sense the eucalyptus is of value, and yet he cannot think that its value is due to the same reason

that arsenic is thought to be of service. The latter drug is used if anæmia is striking, and it is believed that its value is because of its beneficial effects upon the anæmia. This is the commonly accepted view, but we are inclined to think that it is of use in all forms that are stubborn, independent of the condition of the blood, and that its mode of action is no more known than the mode of action in similar cases in which the oil of eucalyptus is of service.

CONCLUSIONS.—From recent studies the following conclusions may be presented:

First. Intermittent malarial fever is a self-limited disease, and a large number of cases get well on removal from an infected locality.

Second. The oil of eucalyptus is of no service in cases of intermitting fever in the blood of which the organisms that are the possible cause of the malaria are found.

Third. The so-called habit-chills are relieved or checked by the use of the drug.

Fourth. Malarial neuralgias, malarial headaches, and vague intermittent symptoms, even complete but mild paroxysms, independent of the presence of any local organic disease, but due to malarial intoxication, are relieved by eucalyptus. The proof that they are due to malarial intoxication has not thus far been found by an examination of the blood, it is fair to state, but only because of the residence in the malarial locality, and because others in the same locality are affected with the disease.

Fifth. After quinine has controlled the paroxysms of intermittent fever and cleared the blood from organisms, eucalyptus will relieve or cure abortive paroxysms, intermittent neuralgias or headaches, or those marked symptoms of malaise, prostration, loss of appetite, and feverishness that are often seen.

Sixth. A dose of five drops, four times a day, preferably administered in capsule, is sufficient to produce the desired result.

INTESTINAL ANASTOMOTIC OPERATIONS WITH SEGMENTED RUBBER RINGS, WITH SOME PRACTICAL SUGGESTIONS AS TO THEIR USE IN OTHER SURGICAL PROCEDURES.[1]

BY A. V. L. BROKAW, M.D.,
OF ST. LOUIS, MISSOURI.

THE future of Intestinal Surgery is indeed encouraging. One after another the many difficult problems are being solved, and conditions heretofore considered so formidable are being reduced to a state of simplicity. It is hardly necessary for me to review the various improved methods of dealing with conditions indicating the performance of intestinal anastomotic operations, or making a rapid and safe resection by means other than the slow, tedious suturing. To obtain good results, time will be found to play a most important part; everything will often depend upon the rapid completion of such operations. The purpose of this paper will be the consideration of intestinal work generally.

For many months I have been experimenting with segmented rubber rings in all the anastomotic operations, and such operations as gastrostomy, cholecystotomy, duodeno-cholecystotomy, jejuno-cholecystotomy and circular enterorrhaphy. The rings used by me are rapidly made—during an operation, if necessary. All that is necessary is some rubber tubing, or a soft, ordinary rubber catheter, and some catgut. I prefer tubing one-sixteenth to one-eighth of an inch in diameter. A section of this of sufficient length to make a ring of the desired aperture is cut into from four to eight segments. Passing heavy strands of catgut through the lumen of these pieces, the ends are tied tightly enough to bring the ends of all the segments together, forming an oval ring. To the catgut strands are tied from four to six silk apposition threads, twelve to fourteen inches long, and the attachment of needles to these threads renders the ring ready for use. Another method is to pass a heavy, double strand of catgut continuously through the segments several times; approximate the ends of the segments, and push the ends of the catgut into the tubing. This ring will have a better surgical finish, and, after the apposition threads are tied between the segments, the ring will maintain its perfect form until the catgut is absorbed. The rings were passed as early as the fifth day, in one of my experiments. In forming an anastomosis, after ordinary No. 6 darning needles are attached to the apposition threads, compress the ring and pass it through the opening made in the lumen of the bowel, then pass the threads through the intestinal wall from within outward. Ascertaining that the ring rests well in place, proceed to the second in the same manner; appose, and after scarification of the marginal serous surfaces, as suggested by Senn, tie the apposition threads. When possible, it is well to utilize omental grafts, which add to the security.

With two such rings, circular enterorrhaphy may be performed, the rings corresponding in size to the lumen of the bowel, care being taken that they are not so large as to press too much upon the delicate mucosa or to overstretch the bowel, as a local gangrene might then follow. Introducing a ring at each end of the gut, at the point of section, the threads are passed through the wall less than one-third of an inch from the divided margins. The distal end of the gut is invaginated, and the proximal gut pushed into the distal, bringing the serous surfaces in contact. The threads are then tied, and a few Lembert sutures added, the entire operation

[1] Read before the Southern Surgical and Gynecological Association, Nashville, Tennessee, November 13, 1889.

requiring less than ten minutes. In one-half of my experiments with this operation, the results were excellent; of the fourteen dogs operated on by this method, in seven the results were all that could be desired; marked stenosis was found in several cases, and in all a ridge at the seat of the operation. Because of the high mortality, circular enterorrhaphy cannot be compared to lateral approximation. The use of the described segmented rubber rings is not limited to the intestinal tract, but they will be found of great aid in performing all the operations named. In gastrostomy a single ring is used, about an inch and a half in diameter, with six to eight apposition threads. The stomach drawn through a median incision and the opening made, the ring is introduced and the stomach returned to the abdominal cavity. The needles are then passed through the abdominal walls, and the threads tied in pairs, and if desirable the margins of the opening in the stomach may be stitched to the skin, the operation being complete in fifteen minutes or less.

In cholecystotomy, after packing the neighborhood of the gall-bladder with flat sponges to prevent accidental leakage, the viscus is aspirated or incised, and the contents removed. Enlarge the opening sufficiently to admit a small, segmented ring of three-quarters of an inch in diameter, with six to eight apposition threads; pass the threads through the wall of the gall-bladder from within outward, uniting the skin and wound margins by a few extra sutures. The use of the ring will remove the danger of extravasation, and save time. The gall-bladder may be united to the intestinal tract in two ways. Introducing a ring into the gall-bladder, another into either the duodenum or jejunum, the parts are placed *vis-a-vis*, and the threads tied; a few Lembert sutures complete the operation. I believe it will be but a question of time when the ring within the gall-bladder will find its way into the intestinal tract. In using a single ring, the intestine is clamped, and the abdomen packed with flat sponges. A ring is used with the threads looped, each loop containing a needle. An incision of half an inch is made in the *intestine*, after the gall-bladder has been emptied by incision. A ring one-half inch in diameter is introduced into the intestine, and the threaded loops passed through the intestinal walls less than half an inch from the wound margins. After passing the threads through the intestinal walls, the loop may be cut and one-half only carried through the gall-bladder, then tying the halves. A few extra Lembert sutures complete the operation. This description applies to either duodeno- or jejunocholecystotomy. These segmented rings may also be used in attaching cyst walls to the parietes when removal is contraindicated, or impossible. The same treatment might apply to abscesses or other accumulations where free external drainage is indicated. In a recent paper on this subject, I mentioned a new procedure of closing large wounds of the intestine, especially gunshot, where by ordinary suturing stenosis would result. My experimental work with this device has been highly successful. This method applies to wounds of the surface of the intestine; those of the mesenteric portion usually require resection. By this simple method, wounds the size of a half dollar may be closed in less than five minutes. The wound being trimmed and enlarged with scissors, a ring two and a half inches in diameter, made of eight segments of tubing, with six apposition threads, two on each side, is so arranged that when the apposition threads are tied, the ring is held bent evenly on itself. Such a ring is introduced into the bowel, the end apposition threads passed, then the lateral, the ring doubled on itself, the end threads tied first, then the lateral, using a single catgut suture in drawing the wound margins together at the point of flexure in order to prevent eversion. A few Lembert sutures complete the operation. If two wounds are close together in the same loop, a lateral anastomosis might be formed, if possible. With more than two wounds close together, excision and lateral anastomosis will require less time than circular enterorrhaphy, or the sewing up of several wounds. Other conditions where the single ring may be used are perforating ulcers, fistulas, etc.

The great advantage of the segmented rubber rings over other devices used, is the simplicity of their construction and the rapidity with which any number may be made. The large aperture of segmented rings makes it possible to perform ileocolostomy by the following method, which I believe is original: The ileum being divided a short distance from the cæcum, the divided end of the distal bowel is invaginated into itself and secured by a continuous suture through the serous and muscular coats. Above the proximal end a clamp is placed, and a ring adjusted to the lumen; a slit is then made in the convex surface of the ascending colon, and a ring introduced. The bleeding checked, the proximal end of the divided ileum is inserted into this slit, the threads tied and Lembert sutures added. This operation may be quickly performed, and is indicated in such cases as irreducible intussusception of the ileum into the cæcum and malignant disease of the colon.

While carrying out my study of this subject, I made experiments with wholly absorbable rings. They present no practical advantages over the rubber segmented rings, require a longer time in preparation, but very much less time, however, than Senn's bone plates. The aperture of the rings may be made as large as desirable. The absorbable rings are very readily made by decalcifying the long bones

of chickens, or the long bones of small animals; the process of decalcifying being the same as for making bone drainage tubes as described by Macewen (*Year-book of Treatment*). Through four or more sections of such decalcified bone tubes, are passed continuously strands of catgut in the same manner as described for making the segmented rubber rings. After completing the rings, they should be subjected to pressure for a few minutes, then irregularities removed with scissors, and the rings placed in alcohol between glass slides such as are used in microscopical work. The attachment of the apposition threads is exceedingly simple, the threads being tied between the segments of decalcified bone tubing to the central catgut strands. A second wholly absorbable ring may be made from the arteries of an ox, or other large animal, the preparation being very simple. The arteries to be used are dissected out from their sheaths, cut into short segments, boiled for a few minutes, and glass rods inserted into the lumen to maintain a proper tubular shape. The rods are then placed in strong alcohol. After a few days, the sections of the arteries may be drawn from the rods and placed in alcohol. Through four or more short sections of arteries so prepared are passed continuously double strands of catgut, and a ring formed in the same manner as the described segmented rubber rings; the apposition threads are attached between the segments likewise. For the closure of small wounds of the intestines, I have devised a method of quill suturing which has experimentally given excellent results. The suture to be described is wholly absorbable, and is to be recommended particularly for the simplicity, safety, and rapidity of application. Preparation of the absorbable quill suture is an easy matter. The tibia of a young ox is boiled sufficiently to remove excess of grease and oily matter, is then sawed through transversely into two or three parts, and placed in 30 per cent. solution of hydrochloric acid, the acid being changed every second day until decalcification has taken place. Remove excess of acid by soaking the sections of bone in water to which an alkali has been added. The bone may now be cut with a penknife into rods from one to three inches in length, one-sixteenth of an inch in thickness, and one-fourth of an inch in width. Small openings are made in the bone rods for the passage of the apposition threads, which are attached in this manner: A strand of chromatized catgut, or well-prepared juniper catgut, thirty inches in length, is doubled and a single knot made in the middle of the doubled catgut strand (silk may be used if preferred), the loop and end threads are passed through small openings made in the decalcified bone rods. The rod should be perforated at points half an inch apart, the loop being passed through first, and the single threads through the openings on either side. The manner of applying this suture is as follows: After clamping the intestine, the approximation threads of each rod should be threaded to separate needles, the rod introduced through the opening in the intestine, and the needles passed through the intestinal walls from within outward, about one-fourth of an inch from the margins of the wounds; the second rod is applied in the same manner; traction is made upon the threads to see that the rods rest well in place; the central double threads are now tied, and lastly the single threads. One or two extra Lembert sutures may be added if thought advisable; usually it will not be necessary. This method of suturing will be found to bring into perfect apposition the serous surfaces, and reduce to the minimum—in fact, to do away with—the tendency to eversion of the mucosa. The rapidity of the application will appeal at once to the surgical mind. I claim for this suture accurate, rapid and safe closure, particularly of small wounds of the convex surface of the intestine. In cases of emergency, short sections of rubber tubing may be substituted, but will require an additional Lembert suture or two. Very large wounds may be closed, with less likelihood of stenosis, by use of the single segmented rubber ring as described. There is a brilliant outlook for the possibilities of intestinal operations. The application of anastomotic methods especially is to the progressive surgeon a field of unlimited developments, and with a thorough understanding of its principles one is master of the many difficult situations. The indifferent success which has been almost the rule in the past, will give way to a brighter future. The former difficulties arising in the cure of fecal fistulas need no longer be taken into consideration, for by these new procedures assurance of perfect results awaits the operator. Who would now treat a gangrenous hernia leaving the gut in the wound, to discharge its fecal contents in such preternatural situation? Such treatment, I believe, will soon be a matter of the past.

Appended is a series of operations, with the results:

Gastrostomy, two experiments, two recoveries.

Gastro-jejunostomy, three cases, two recoveries, one death from peritonitis (dog tore out one suture, eight days after operation).

Jejuno-ileostomy, one case, result perfect.

Ileo-ileostomy, two cases, one death due to perforative peritonitis.

Ileo-colostomy, two cases, two perfect results.

Colo-colostomy, three cases, one death.

Ileo-rectostomy, two cases, perfect results.

Circular enterorrhaphy, fourteen cases, seven deaths.

Duodeno-cholecystotomy, three cases, two deaths from peritonitis. For anatomical reasons, this operation is very difficult to perform on a dog.

Single Ring
- Partial Duodenectomy, two cases, one perfect result.
- " Jejunectomy, two cases, two perfect results.
- " Ileectomy, four cases, one death.
- " Colectomy, two cases, two perfect results.

Summary: Intestinal anastomotic operations, fourteen cases, three deaths.

Circular enterorrhaphy, fourteen cases, two deaths.

The single ring formed of eight segments of tubing was used in closing wounds varying in size from a quarter to a half a dollar in nine cases with one death. The clamp devised by me and used in these operations is made of No. 12 copper wire, covered with unperforated rubber tubing of small size.

CLINICAL MEMORANDA.

MEDICAL.

Dengue.— Break-bone fever, spotted fever, Dandy fever, or Abu er rikab (Father of the knees), as it is called in Arabic, has been raging as an epidemic over the whole eastern coast of the Mediterranean from Alexandria to Constantinople since early in August, affecting Smyrna and Beyrout the most severely. In the latter place it is estimated that over 75,000 people, out of a population of 100,000, have been affected. Early in the attack, only those on the plains suffered; later, the fever moved up the mountains, reaching places 4000 feet above the sea-level, though the visitation was not so general at that height. Three epidemics are said to have visited here since 1850, the last occurring in 1884.

The disease is epidemic, but not necessarily contagious, as those infected on the plains going to the mountains early in the epidemic did not infect their nurses. Besides, mountaineers visiting the city for a short time, without meeting any affected persons, take the disease in several days after their return home. It cannot be due to contagion, and must require certain peculiar atmospheric conditions for its spread, as whole villages are prostrated in a few days. The period of incubation seems to be from one to ten days.

The severity of the disease does not appear to depend on the condition of the person affected. In fact, muscular, healthy people have often presented the most severe symptoms of intense pain in the joints and head, and high fever.

The attack in most cases begins with a chill more or less pronounced, then fever with temperature ranging up to 105° or more. Later, the symptoms vary in different persons, pains in the knees, back or any joint, resembling rheumatism, present themselves most frequently. Others may have only headache, or intense pain in the eyes lasting from one day to a week, and accompanied with obstinate constipation and often nausea. The latter, with vomiting, may sometimes be the first symptom. Delirium occurred in several cases observed, and convulsions in some young children. Nausea and vomiting occurring late in the sickness usually terminate the severe pain and remain some time, with gaseous distention of the stomach and intestines, absence of appetite and a disagreeable, bitter taste in the mouth, the latter remaining a week or two after all other symptoms have passed.

One case was sent to the hospital, supposed to have acute gastritis, as nothing could be retained by the stomach and constipation had existed for seven days. An enema and calomel by the mouth opened the bowels, and ice with lime-water arrested the vomiting the second day. The case then developed purpura, and glandular swelling about the throat. The latter symptom occurred with many cases; the former, rarely. A scarlet rash, or papular eruption, showed itself in many cases; in others, an erythematous blush, while many had no eruption, but burning and extreme sensitiveness of the skin, and not a few were troubled with urticaria.

Treatment seems to avail little in arresting the disease, though much can be done to arrest the suffering. The French physicians here employ a cathartic and emetic together as routine treatment, and the results, though disagreeable, are good. The natives and English begin treatment with a cathartic. Quinine, after trial in a number of cases, seemed only to increase the head and stomach symptoms. Antipyrin did good in lowering the temperature, and where delirium occurred it passed away under its use, as the fever lessened. Aconite has been a favorite remedy, and patients taking a mixture of potassium acetate, syrup, and cherry-laurel water seemed to have the stomach symptoms alleviated. The various so-called fever mixtures do well, and iced soda-lemonade proved particularly refreshing. Opium to relieve the pain and chloral to produce sleep are often called for.

After the symptoms have passed away, the weakness left is out of proportion to the amount or severity of the sickness, and persists for some time. Wine, or Easton's syrup, seems to arrest it, and hasten the return of appetite.

A relapse is not infrequent, and in some cases a second has occurred. Native tradition is that it occurs on the twentieth day, and it has in many cases occurred near that time, though not often enough to establish it as a rule. Catarrhal ophthalmia occurred frequently as a sequelæ, and the cases have been particularly obstinate, not yielding to the ordinary remedies until leeches were applied, or some counter-irritant.

Elderly people and quite young children have not furnished many cases of the disease. Deaths have been rare, only occurring in those cases where complications existed or developed.

Previous visitation has not protected from the fever, save in the cases of a number of elderly people, which may also account for so few cases occurring among that class, as all those questioned stated they had it once or more times in former epidemics.

S. P. GLOVER, M.A., M.D.,
Attending Physician to the St John's Hospital, Beyrout, Syria

A Mistaken Diagnosis.—During the past summer I was called to see a colored boy, nineteen years of age, who was said to have "cholera morbus." He had been as well as usual until noon of the day on which I was summoned, when he returned from work and ate a large dinner of pork. Soon after dinner violent epigastric pain

arose, with vomiting, the vomited matter soon becoming bloody.

I found him in intense pain, which radiated over the entire belly; the abdomen was tender and tympanitic; the skin and extremities cold; the face pinched and anxious; the respiration shallow and frequent; the pulse rapid and weak. Vomiting was frequently attempted, the only result being the ejection of greenish matter streaked with blood. He complained of constipation, and of a feeling as if his bowels were "blocked up." He stated that previous to that day his bowels had been slightly loose. Temperature 98° F. I believed it to be a case of ptomaine poisoning. The stomach being empty, no emetic was used. A hypodermatic injection of morphine and atropine was at once employed, iced brandy given by the mouth; he was wrapped in blankets and surrounded by hot bottles, ordered to refrain from all food, and to take a mixture of carbolic acid, morphia, and subnitrate of bismuth. He soon grew more comfortable, and I left him.

Early the next morning the pain, which had again returned, became extremely violent, collapse set in, and he died fourteen hours after the onset of the symptoms, and before I could reach him.

The necropsy (which Dr. Coplin kindly performed) showed a hemorrhagic gastritis, violent recent peritonitis, and that the contents of the bowel had escaped into the peritoneal cavity. The perforation was found in the lower part of the ilium near the ilio-cæcal valve, and on opening the intestine was discovered to be due to ulceration of a Peyer's patch. No other patches were found ulcerated and none infiltrated. The mesenteric glands were considerably swollen, the spleen was enlarged and softened, the liver was grayish-red and fatty, and the kidneys were hyperæmic. The post-mortem examination renders it quite probable that the ulceration was typhoid. In any case an ulcer must have existed for quite a time, and perforation caused by violent vomiting. The absence of previous symptoms, and the presence of an obvious cause for the existing condition, prevented the idea of intestinal perforation in a person laboring under walking typhoid, occurring as a possible diagnosis. It is possible that the great and general abdominal tenderness and tympanites, and the previous diarrhœa, should have aroused suspicion. Dr. Coplin is engaged in making sections of the ulcer for microscopical examination, and we will soon have his report.

J. CHALMERS DA COSTA, M.D.

SURGICAL.

Subcutaneous Herniotomy.—On November 9th, Alex. L., a snow-bound railroad passenger, suddenly discovered that he was ruptured. He at once applied to Drs. Beshoar and Thompson and myself for relief. An examination revealed an oblique inguinal hernia, the tumor being probably omental, about two inches in length, and quite hard. The constriction was at the external ring, but the hernia was not strangulated. The effort at reduction by taxis was not successful, although continued for half an hour with considerable force and under chloroform. Further effort was considered useless. It was suggested that by nicking the ring subcutaneously it could be reduced. Accordingly, Dr. Beshoar introduced the tip of his index-finger within the ring, carrying with it the scrotum. A probe-pointed bistoury was passed along the finger; it was then turned, cutting through the scrotum and nicking the ring, the incision in the scrotum not being more than a quarter of an inch in length. The tumor at once returned into the abdomen. There was but a drop of blood lost. On recovery from the chloroform, a spica bandage and pad were applied. The patient then walked to his hotel, and next day resumed his journey.

N. E. CHARLTON, M.D.

TRINIDAD, COLORADO.

THERAPEUTICAL NOTES.

Pilocarpine in Night-sweats.—The various remedies brought forward at different times for this troublesome state have each in its turn proved useless in certain cases, and while agaricin may be mentioned as one of those which deserve the least praise, in our own experience small doses of pilocarpine amounting to the twentieth of a grain, given from one to two hours before the sweat is expected, are potent for good. The means by which this result is brought about are not far to seek. The drug in all doses greatly stimulates the peripheral ends of the nerves supplying the sweat-glands. In many instances we find excessive secretion dependent upon depression of function, as in a serous diarrhœa or a local sweating of the feet. These states pass away just so soon as the parts regain their normal tone through proper treatment. The night-sweats of phthisis are improved by pilocarpine because this drug in all doses stimulates the sweat-glands. In large dose this stimulation amounts to free diaphoresis; but in the minute dose such as we name, the stimulation just balances the depression, and a normal tone is acquired. While it is true that pilocarpine and atropine are physiological antagonists, it will be found practically beneficial to prescribe small doses of both in such cases as refuse to respond to either one alone, as by their antagonism they prevent overaction on other parts of the body, and both act in harmony in so influencing the sweat-glands as to be of service to the physician.

The Value of Large Doses of Hydrochloric Acid and Nitrohydrochloric Acid after an Alcoholic Debauch.—The common methods of treating the patient who comes to the physician suffering from such symptoms are very well known, particularly as they are applied to persons who for days at a time have swallowed alcoholic drinks till they are on the verge of mania-potu. Much more commonly do we see persons who, having imbibed too freely, have heavy heads, coated tongues, and sour stomachs after only one evening's carousal. Though spirit of Mindererus has been for years employed at such times, we believe that hydrochloric acid is much better. The use of large doses is an important part of the treatment, and the administration of thirty to forty drops of the officinal dilute acid is about the proper quantity. This should not be too much diluted, and half a glass of water is sufficient when it is taken through a tube. In those cases in which torpidity of the liver has existed before the "excess," or where it follows it, a large dose of the *undiluted, ruby-red, freshly mixed* nitrohydrochloric acid is the better remedy

of the two; as much as six to ten drops of the strong acid in a glass of water being given at a time, and repeated every four hours, till the symptoms are removed or bilious purging is produced.

MEDICAL PROGRESS.

The Effect of Salt upon Bacteria.—Prof. J. Forster, of Amsterdam, has recently studied the effect of salting or pickling meat upon the bacteria present. He found that cholera bacilli were soon destroyed under the influence of abundance of salt, usually in a few hours; but that typhoid bacilli, pyogenic staphylococci, the streptococci of erysipelas, and the bacilli of porcine infectious diseases frequently retained their vitality for several weeks, or even months, in spite of the presence of abundance of salt. The same was also true of the bacilli of tubercle. In some cases, these bacilli were found alive after being two months in pickle, their vitality being proved by their capacity for infecting cultures. Portions of the viscera of a tuberculous animal, preserved for a considerable time in salt, were found capable of causing tuberculosis in a healthy animal when introduced into its peritoneal cavity. Experiments on the spleen of an animal which had died of malignant anthrax showed that 7½ per cent. of salt in the organ possessed the power of destroying the bacilli of this disease in about eighteen hours. From these facts it would appear that salting or pickling has but little destructive effect on many of the more common forms of bacilli found in diseased meat.—*British Medical Journal*, October 26, 1889.

Drugs Excreted with the Milk of Nursing Mothers.—Fehling has opened an important field of inquiry by a series of experiments to determine what drugs may be safely given to nursing mothers. He found that salicylate of sodium was dangerous to the infant when given to the mother in doses of forty-five grains daily. Iodide of potassium could be safely given in doses of three grains daily. Iodoform entered the system of the infant more readily through the mother's milk than when given to the child. Even when the wounds of the mother were dressed with iodoform, iodine was found in the child's urine. He found that mercurial salts given to the mother affected the child very slightly if at all, and that twenty-five drops of tincture of opium (German Pharmacopœia) and one-tenth to three-tenths of a grain of morphia could be safely given to the mother. Chloral might be given in doses of twenty-three grains to forty-five grains. Atropine administered to the mother affected the child very quickly, even in small doses. He denies that acids have an injurious effect on the child.—*Medical Chronicle*, September, 1889.

Dry Antiseptic Operations.—Dr. Landerer, of Leipsic, has invented a dry method of operating which consists simply in not allowing a drop of fluid of any kind to come into contact with the wound during operation; irrigation is entirely dispensed with, and wet articles for sponging are discarded. The instruments are boiled, and afterward kept in weak carbolic solution. The hands are cleansed according to Fürbringer's direction, only that instead of pure alcohol a 1 : 2000 solution of sublimate in alcohol is used. The field of operation is similarly treated. After the first incision is made no more fluid is permitted to come into contact with the wound, which is sponged with pieces of sublimated absorbent gauze, and all parts are kept tamponed with it, except the point where the surgeon is working.

Hemorrhage is much lessened by this method, hardly any vessels in the muscles requiring ligation. When the operation is finished, and the larger arteries are tied, the wound is to be kept tamponed for a few minutes with gauze, after which the wound presents absolutely dry surfaces, and is in excellent condition to unite primarily. Buried sutures are used to bring the deeper portions together. No drainage-tubes are applied, but the blood is forced out of the wound by direct pressure. Even cavities may be treated in this manner (as after castration) provided the walls can be brought together. The bandages are to be applied with moderate pressure.

The advantages claimed for this method by the author are the following:

1. The patient does not get wet or chilled.

2. Hemorrhage is minimized. In cases of amputation of the breast, where the axillary glands are removed, the towel placed beneath the shoulder is not even wet.

3. No antiseptic substances are absorbed, and, therefore, no intoxication is possible.

4. The duration of operations is shortened, because there is not so much time spent in controlling hemorrhage.

5. Rapid and safe recovery. In the ninety cases of the author he never once observed a flush around the wound; the temperature never once rose above 100.4°. There is no secretion from the wound, so that only one change of dressing, to remove the stitches, is necessary. The patients are not prostrated, even after large operations.

6. The great convenience of the method. Instead of big bottles, unreliable dishes, and fluids, as are met with in country practice, well-packed gauze may be carried in a small tin or glass vessel, thus simplifying matters greatly for the general practitioner.

7. The hands of the surgeon are not injured or roughened.—*Langenbeck's Archives; Annals of Surgery*, November, 1889.

Eucalyptus in the Treatment of Whooping-cough.—Dr. Hardwicke, in a recent number of the *Lancet*, highly recommends oil of eucalyptus in the treatment of pertussis. He uses it in the form of a spray, usually combining with it terebene. The following is his formula:

Oil of eucalyptus . . .	2 drachms.
Terebene	2 "
Alcohol	1½ ounces.—M.

This is to be used, with an ordinary atomizer, four times daily. Internally he prescribes terebene and paregoric in the following mixture:

Terebene	1 drop.
Camphorated tinct. of opium	10 drops.
Carbonate of magnesium .	2 grains.
Water	1 drachm.—M.

To be taken every three hours. The carbonate of magnesium is added simply to hold the terebene in sus-

pension. In every case in which this treatment was carried out a cure was effected in about two weeks.

Ointment for Goitre.—The following is the formula of an ointment used by PROF. DA COSTA in the local treatment of goitre:

Iodine	30 grains.
Oil of juniper	5 drops.
Lanolin	1 ounce.—M.

—*College and Clinical Record*, November, 1889.

Treatment of Intertrigo.—For the treatment of intertrigo PROF. LIEBREICH recommends an ointment prepared according to the following formula:

Boric acid	1 part.
Vaseline	20 parts.
Lanolin	100 "

Before a second application of this ointment the skin should be thoroughly washed.—*Journal of Cutaneous and Genito-Urinary Diseases*, November, 1889.

Castor Oil and Chocolate Tablets.—DR. GIRARD prescribes castor oil to children in cocoa tablets, which are said to be palatable and readily taken. The following is his formula:

Powdered cocoa	50 parts.
Pulverized sugar	100 "
Castor oil	50 "

Vanilla in sufficient quantity to flavor.

This can be made into pastils of which four or five will purge a child.—*Journal de Médecine de Paris*, October 20, 1889.

Ointment for Hemorrhoids.—KOSSOBUDSKI recommends the following ointment for the treatment of external hemorrhoids:

Chrysarobin	12 grains.
Iodoform	5 "
Extract of belladonna	9 "
Vaseline	1 ounce.—M.

This should be applied several times daily, washing the parts before each application with a two per cent. carbolic solution, or a one per cent. creolin solution.

For internal hemorrhoids he uses suppositories made according to the following formula:

Chrysarobin	1½ grains.
Iodoform	⅓ grain.
Extract of belladonna	1 grain.
Cacao butter	30 grains.—M.

After two or three months' use of these suppositories, the majority of cases are cured.—*Deutsche med. Wochenschrift*, November 14, 1889.

Corrosive Sublimate in Dysentery.—CHOWDHOVRY, of India, in the *Lancet* of November 2, 1889, states that he has had greater success in the treatment of dysentery with bichloride of mercury than with ipecacuanha. The latter treatment he found unsuited to many patients, the nausea produced seriously interfering with nourishment, though small doses, three to five grains, combined with sodium bicarbonate are often useful in acute dysentery. In chronic dysentery at the Burdwan Hospital, with every variety of treatment, the mortality has remained very high. Thinking that ipecacuanha owed its power in this disease to stimulation of biliary secretion, and believing that corrosive sublimate possessed the same influence with no nauseating effects, he resolved to give it a fair trial. His expectations were fully realized and with the administration of this drug many chronic and seemingly hopeless cases were cured in a shorter time than could have been expected with any other method. The dose he administers is small, five minims of the British liquor hydrargyri perchloridi (about 1 : 100 grain of sublimate) well diluted every four hours.

The Inheritance of Tuberculosis.—To determine if the children of tuberculous parents inherit the disease or simply the predisposition, DR. SANCHEZ-TOLEDO made the following experiments:

In the first series, on fifteen pregnant guinea-pigs, 1 c.c. of the tubercular virus of Koch was injected in the jugular vein. At the end of twelve or fifteen days, the animals died with their organs filled with bacilli. Thirty-five fœtuses were removed in whose organs no traces of the germs were found. Cultures of the blood, liver, and spleen remained completely negative. Thirty-five guinea-pigs inoculated with the fœtal organs remained in good health, and when killed no trace of tubercular disease was found.

In another series, eleven pregnant guinea-pigs were inoculated by injections into the pleura, and their seventeen fœtuses gave the same negative results.

Finally, in a third series, nine pregnant guinea-pigs were inoculated under the skin, with cultures or the fresh expectorations from phthisical patients, with the same results as above.

The author deduces from these experiments that the bacillus tuberculosis rarely enters the placenta, and that in consequence direct hereditation of tuberculosis is very exceptional.

As to the rarity of the transmission compared with anthrax, chicken cholera, etc., he believes it is because the microbes of these diseases live in the blood, whilst the habitat of Koch's bacteria is the lymphatic system. —*Lyon Médicale*, October 20, 1889.

Food for Gastro-enteritis of Children.—In the *Lyon Médicale*, DR. DUJRI advises the following food in gastro-enteritis of infants:

Wheat	1 tablespoonful.
Oatmeal	½ "
Barley	½ "
Water	1 quart.

This is to be concentrated by boiling to one pint, strained, and sweetened. The result is a mucilage readily taken by children. In gastro-enteritis the patient should be given small quantities of this mucilage at frequent intervals, and no other food administered until the stools assume their normal color.

Wash for Stomatitis.—

℞.—Sod. salicyl.	ʒv.
Aq. dest.	f ʒiijss.—M.

The mouth is to be washed with this at intervals of two or three hours.—*L' Union Médicale.*

THE EMPLOYMENT OF ANTIFEBRIN IN RHEUMATISM.

SINCE the discovery of the anti-rheumatic powers of salicylic acid by Germain Sée, who was using the drug for the purpose of reducing the pyrexia accompanying articular rheumatism, therapeutists have sought in the realm of similar substances for a drug which would benefit those cases suffering from the poison which salicylic acid was unable to modify. To this end, salicin and many salicylates have been employed, and carbolic acid, salol, antipyrin, and phenacetin have all proved to be of but temporary value in the treatment of an affection whose pathology has so far remained a closed door in the face of the pathologist.

The studies of Guttmann with antifebrin in a very large number of cases of rheumatism, embracing all its forms, both chronic and acute, have given most encouraging results; and we have seen the drug act most happily in several cases which had refused to yield to the iodides and salicylates: all of these cases were of the severe acute form, suffering intense pain from the articular inflammation, but devoid of any cardiac complications. It at once becomes evident that a drug such as is antifebrin may do good in a case of rheumatism in three entirely separate and distinct ways, any one of which may be active at once or all active together, hand-in-hand in the improvement of the patient's state. Any substance possessing strong antipyretic power must be of value under such circumstances in the lowering of the fever which follows its administration, with the resulting quieting of an excited system, and in putting aside the delirium associated with a condition of hyperpyrexia. Not only does such a drug act favorably in this manner, but the analgesic effects of such a substance must exert a powerful influence for good. By benumbing the sensibility of the patient to the excruciating pain consequent upon movement, and so putting aside the nervous wear and tear of sleeplessness and suffering, the patient's state must improve, or, at least, not grow worse from the exhaustion of the long hours of agony. Further than this it would seem probable that antifebrin possesses a direct anti-rheumatic influence, allaying the diseased processes even in those forms where, pain being largely absent, the improvement must be real and not apparent as a result of the relief of pain and gain in sleep.

The intention of this editorial is not to extol the value of antifebrin in rheumatism to the exclusion of other means of relief, nor to recommend its use before the more thoroughly tried salicylates and iodides, but to draw to its standard a certain number of cases which persistently resist treatment of the ordinary stamp and put the physician to his wits' end for a change of treatment at least promising some chance of relief. Many of the readers of THE MEDICAL NEWS have doubtless seen just such cases, and many of them must have learnt by sad experience that acute articular rheumatism is in many cases bound to run a course of so many weeks or days, do what we will. Under these circumstances nothing acts, further than a palliative, and the patient and his friends become impatient for a change. We have found that antifebrin in such cases will often relieve the pain and so permit a refreshing sleep, in doses of from four to eight grains three times a day, and that these amounts do not cause the excessive sweating which the necessarily large doses of salicylate are sure to produce—sweats which leave the patient oftentimes almost dyspnœic from very weakness. Whether this temporary relief produces such changes in the system as to permit of a better battle against the disease, or whether it actually counteracts the rheumatic poison, we know not; but we do know that following its employment the relief is not only temporary, but often permanent, and that a very distinct step in advance is made toward the close of the attack if any influence at all is felt.

REVIEWS.

A MANUAL OF OBSTETRICS. By A. F. A. KING, A.M., M.D. Fourth edition, 12mo., pp. 432. Illustrated. Philadelphia: Lea Brothers & Co., 1889.

DR. KING, in the preface to the first edition of this manual, modestly states that its "purpose is to furnish a good groundwork for the student at the beginning of his obstetric studies," and candidly admits it to be "in great part a compilation from more elaborate text-books." Were we inclined to find fault, these admissions of the author would at once disarm us. Its purpose is attained; it *will* furnish a good groundwork to the student who carefully reads it; and further, the busy practitioner should not scorn the volume because written for students, as it contains much valuable obstetric knowledge, some of which is not found in more elaborate text-books.

The chapters on the anatomy of the female generative organs, menstruation, fecundation, the signs of pregnancy, and the diseases of pregnancy, are all excellent and clear, but it is in the description of labor, both normal and abnormal, and its management, that Dr. King is at his best. Here his style is so concise, and the illustrations are so good, that the veriest tyro could not fail to receive a clear conception of labor, its complications and treatment. Particularly to be commended are the chapters upon placenta prævia and post-partal hemorrhage. We regret that Dr. King has not seen fit to insist upon the antiseptic treatment of normal labor, though in septic conditions his descriptions of antiseptic technique are entirely satisfactory.

A most useful chapter of twenty-two pages upon the jurisprudence of midwifery closes the volume—useful because on a subject so constantly neglected in college instruction.

Of the 141 illustrations it may safely be said that they all *illustrate*, and that the engraver's work is excellent. The name of the publishers is a sufficient guarantee that the work is presented in an attractive form, and from every standpoint we can most heartily recommend the book both to practitioner and student.

THE YEAR-BOOK OF TREATMENT FOR 1889. 12mo., pp. 344. Philadelphia: Lea Brothers & Co., 1889.

WERE it possible for the average practitioner to read one-half of the contributions annually made to the art of medicine, there might be no absolute necessity for such a volume as the one before us; but valuable articles are so numerous, and scattered through so many journals, that those of us who would keep pace with progress are compelled to resort to abstracts and compilations. Among such works, one of the most familiar is the *Year-Book*. Contributed to by Sir Dyce Duckworth, J. Mitchell Bruce, James Frederick Goodhart, Reginald Harrison, D. Berry Hart, Malcolm Morris, Frederick Treves, and others, it has won for itself, in other years, a well-deserved reputation which the number for 1889 sustains. All the important advances in therapeutics in every department of medicine are here found in the form of concise abstracts, usually with the suggestive comments or criticisms of the contributor. These comments by recognized authorities raise the book far above the level of a compilation, and add greatly to its value. To every practitioner of medicine the *Year-Book* offers valuable assistance, and to those of us far removed from the medical libraries and societies of a large city it becomes a necessity. Not the least important feature is the excellence of the index, which is most carefully prepared. From every standpoint we can heartily recommend the book to the practitioner of medicine, general or special.

CORRESPONDENCE.

LOUISVILLE.

(*From our Special Correspondent.*)

To the Editor of THE MEDICAL NEWS,

SIR: So far as the number of matriculates in medicine is concerned, Louisville ranks third as a medical centre among the cities of the Union. Carefully compiled statistics of the Illinois State Board of Health show that in the year 1887–88 New York State had 2309 matriculates, including regulars, homœopathists, and eclectics; Pennsylvania, 1267; while Louisville, the only city in the State of Kentucky containing medical schools, had 793 students enrolled in her colleges, all of whom belonged to the regular school. Since these statistics were published, another school has sprung into existence which presents anomalous features, and is, I believe, the only one of its kind in this country. It is a "regular" school of medicine, with a charter prescribing a minimum course of instruction, and giving the Faculty a right to confer the degree of Doctor of Medicine. The anomalous feature is the fact that the Faculty is composed of both whites and negroes, while the students are entirely of the latter class. What the requirements are for admission, or the number of matriculates, or the thoroughness of the course of instruction, your correspondent is unable to discover. It is reported that degrees are obtained with a celerity that would astonish even our older physicians accustomed to the "two years of five months each." Beside this experiment, there are four other schools, two summer and two winter, all of which are prosperous. A few years ago there was much rivalry between the various medical teaching bodies of this city, and charges of cut-rates, fraudulent matriculation, and unfair advertising, not to speak of still more severe accusations, were brought by the several schools against each other. Hospital appointments were the chief "bone of contention." As there is but one public hospital here, containing about 300 beds, in the past it was the custom of the school having the largest number of resident physicians appointed to this hospital, to utilize this fact as an evidence of its superiority over its fellows. Fortunately, the purely commercial spirit has largely given away to scientific zeal and a striving to keep pace with the requirements which the medical advancement of the last decade has made. The oldest of the schools, and one enjoying great prestige, is the medical school of the University of Louisville. Its importance as a factor in the development of medical teaching throughout the United States is not sufficiently appreciated. Comparatively few of the readers of THE MEDICAL NEWS know that as far back as 1848 Samuel D. Gross occupied the Chair of Surgery, and that in 1850 he resigned from the University of New York to return again to Louisville as a member of its

Faculty. In 1852 Austin Flint was appointed to the Chair of Practice of Medicine, and in 1847 Benjamin Silliman was elected Professor of Chemistry. Dr. Lunsford P. Yandell, who was widely known through the South, was connected with the school from its inception in 1837. In 1859 he was succeeded by his son, Dr. David E. Yandell. Dr. Theophilus Parvin, and Dr. James W. Holland, now of the Jefferson Medical College, have both occupied chairs in the school. Philadelphia contributed more to the successful founding of the first medical school in Kentucky than is generally known. In 1819 the Medical Department of Transylvania University was founded at Lexington by Dr. Charles Caldwell, a graduate of the University of Pennsylvania. The school grew apace, and in 1825 the classes numbered but little short of 300. Owing to the more rapid growth of Louisville and Cincinnati, the school was removed from Lexington to Louisville, where it was called "The Medical Institute," and afterward "The Medical Department of the University of Louisville." In 1847 this school had no less than 343 students enrolled upon its list, and in 1848 the number had increased to 406. At that time the college was matriculating a greater number than any other school in the Union, excepting the two in Philadelphia. As a result of the War, no lectures were delivered in 1862 and 1863, but since then the classes have grown steadily, and now number 350 matriculates. This school has established a laboratory of bacteriology, but, unfortunately, the shortness of its required course will prevent it from ranking with the foreign schools where a classical education is a requisite for admission, and where the course numbers almost as many years as we number months. In order to comply with the law which has just been passed in several States, in regard to the preliminary education for the study of medicine, the Faculty have arranged for the examination of all persons intending to practise medicine, granting a certificate of preliminary training to those who pass the required standard.

Were it not that this letter has already become too long, notes of interest concerning other schools of Louisville would be included, and another letter containing them will shortly be sent for publication.

BALTIMORE.

(*From our Special Correspondent.*)

To the Editor of THE MEDICAL NEWS,

SIR: The Medical and Chirurgical Faculty of Maryland, a society hoary with age, whose founders were among the leaders of medical and social progress a century ago, has taken a new lease of life and begun to shape itself after the State medical societies of neighboring States. To this end it has reduced its fees, and has determined to hold semi-annual meetings, one in Baltimore, as heretofore, and one in a selected town or city of the State. The first of these "out-meetings" took place a few days ago, in Hagerstown. A number of physicians of Baltimore attended, and very considerable interest was shown by the professional men of Hagerstown and adjacent districts. One of the papers read, on typhoid fever, gave the resident brethren an opportunity to show that they knew a thing or two about the disease, and their remarks showed that in knowledge of this subject they equalled, and in practical experience probably surpassed, many of their guests. The discussions of abdominal surgery showed that the surgeons of the counties are not behindhand in this field of operative work. The city members returned greatly impressed with the courtesy of their hosts, and with the desirableness of such reunions of the practitioners of the State.

At the Hagerstown session a movement was set on foot to secure a non-political State Examining Board. A law was passed by our last Legislature, appointing the State Board of Health a medical examining board, with powers limited to the examination of such practitioners as did not possess some sort of diploma. It was accepted by us as "better than nothing." As no appropriation was made to enable the Board of Health to buy postage stamps, bill-heads, etc., for its new work, quackery has continued to luxuriate as formerly in the rich pastures which Maryland affords. As the Board of Health is appointed through political influence, and is, therefore, afraid of hurting the feelings of the unclean, ignorant, or selfish among its constituents, the desire of physicians is now to have a special "examining board" appointed from a number of medical men nominated by the medical societies, due provision being made for the examination of homœopathists, etc.

We have two large new hospitals: the Johns Hopkins, which was formally opened a short time ago, and the Hospital of the Sisters of Mercy, which will soon be ready for occupation. The Johns Hopkins Hospital, situated in a beautiful square, possessing one of the finest outlooks in the city, representing in its internal construction the very latest ideas in sanitary science, and manned by a corps of distinguished scientific and practical men, has already attracted to its wards numbers of most interesting cases, the material exceeding in point of clinical interest the utmost expectation of the professors. Here each professor, with his group of special students about him, studies the phenomena of disease with an accuracy bred of careful training, and with an armamentarium complete in every necessary particular.

The Hospital of the Sisters of Mercy is a fine building situated next to the College of Physicians and Surgeons, presenting, in so far as means would permit, the modern improvements so elaborately and expensively worked out in the Johns Hopkins Hospital. It is to be hoped that the old custom of the Sisters of Mercy, of appointing convalescents and common servants to nurse the sick, will give place to the employment of trained nurses for this purpose. The Faculty of the College of Physicians and Surgeons has exclusive medical control over this hospital, which will have accommodations for 300 patients, and doubtless will receive most of the accident cases from the business centres of the city.

An announcement has just been made that post-graduate clinical courses may be expected during the present winter at the Johns Hopkins Hospital, which will be open to a limited number of physicians. Prof. Osler will give his class the privilege of visiting his wards daily in his company, and learning under his direction the most approved methods of case-taking and of diagnosis and treatment of disease, and will study with them select cases from his dispensary service. Special courses will be given in laryngology by Dr. Mackenzie; in diseases of children, by Drs. Osler and Booker; and in diseases of the nervous system and electro-therapeutics, by Drs.

Osler and Thomas. Laboratory courses in clinical microscopy and urinology will be given by Dr. Lafleur, and lectures will be delivered, in January, on phthisis, and in February, on practical cerebral localization. Opportunities will also be afforded for the working out of special lines in medicine and therapeutics by advanced students.

A limited number of physicians will be admitted to Dr. Halstead's bedside clinics, and to his private operating-room. He will deliver didactic lectures on antiseptic surgery, and clinical lectures on surgical tuberculosis, intestinal suture, and transfusion. Practical work may be done in the dispensary in general surgery, genito-urinary surgery, diseases of the skin, and diseases of the eye and ear.

The privilege of observing Dr. Kelly's operations in gynecology in his private operating-room will be extended to a few selected graduates in medicine.

Practical courses in hygiene, under the direction of Drs. Billings and Abbott, will extend over three months, beginning in March, 1890. Among the subjects studied will be the physical, chemical, and bacteriological conditions of air and water; the nature and action of ferments and disease germs; the methods of sterilization and disinfection.

A post-graduate lecture course will be given by Dr. Hurd on psychiatry.

The pathological laboratories, under the charge of Drs. Welch and Councilman, have been in operation for some time, opportunies being offered for both elementary and original work. Special attention is given in them to bacteriology.

Graduates of medicine may obtain all the above advantages for $100. The fee for all courses in any one department is $50; for a single special course, $25.

CINCINNATI.

(*From our Special Correspondent.*)

To the Editor of The Medical News,

Sir: Ten years ago laparotomy in Cincinnati was so fatal as to be approached with dismal foreboding, and the operation was never performed without the utmost antiseptic precautions or complete Listerism. To-day it has become common and is attended with an exceedingly low rate of mortality. Then, it was practised only in private or before a selected few who received with their invitations a request to be particularly careful as to their toilet that morning; now, it is practised in the public amphitheatres without special restriction and with only ordinary care as to cleanliness and moderate antisepsis.

Including laparotomies for all purposes, the operation has been performed in this city more than twenty times within the last month.

Dr. Thaddeus A. Reamy heads the list with twelve operations. Of these, three were performed in the amphitheatre of the Good Samaritan Hospital in the presence of the class of the Medical College of Ohio, six in Dr. Reamy's private hospital, and three in his private practice. Of the three performed at the Good Samaritan Hospital, one was for the removal of double intra-ligamentous cysts of the broad ligaments, one for pyo-salpinx, and one for hydro-salpinx. Of the cases operated upon in his private hospital two were pyo-salpinx, one a cyst of the broad ligament, one a hydro-salpinx, and two fibro-cystic tumors of the uterus. Of those in his private practice, one was for the removal of a small ovarian cyst, and two were for disease of the tubes and ovaries; one of the latter, the removal of a fibro-cystic tumor, proved fatal. All the other cases were successful.

Dr. P. S. Conner has had a successful operation for gunshot wound of the intestine. Two bullet wounds had been received, one ball entering about an inch to the right of and slightly below the umbilicus, the other about an inch to the left of the ensiform cartilage. Only the former, however, caused any damage. Nine perforations of the intestine were repaired, the operation being performed twelve hours after the receipt of the wounds. Recovery was prompt and complete.

On November 12th Dr. Conner sewed up ten wounds of the intestine four hours after the receipt of a pistol-shot wound. Considerable hemorrhage had taken place into the pelvis, the blood coming from a wounded vessel outside of the peritoneum, the location of which could not be determined. No hemorrhage of moment occurred after the operation, but the patient (a woman) died from the loss of blood shortly after its completion.

Three cases of ovarian tumor have proved to be cystic sarcomata. Two were operated upon by Dr. C. A. L. Reed, and one by Dr. George E. Jones. Strange to say, removal of as much of the tumor as could be taken away was in each instance followed by seemingly complete recovery, now of two weeks duration in the most recent case.

Drs. C. D. Palmer and E. G. Zinke have each performed two operations, the particulars of which I have not been able to obtain.

At least two exploratory laparotomies have been made. One of these, by Dr. E. W. Walker, at St. Mary's Hospital, was for intestinal strangulation. An extremely hard annular constriction of the bowel was found at the junction of the sigmoid flexure with the rectum, but as the patient was *in extremis* further procedure was abandoned. Microscopic examination of the specimen obtained at the autopsy revealed an extremely dense adeno-fibroma surrounding the bowel and completely closing it. The case was one of especial interest from the almost total absence of previous symptoms. The patient, a professional ball-player, aged twenty-three, of excellent physique, had no recollection of any previous illness until two or three weeks before the fatal occlusion. At that time he suffered from constipation of about a week's duration, but was relieved by a cathartic. No syphilitic taint could be discovered. The location of the stricture was determined by the attending physician, Dr. J. L. Cleveland, before the exploratory incision was made.

"Women, wind, and water penetrate everywhere," but as yet the female members of the medical profession are not represented in any of our college faculties. *Apropos* of this statement I may say that a movement is being made by prominent Presbyterian women and a few of their professional friends to found a new hospital for women and children, and to have connected with it a college "for the education of lady physicians." We have already a Woman's Medical College, fairly prosperous, although not overburdened with students, and there

is no crying need for another; but, with the exception of the clinical department, the faculty of this school is wholly masculine.

The medical profession of Cincinnati is infested with all sorts of parasites. Probably the most diabolical of the fungi is the so-called Vitapathic College, an institution chartered by the State, which for many years has continued to graduate men and women after a few weeks of alleged study and a fee, licensing them to solemnize marriage, perform the functions of a minister of the gospel, and practise the healing art. A graduate of this institution recently called to treat a case of cancer of the stomach, as diagnosticated by a leading surgeon, discovered that the patient was suffering from the invasion of that viscus by a lizard, and immediately began a course of emetics. The sufferings of the patient were promptly arrested, but the health officer refused to accept the certificate of death as prepared by the learned vitapath and the coroner was called to investigate the case. It is thought, however, that there is no law by which the culprit can be held liable, for although he is reported as having admitted that he received his diploma within one month after entering the "college," he is known to have practised ten years in this, the most gullible of all communities.

A recent decision by the Board of Public Affairs gives to the University of Cincinnati the right to erect buildings for educational purposes in Burnet Woods, one of the largest and handsomest of our parks. The University Board propose to bring the institution up to a point of excellence which will rival all other American schools. A suitable building is to be dedicated to the medical department, which will be richly endowed. Dr. J. C. Culbertson, editor of the *Lancet-Clinic*, is at present the life and soul of the University Board, and the probabilities are that, unless he is hampered by an unlooked-for financial shortage, he will not rest until he has established a medical college that is not only fully equipped, but one that will prove a formidable rival of the existing medical colleges of the South and West. The question which is agitating the profession is: Will the now prosperous colleges voluntarily surrender to the University and be absorbed as its medical department, or will they more slowly succumb to the inevitable death which is predicted for them should the University be successful in its project?

NEWS ITEMS.

Johns Hopkins Medical Society.—At the Johns Hopkins University a society of medical students has been organized on the plan of those in Berlin, the object being to bring the men of the various departments into closer connection, to stimulate original research, and to protect the claims of priority of work done by the members.

Medico-Legal Society of New York.—The November meeting of the Medico-Legal Society was held on November 20th, at the Hotel Buckingham. Clark Bell, the president, occupied the chair. The following corresponding members were elected: Dr. Joseph Morhman, of Toronto; Martha J. Lamb, of New York; Dr. C. Spadaro, of Bari, Italy; Dr. William M. McArthur, of Brooklyn; Dr. H. A. Bulloph, of Short Hills, N. J.; Professor Philippo Serafini, University of Pisa, Italy. A paper entitled "The Pathology of Death by Electricity," was read by Dr. P. E. Donlin, and another on "Life Insurance," written by Daniel Jordan, of New Brunswick, was read by the secretary. Arrangements were made for the annual dinner of the Society on Dec. 18th.

The Coronership of Queens County, New York.—Dr. Edwin A. Goodridge, of Flushing, failed to be elected one of the coroners of his county, but he may yet be successful through legal proceedings. A plurality of votes were cast for him, but his name was printed Goodrich upon the ballots. Dr. Goodridge is said to have been made a candidate without his consent.

Dr. Ricord's Record.—At the time of his decease, October 22d, Dr. Phillippe Ricord was the senior member of the Academy of Medicine, having been introduced forty years ago. The number of his decorations was not less than two hundred, an enormous number for a medical man to accumulate. Less than a month before his death he was still in practice, in a manner quite active for a man approaching his ninetieth birthday. Ricord was disinclined to the pen, but as a wit and attractive lecturer he made a memorable name and record.

The Middleton-Goldsmith Lecture.—Professor William Pepper, Provost of the University of Pennsylvania, will deliver the Middleton-Goldsmith Lecture before the New York Pathological Society, in the hall of the New York Academy of Medicine, on Wednesday evening, January 15, 1890. The subject of the lecture will be "Hepatic Fever."

Bacteriology Illustrated.—Dr. George M. Sternberg, of the Army, has been appointed to deliver a lecture before the Brooklyn Institute, on the 26th inst. He has selected for his subject "The Methods of Research in Bacteriology," to be illustrated by living forms of bacterial life thrown upon the screen.

Death from Glanders.—Dr. Hoffman, a pathologist in the General Hospital, Vienna, while making some experimental studies with the virus of glanders, gave himself a hypodermatic injection of morphia for a slight attack of muscular rheumatism. The syringe was one which had previously been used for the inoculations of cultures of the glanders bacillus, and, as might have been foreseen, Dr. Hoffman died in a few weeks from the disease.

Vacancies in the Medical Department of the Navy.—Surgeon-General Brown, of the Navy, has recently made his annual report to the Secretary of the Department. From it we glean the following facts concerning the condition of the medical arm of that service:

Vacancies in the Medical Corps: The Bureau called attention in its annual report of last year to the eleven vacancies then existing in the Medical Corps, and stated that a bill for the improvement of the condition of Assistant Surgeons, in rank and pay, had received the recommendation of the Department, and had been presented to Congress, with no near prospect of a successful issue.

On April 1st the Medical Examining Board was convened at the Naval Hospital, Brooklyn, its present loca-

tion. Since March 1, 1880, the Board, except for a few weeks during the summer, has been continuously in session at the Naval Hospital, Philadelphia, without the desired success in obtaining enough qualified young gentlemen to fill the vacancies.

As the graduates of the medical schools of the Pacific Coast, by distance and cost of transportation, were practically prevented from appearing before the Medical Examining Board, and as it seemed desirable to have in the future some members of the Corps who were citizens of the Pacific States for duty at home and on the Pacific and Asiatic stations, in the furtherance of availibility and economy a Medical Examining Board was constituted at the Naval Hospital, Mare Island, California. Notice was given to the deans of the chief medical colleges, and published in the principal medical journals, of the vacancies existing, and of the presence of the Boards at New York and Mare Island.

In addition to the eleven vacancies existing October 25, 1888, six more occurred during the year, four by death and two by retirement. The transference of the Medical Examining Board from Philadelphia to New York, and the establishment of another Board at Mare Island, has been attended with gratifying results; without lowering the standard of proficiency in the examination, a greater number of candidates have presented themselves, and twelve have passed the examination.

At present there are eight vacancies, and the Bureau has reason to hope that these vacancies will be filled at no very distant day. The Boards have been continued in their particular localities for another term.

New York County Medical Society.—At a meeting of the New York County Medical Society, on November 25, 1889, the following committees were appointed: On Ethics—Drs. E. L. Partridge, Henry E. Crampton, O. B. Douglas, A. M. Jacobus, and E. S. Leck. On Hygiene—Drs. Simon Baruch, R. C. M. Page, J. H. Emerson, Cyrus Edson, and Henry D. Chopin. On the Prize Essay—Drs. L. Bolton Bangs, E. H. Grandin, and Andrew F. Currier. Auditing Committee—Drs. William Stevens and Robert M. Fuller.

Drs. Julius Althaus, of No. 36 Bryanston Square, London, England, M.D. Berlin, Senior Physician of the London Hospital for Nervous Diseases, and Henry Morris, Surgeon of the Middlesex Hospital, England, were elected honorary, and Drs. James C. Edgar, Robert H. Wylie, John A. Fordyce, William H. Nammack, William L. Stowell, and William L. Russell, active members.

Dr. Malcom McLean read a paper on "Conservatism in Gynecology and Obstetrics," which was listened to with much interest, and afterward discussed.

Epilepsy and Mania in a Medical Student.—Dr. Henry C. Cooper, of the New York University Medical College, caused the arrest, November 6th, of a student named Allen, for examination in regard to his mental condition. If the report is true, as given in one of the New York papers, the case of Allen may be set down as one of the most unusual manifestations to be found in the history of epilepsy. The paper reports Dr. Cooper as follows: "This case is a very depressing one, but I will give a brief outline of the facts for publication. Allen first came to the University College in 1878 as a medical student. He soon developed symptoms of epilepsy, and had numerous fits in the College buildings. His general mode o action and study was so peculiar that we persuaded him to abandon the idea of becoming a physician, as he was unfitted in every way for the medical profession. He still contiued to frequent the College, however, and we tolerated his presence, looking upon him as a peculiar, but harmless, individual. Last Thursday he came as usual, and went to the dissecting-room. Six students were at work upon a negro subject, and he watched their operations. Suddenly Allen picked up a loose piece of the fascia, walked to a seat a few yards away, sat down, and slowly and deliberately devoured it. The students in the room were horrified, and reported the case to me the following day. I deemed it my duty to lay the facts before the Faculty, and we came to the conclusion that poor Allen had become afflicted with a mania which might render him a dangerous man to be at large. Accordingly, we took measures to have him examined mentally." The doctor declined to express an opinion as to the form of mania afflicting Allen. He said, however, that he believed it an almost unprecedented case in this country.

New Jersey Sanitary Association.—The New Jersey Sanitary Association met in the State House, Trenton, on November 22d and 23d. The officers were Dr. Dowling Benjamin, of Camden, President, and Dr. D. C. English, of New Brunswick, Secretary. Papers were read on the following subjects: "The East Orange Sewage Disposal Works," by C. P. Bassett, C. E.; "The Passaic River Drainage," by G. W. Howell, C. E.; "The Improvement of Sanitary Conditions in the Health and Pleasure Resorts of New Jersey," by Dr. Henry Mitchell; "The Climatic Treatment of Gastro-intestinal Diseases in Children," by Dr. Boardman Reed; "The Need of Medical Officers in School Districts," by Dr. G. F. Wilbur; "Physical Culture in the Schools in Its Hygienic Bearings," by Prof. James M. Green; "The Relation of Conduits to the Healthfulness of Water," by Dr. W. K. Newton; "Tuberculosis," and "Typhoid Fever in Munich," by Prof. S. G. Dixon, of the University of Pennsylvania; "The Present Special Sanitary Needs of Our Cities," by James C. Bayles, formerly President of the New York City Board of Health. The annual address by the President was on "The Thermometry of Hygiene."

Obituary.—Dr. William Wilson, who died suddenly, November 16th, in a New York City police station, from heart disease, was a prominent citizen and official of Ottawa, Canada. He was a graduate in medicine and law, and had brought his daughter to New York in order to gratify her choice of entering upon the life-work of a trained nurse. Dr. Wilson had been for several years the chief law clerk of the Dominion House of Commons.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

ORIGINAL LECTURES.

TUMORS OF THE FEMALE BREAST.

A Clinical Lecture

BY J. WILLIAM WHITE, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

THE extreme frequency of tumors of the kind that I intend presently to show you renders the subject one of great interest, not only to the surgeon, but also to the practitioner, who usually is responsible for the early recognition of the growth, and upon whose advice, if he does not care to operate himself, the patient seeks the aid of the surgeon. Some preliminary remarks upon the anatomy of the gland may aid us in systematizing the general subject of the diagnosis of these growths. The mammæ are compound racemose glands, made up of fifteen or twenty lobes, each with its principal excretory duct, which empties into a sac at the base of the nipple, and contracts again into a tube which is continued to and ends upon the summit of the nipple. Each of these lobes is made up of a number of lobules, each lobule in its turn being composed of a number of gland acini or vesicles held together by connective tissue. The mammæ rest upon the great pectoral muscles to the sheaths of which they are loosely connected by delicate fibrous tissue. They are richly supplied with blood and with nerves, are surrounded by an adipose layer, and are covered anteriorly by skin.

For clinical purposes, we may regard the gland as made up essentially of connective tissue, and of an epithelial or secreting structure. Simplifying the anatomy in this way, we may also, to a large extent, simplify the pathology, following the excellent classification of Mr. Mitchell Banks. By doing this, we can divide the new growths which infect the mammæ, as follows :

First. Tumors derived from connective tissue, and representing it in a fully developed state. These neoplasms are innocent and include the varieties known as lipoma, fibroma, myxoma, and chondroma.

Second. Tumors derived from hypertrophy of highly organized structures—neuroma and angeioma.

Third. Tumors derived from the epithelial or secreting structure and maintaining the general type of the latter. These tumors are either innocent or are on the border-line between benign and malignant disease. They include the adenomata, the adeno-fibromata, the adeno-cystomata, and the adeno-sarcomata.

Fourth. Tumors, derived from the connective tissue, but instead of presenting it in a fully developed or mature state, having it in an embryonic or immature condition. These neoplasms are malignant and include the large class of sarcomata.

Fifth. Tumors derived from the epithelial or secreting structures, but with those elements or structures atypical. These are, of course, malignant, and include the class of carcinomata.

Lipomata of the breast are exceedingly infrequent The growth is situated usually between the skin of the breast and the breast itself, consisting of a superficial, slowly growing mass, having the characteristic doughy feeling and becoming dimpled upon the surface if the skin over it is compressed. It is, of course, perfectly innocent and can with safety be enucleated.

The *fibromata* occur with somewhat greater frequency, and are among the growths most often mistaken for carcinomata. The important points of differential diagnosis are as follows: Fibromata rarely exceed in size the dimensions of a walnut, and are sometimes no larger than a hickory-nut; they appear early in life—may occur, indeed, shortly after puberty; they have no tendency to infiltrate the skin or the surrounding parts; they grow very slowly; pain is not common; there is no secondary involvement of the lymph glands; they never affect the general health (except as they may influence nutrition through the fear of the patient that she has cancerous disease); if removed, they rarely or never recur. In other words, they are innocent growths, which are to be distinguished by their occurrence at an early age and by the absence of the characteristic symptoms of carcinoma, which is the neoplasm they most closely resemble.

The *myxomata* begin in the connective tissue uniting the various ducts and lobules of the gland, which tissue tends to revert to its original condition, and to become transformed into a jelly-like, translucent substance. They grow to a moderate size, affect the skin sometimes as does carcinoma, and usually cannot be diagnosticated with absolute certainty without an exploratory puncture. A tendency to recurrence is said to have been observed in these growths, and it is, therefore, advised by high authorities, that when the diagnosis of myxoma has been assured the entire gland should be removed.

Chondromata, *angeiomata*, and *neuromata* have the well-known characters of these growths, when they occur in the mammary gland, as when they occur elsewhere. They may easily, therefore, be recognized, but are so exceedingly uncommon, as to be classed rather as surgical curiosities, than as growths likely to fall under the attention of the general practitioner.

The third class is a complex one and presents the greatest difficulties both as to pathology and clinical differentiation. Running over it rapidly we may say that pure *adenomata* are of the most extreme rarity. One might practise surgery for many years without meeting with a growth of this character. They are composed of fully developed glandular tissue. They have two peculiarities which make them more serious than might be supposed from the place which they occupy in the pathological series, viz., they are apt to recur after removal and they tend to become transformed into carcinoma, by breaking-down of the basement membrane of the vesicles permitting an infiltration of epithelial elements into the surrounding connective tissue. Clini-

cally they are small, hard, painless, nodulated tumors, freely movable, of slow growth, and apt to affect middle-aged married women who have suckled a number of children. The *adeno-fibromata* are much more common, and, indeed, are said to occur with more frequency than any other non-malignant tumor of the breast. They appear at an earlier period of life than does carcinoma, are hard, nodular, movable tumors, and are altogether without the characteristic signs of malignancy. They cannot be distinguished clinically from the pure fibromata. The *adeno-cystomata* are growths of greater or less density, often attaining a large size, and consisting at first of numerous walled cavities into which there is apt to occur an intracystic growth, which often quite fills them. They grow slowly, reach a large size, affect middle-aged women, and sometimes involve the skin, not by infiltration but by pressure.

The *adeno-sarcomata* are distinctly malignant, and differ but little from the pure sarcomata, the diagnosis usually depending upon the microscopic examination after removal.

Turning now to the characteristics of the tumors which belong to our fourth class, or those of *sarcomata*, it may be said that when we meet with a painless, elastic or semi-fluctuating tumor, having a tendency to infiltrate, to grow steadily and rapidly without becoming adherent to the skin or the chest-wall, which occurs in a person from twenty-five to thirty-five years of age, which is not accompanied by any enlargement of the axillary or other lymphatics, and in which the veins are enlarged over the surface of the growth, the diagnosis of sarcoma may be considered to be reasonably well assured.

The most interesting and important class of cases remains to be described, viz., *the carcinomata*, constituting about eighty per cent. of all breast growths. Occurring with enormous frequency and attended with almost unvarying fatality, these tumors are certain to come under the observation of every practitioner. Their well-known and easily recognized peculiarities may be summed up as follows: 1. The patient is past middle age, usually past the climacteric. The disease is associated with the involution, the disuse and atrophy of the gland, not with its evolution. 2. The tumor contracts adhesions as it grows, drawing upon the connective tissue about it (causing puckering of the skin), and upon the milk ducts (causing retraction of the nipple). 3. It infiltrates the surrounding structures, the skin above and the muscles beneath. 4. It spreads to distant parts early in its development by means of the lymphatics, the nearest glands becoming indurated and progressively enlarged.

These are the four characteristic signs of the variety of cancer known as scirrhus, the encephaloid differing in consistency and size, being usually much softer and larger. Other valuable symptoms are shooting pains, general cachexia, ulceration, chronic eczema or nodular growths in the skin, or sero-sanguinolent discharge from the nipple.

I have now run over the main diagnostic points which will enable you to recognize and classify satisfactorily the various neoplasms of the breast which may present themselves to you. The inflammatory conditions of the breast which may simulate new growths are chiefly *chronic induration of a lobule* and *cold encysted abscess*, both of which are apt to be associated with lactation. The former may sometimes be recognized by its ill-defined margins, its tenderness on pressure, and by the fact that several lobules or even both breasts are not infrequently affected. The latter, in addition to these symptoms, is often accompanied by some œdema of the skin.

Glandular or *retention cysts*, *serous cysts*, and *hydatid cysts* may be known by their fluctuation, but are sometimes so tense as to be of stony hardness. An aspirating needle will reveal the character of the growth, the fluid in the retention cysts being usually dark and bloody, in serous cysts clear and albuminous. The presence of hooklets would, of course, establish the diagnosis of hydatids.

Supra- and *sub-mammary abscess* and *galactocele*, or *milk cyst*, have an almost constant association with pregnancy or lactation, sometimes with a recent traumatism superadded, or with the sudden cessation of discharge from the nipple. The diagnosis is usually not difficult, and is based upon the history and the presence of inflammatory or retention symptoms.

You will find that your difficulties in diagnosis among all the various growths and enlargements affecting the female breast will be greatest with the tumors of small size, seen soon after their appearance. There is, of course, a period in the life-history of each tumor, however serious it may be, when it is small and movable and painless, when surrounding structures and neighboring glands are not involved, and when your opinion will perforce be more largely influenced by the age of the patient, her personal and family history, the presence or absence of lactation, etc., than by the physical characteristics of the growth itself. If, on the contrary, one or two years have elapsed since its appearance, and it still retains the above-mentioned features, it is safe to say that there is but little likelihood of malignancy.

When, as in the case of the patient whom I now show you, a young woman, aged twenty-five, presents herself with a small, painless, solid growth stationary for a year, freely movable, and with no symptoms of malignancy, what is your duty toward her? You may decide that there is a high degree of probability that you are dealing with a fibroma, or an adeno-fibroma, which would perhaps be harmless if left undisturbed, but there are other and important factors to be considered. You will constantly find in such cases that the patient is profoundly worried and distressed, that her pleasure is destroyed, her sleep broken, her nutrition affected by the presence of this growth. She is certain to have known, or, at least, to have known of, some one who has died of a breast cancer which in the beginning more or less closely resembled the swelling in her own breast. These constitute in themselves, in my opinion, good reasons for operation in the large majority of such cases. Then, too, we must, as I have said, frankly admit, that in the early stage of all growths there will be very considerable doubt in the mind of even the most experienced surgeon as to the ultimate outcome of any particular case. While the age of the patient, the absence of any family history of cancer and of any sign of that disease, may make its later appearance extremely improbable, it cannot be denied that there are many instances in which a too favorable opinion given at first has to be modified as the

disease progresses, and in these cases both patient and surgeon are apt to feel that possibly a chance has been lost of which advantage might have been taken. Nor should the undoubted possibility of the transformation of an innocent into a recurrent and truly malignant growth be lost sight of.

For these reasons it is my custom to advise operation in such cases whenever the general health of the patient is reasonably good. It is not necessary at this time to sacrifice the entire gland. We are dealing with a growth which probably belongs to one of our first two classes, or to one of the innocent varieties included in our third class, and has no tendency to return. We will probably find it encapsuled and will recognize that there has been no infiltration of surrounding structures. We can, therefore, spare the patient the unnecessary mutilation of an excision of the entire mamma. A careful microscopical examination shall at once be made, and if then there prove to be any distinct tendency to malignancy, a second operation, having for its object the removal of the whole gland and the cleaning out of the axilla, will be recommended. This should be understood by the patient, who will ordinarily, as in this case, willingly acquiesce, appreciating your desire to perform the least serious operation that will make her safe. The method of withdrawing a portion of the growth by an augur-like arrangement, recently suggested, has not been found satisfactory, as the very growths in which it would be of the most use, viz., those on the border-line between innocency and malignancy, are just those which present the greatest difficulties of microscopical diagnosis, and in which more complete sections are, therefore, necessary.

Under our present antiseptic methods, union by first intention ought to be the almost invariable rule in all these cases, and the operation for excision of a movable growth of moderate size should be without shock, pain, or risk of any sort.[1]

In approaching the second case which I have to present to you we find a woman, past middle life, with a tumor having all the characteristics of carcinoma, of moderate size, the skin slightly infiltrated and the axillary glands somewhat involved. In such cases, in all the undoubtedly malignant tumors—and especially in dealing with the carcinomata—the duty of the surgeon is, to my mind, perfectly clear. I have not now the time to give you my reasons in detail for all the opinions I am expressing to you, but must ask you to believe that they are founded on an experience which has been exceptionally large, thanks to my relations with Professor Agnew. I have had with him, in addition to my own experience, the opportunity of assisting at the operations upon and participating in the after-treatment of what may fairly be called an enormous number of these cases, and have watched their progress from first to last. The diagnosis of malignancy having been established, there are always certain questions in regard to prognosis which the surgeon will at once have to answer, either to the patient or her friends—and there are certain facts which, with or without questioning, it is his duty to lay before some intelligent member of the family.

In the first place, it should be clearly understood that the disease is, with or without operation, almost necessarily a fatal one. A careful study of recorded cases, in which a claim of cure has been made, will show that in many the diagnosis was not confirmed by microscopical examination, and that in more the report of "cure" was made at a period of twelve, eighteen, or twenty-four months after the operation. It is certainly unsafe in giving your prognosis to do more than express the hope that the case in question may prove to be one of the extremely rare ones in which the patient enjoys good health for many years—sometimes long enough to die of something else. This explanation will usually be followed by inquiries as to the probable duration of life, if the patient is not operated upon. In reply to this, it may be said, that according to the best authorities, the average length of life in cases of scirrhus, dating from the time of its first discovery, is about two years and a half.

Sibley places this period at a little over thirty-two months, Baker at forty-three months, and others at different dates, the time which I have mentioned—namely, two years and a half—being, however, about the average. Agnew says the shortest period at which he has seen death result from untreated carcinoma is six months, and the longest nine years. If the cancer is encephaloid, it is likely to progress more rapidly and to bring about an earlier fatal termination, the average duration of life in these cases being under a year (Jacobson). The next question will probably be: What is the probable duration of life after such an operation as is contemplated? To this it may be replied, that if the case is recognized early and the operation is promptly assented to, it may be said to increase the chance of life by at least a year, possibly by a year and a half, bringing it up to from three and a half to four years. If the discovery of the disease and the operation are later, the result will not be so good, the average date of recurrence after such late operations being from ten months to a year and a half.

As to the risks of the operation itself, which must also be considered, if the surgeon is familiar with the antiseptic method, and if he has had any experience in operating upon this class of cases, it is safe to assure the patient, if she be in reasonably good general condition, that there is almost no risk to life involved in removal of a mamma.

After having, as I have said, assisted Dr. Agnew in a very great many operations of this kind, and after having operated upon a number myself, the total running up into the hundreds, I can safely say that there has not been, in either his practice or mine for some years, a single death as a result of an operation for carcinoma of the breast. Indeed, with perhaps one or two exceptions, there have not been for years any conditions subsequent to operation which even gave rise to a moment's anxiety as to the life of the patient. This is not an exaggerated statement, but is one which has only been made possible by the rigid application of antiseptic methods which not only brought the mortality down to *nil*, but immediately reduced the average time of healing, even after the largest wounds, from three or four weeks to ten or twelve days.

There are, of course, cases in which it will not be

[1] The operation was performed in the usual way, the growth being removed by dissection from the neighboring structures. It was enclosed in a firm capsule, and proved to be an adeno-fibroma with a great excess of the fibrous element—almost a pure fibroma. No drainage was used. The wound healed in six days.

proper to recommend operation. I would say, in a general way, that those are cases in which the extreme age of the patient, or the presence of some intercurrent disease, or the existence of some bad habit, such as alcoholism, or, preëminently, the involvement of such an extensive cutaneous and glandular area as absolutely to preclude the possibility of the entire removal of all the glands, as well as of the tumor itself, should constitute powerful arguments against operation.

On the other hand, even great involvement of the glands should not be considered as constituting invariably an insuperable bar to operation. There are reasons which may make operations justifiable, even in this class of cases, as for example; where ulceration and fungous growths have been extensive and the patient is seriously annoyed by offensive discharges, or weakened by frequent bleeding, or, in other cases, where the pain is so great as to make life unendurable.

In such instances, it is quite proper for the surgeon to operate with a clear understanding that the operation is palliative in its character, as it is, unfortunately, in nearly all cases.

Of course, the surgeon would not think of operating in the presence of carcinoma elsewhere, as in some of the viscera.

It should be remembered, however, among the arguments in favor of operation that visceral cancer is painless, as a rule, and that if internal recurrence takes place the patient will at least escape the distressing accompaniments of death by exhaustion, hemorrhage, or septicæmia, as in cases of neglected and ulcerating carcinoma.

Having advised operation, then, in carcinoma or in any other malignant tumor of the breast, what is the best method of operative procedure? I will not detain you with the details of the antiseptic methods employed; they are already familiar to you, and consist in the most scrupulous preparation of the skin of the patient, the hands of the operator, the instruments, dressings, ligatures, sutures, etc. All that I desire to-day to call your attention to is the method which I shall presently employ, and which, as I say, has been used with much success by Dr. Agnew, and in a smaller number of cases by myself. The chief question at issue among surgeons, so far as I know, in regard to the operation itself, is chiefly as to its extent—*i.e.*, as to the necessity in every case for the removal of the entire breast and the chain of axillary glands. A minor question, also under discussion, refers to the amount of skin removed. Is it, or is it not, necessary in removing the breast, to take with it all the skin which covers it—in other words, to perform the so-called "dinner-plate" operation? In reply to these questions, I would say that, first, as to the removal of the entire breast, there seems to me every reason for advocating it. Mr. Butlin, in his recent excellent work upon the *Operative Surgery of Malignant Diseases*, has brought forward what seem to him good reasons for believing this to be, both theoretically and practically, unsound; but his arguments are not convincing to my mind. The tendency of malignant growths to extend rapidly far beyond the possibility of recognition by not only the eye, or the touch, but even by the microscope, is so well known that it seems the obvious duty of the surgeon to remove every particle of such tissues in the immediate vicinity of the growth as can be taken away without undue mutilation or deformity, and with a reasonable degree of safety to the patient. I, therefore, would strongly recommend you, in cases of this kind, not to rest satisfied with anything less than the removal of the entire breast, of every portion of suspected skin, and of all the lymphatic glands of the axilla, whether they are or are not perceptibly enlarged. The severity of the operation is not materially increased in this way, while there can be little doubt that life is prolonged, and possibly the best chance is given for avoidance of recurrence, although it must always be recognized and admitted that that chance is an exceedingly small one.

As to the removal of skin, while every portion which is in the least adherent, or puckered, or even doubtful in appearance, should not only be removed, but should be given a wide berth, it seems scarcely justifiable in the light of our present statistics to subject every woman who undergoes this operation to the prolonged and tedious experience involved in the healing of an open wound of large size. It undoubtedly also increases the pain, the discomfort, and the risk of convalescence, and I have yet to learn that its indiscriminate employment brings with it any compensatory immunity from recurrence. The burden of proof rests with its advocates.

I will now proceed with the operation best suited to such cases as the present one. An elliptical incision is made, including the nipple and all the affected portion of skin, and a broad area on either side of it. The incisions extend from the sternum on the affected side to a point just below the axillary border of the pectoralis major.

The lower flap is dissected up rapidly, the dissection being carried well beyond the limits of the breast. The connective tissue beyond the breast limits, and the fascia overlying the pectoralis muscle, being recognized before the dissection stops, the flap is reverted, a few large bleeding vessels are picked up by hæmostatic forceps, and the space beneath the flaps is filled with antiseptic gauze or with towels wrung out from a hot bichloride solution. A similar flap is then formed on the upper semi-circumference of the gland.

After this, the gland having been loosened well around its border, and especially at the part toward the sternum, the operator seizes it with the hand, raising it by forcible traction made in the direction of the fibres of the pectoral muscle, to which it is often adherent. If this be the case, he will often remove with the tumor a portion of the attached fascia and muscle. This, however, is not to be regarded as a disadvantage, as such portions of tissue will probably be implicated and might escape the knife. The points of attachment are also those to which especial attention should be paid, all doubtful portions of the great pectoral being freely removed. The axillary cavity is entered by an incision through the fascia, near its anterior border, and the glands removed by blunt dissection, chiefly with the finger.

The wound is dressed with the same care observed in all the other steps of the operation. The rubber drainage-tubes are removed on the second or third day.

[Union by first intention on the eighth day was obtained. The highest temperature was 99.3°.]

ORIGINAL ARTICLES.

TREATMENT OF TUBERCULOSIS.

BY J. LEWIS SMITH, M.D.,
OF NEW YORK.

Prophylaxis.—In order to employ prophylactic measures most successfully, it is necessary to have full and accurate knowledge of the circumstances or conditions in which the disease, which we endeavor to prevent, originates. Therefore, before we consider the measures which are designed to prevent tuberculosis, we will briefly relate the following authenticated instances, which show the different modes in which this fatal malady is contracted.

H. Reich states that in an inland town in Europe, a midwife with advanced phthisis, was in the habit of blowing into the mouths of newly born infants, and ten of these infants died of tuberculosis, apparently contracted in this manner. At the same time the infants in the practice of a healthy midwife in the same town remained well (*Berlin. klinische Wochen.*, 1878). Dr. E. I. Kempf relates the following equally striking instance of infection (*Louisville Medical News*, March 22, 1884). In the fall of 1880, a girl of eighteen years, whose brother had died of consumption, was found to have tubercles at the apices of both lungs. She belonged to a sisterhood, and slept in the general dormitory with the other sisters. In four months nine of her companions began to cough, and were found to have tubercles. No one of the sisterhood had previously had disease of this kind. Dr. A. Ollivier, physician to l'Hôpital des Enfants Malades, Paris, states that a family previously in robust health occupied two small rooms opening into a narrow court. The parents, a young son, and the baby, slept in one of the rooms. An older son, who had been living elsewhere contracted phthisis, returned home, and slept in the same apartment. He died January 16, 1883. His mother, who was constantly at his bedside began to cough, emaciated, and died of the same disease in the following May. Seven days after the death of the mother, her infant had tubercular meningitis, of which it perished, and a little later the older child who occupied the same apartment, sickened and died like the mother. The father only remained of those who occupied the small room, and his immunity was probably due to the fact that he was most of the time in the open air (*Etudes d'Hygiène Publique*, 1886). The fact has long been noticed that wives in their close ministrations on phthisical husbands, occupying not only the same rooms, but the same beds, and using the same towels, are very liable to contract this disease. Moreover, I have noticed in the wards of phthisical patients in Charity Hospital and elsewhere, that young infants of tubercular mothers usually contract phthisis, which is likely to be general, and not infrequently they die before the mothers. Formerly it was supposed that tuberculosis was transmitted to such infants by inheritance, but now that its infectiousness is known, it seems probable that the transmission of this disease from the mother to her infant is post-natal and due to her intimate relations with it.

The recent experiments of Cornet (*Wiener med. Wochen.*, June 2, 1888) show that the walls and furniture of a room occupied by a phthisical patient are liable to become infected by the lodgement of the tubercle bacilli upon them, so that a healthy person occupying this apartment, simultaneously or subsequently, is in danger of contracting this disease. He rubbed the walls and bedsteads in the ward occupied by phthisical patients with disinfected sponges, avoiding such surfaces as might be infected by the hands and sputum of patients. Ninety-four animals were inoculated with these sponges and 52 of them died from causes apparently different from tuberculosis. The remaining 44 were killed after forty days, and 20 of them had tubercles. In a second experiment, 168 animals were inoculated with the dust from the walls of an infected apartment, and 90 of them died soon afterward, of which 34 were tuberculous. Of 311 animals inoculated in all, 167 died in consequence of the operation, and of these 57 were found to be tubercular and 85 without tubercles. Control experiments with dust from rooms not occupied by tubercular patients, and from the crowded streets, gave a negative result as regards the development of tuberculosis.

The important observation has been made that the dust is not infectious in rooms occupied by tubercular patients who have uniformly expectorated into cups or spittoons, which have been emptied and disinfected at proper intervals. Several observers state that their observations clearly establish the fact that neither the tubercle bacilli nor spores are exhaled in the breath of the phthisical patient. On account of the weight of these organisms it is said that they cannot be detached from the sputum, or the moist surface of the respiratory organs, so as to infect the breath in ordinary respiration. But this is a subject which requires further investigation. Certain it is that particles of dried sputum loaded with the bacilli received on towels, handkerchiefs, or other surfaces, are liable to be wafted by currents of air so that those who minister to a patient are in constant danger of contracting the disease by inhaling these particles if proper precautionary measures are not employed.

Another and probably a common mode in which the tubercle bacillus enters the system, is in the ingesta, like the bacillus typhosus of typhoid fever.

Tuberculosis is a common disease in cattle, and recent observations and experiments show that it has probably in numerous instances been caused in man by the use of milk from tubercular cows. Gerlach fed such milk to young animals and produced in them tuberculosis, manifested primarily along the alimentary tract and in the adjacent lymphatic glands. Alibert fed a litter of young pigs with the milk from a tuberculous cow, and all of them died from tuberculosis. Tubercles frequently occur in the udders of tuberculous cows, and by their presence in the tissues which secrete the milk, the milk itself is infected. Nocard discovered the tubercle bacillus in eleven examinations of the milk from tubercular cows. In the examination of 600 cows in the Edinburgh dairies, 37 were found with inflamed udders, and the milk obtained from 6 of these was found to contain the tubercle bacilli, showing that in at least these 6 cases the udders were the seat of tubercles (*Annual of the Universal Medical Sciences*, vol. i., 1889). Klebs, Bollinger, Koch, Stein, Toussaint, and Chauveau may be mentioned among those who state that milk from the tubercular udder of the cow, if given in a raw state and sufficiently long, will cause tuberculosis.

The experiments of Cornil throw light on the manner in which tuberculosis is caused by the use of infected food. He ascertained that cultures of the tubercle bacillus, introduced into the intestine of an animal, penetrated the mucous surface very quickly. In four days after introducing the culture into the œsophagus of the guinea-pig, he found submucous lesions of a tubercular nature, and even tubercular mesenteric glands without appreciable injury of the epithelial cells where the culture was introduced. Cagny relates the following instructive instance, showing how the ingesta may be the vehicle of the tubercle bacillus in animals. A man having tuberculosis, was in the habit, while walking in his garden, of expectorating on the ground. He was closely followed by chickens that swallowed his sputum with avidity. In a few weeks nearly all the chickens were found to be tuberculous, their livers especially being affected, so that it was necessary to destroy the whole brood (*La Semaine Méd.*, August 1, 1888).

Not only the milk, but the flesh of a tuberculous animal may communicate tuberculosis. At the meeting of the Congress for the Study of Tuberculosis, held in Paris, July, 1888, all the members present regarded the use of the flesh, and especially the milk, of tuberculous animal as dangerous, and recommended their "complete seizure." Jorissenne states that four cows in every one hundred are tuberculous, and in one shed of twenty cows the milk drawn from tuberculous teats presented a "prodigious number of bacilli." In Montauban during seven years, 4.07 per mille of the cattle that were slaughtered were tuberculous, and T. Spillman found 30 to 40 per cent. of the stall-fed cows of Nancy tubercular. In addition to cattle, hogs and the various domestic feathered animals are liable to tuberculosis, but the percentage of those that are affected varies in different localities, the number being greatest in animals that are stabled or penned. Tuberculosis is so common in the domestic animals that measures designed to protect families who obtain so large a proportion of their food from this source are urgently required. The possibility of the transmission of tuberculosis by vaccination has attracted considerable attention in Europe, and was discussed at the Parisian Congress held in July, 1888. To guard against this transmission, the animals furnishing the virus are, in several of the vaccine establishments, killed before the points are used, and these points are rejected if the organs exhibit evidence of disease. Still it is believed that the pure vaccine lymph, even from a tubercular animal, does not contain the bacillus, but the point may contain it if there be an admixture of blood.

Tuberculosis is most prevalent where people congregate, as in schools, factories, prisons, the city tenement houses, and least prevalent where people lead isolated outdoor lives, as the agriculturists. The effect of confinement was clearly shown by the experiments of Trudeau. He inoculated two sets of rabbits with tubercular matter: the one set, confined in a damp, dark subterranean place, were found when killed to be extensively affected with tuberculosis, while the other set, allowed to run free in the sunlight, were but slightly tuberculous (THE MEDICAL NEWS, October 27, 1888). Ziemssen says that fifty per cent. of the Sisters of Charity in the Munich Hospital die of tuberculosis. The robust and rosy-cheeked candidates of the order arrive from the country, but in the confinement of the hospital their health gradually fails, and one after another contracts tuberculosis and dies. So great is the difference in result between life in the open air and in confinement.

Again, some individuals are especially liable to contract tuberculosis on account of certain local ailments. Caseous substance occurring in any part of the system affords a nidus in which the tubercle bacillus, if it obtain a lodgement, is readily propagated. Caseation occurs most frequently in the inflammations of scrofulous children, and hence scrofula has long been regarded as sustaining an intimate causal relation to tuberculosis Strumous children with cheesy cervical glands, cheesy bronchial, axillary, or mesenteric glands, or cheesy pneumonia, usually die of tuberculosis. If exposed to cases of tuberculosis they are in imminent danger of contracting this disease. The tubercle bacillus

may also gain admittance into the system through sores or wounds of the skin or mucous membrane. Perhaps the most striking examples bearing on this point were collated by Dr. Meyer and published in the *N. Y. Med. Presse*, June, 1887. In 18 of 28 cases, the Jewish rite of circumcision had been performed, in which the operator frequently sucks the wound with his lips. In these cases of tuberculosis following circumcision, ten or fourteen days after the operation the inguinal glands were observed to be swollen, indicating commencing infection of the system. It therefore behooves one having an open sore upon the skin, or a lesion upon the mucous surface, as in catarrh of the Schneiderian or bronchial surface, to avoid close intimacy with a tubercular patient.

Prophylactic Measures.—Since tuberculosis originates in so many different ways, measures designed to prevent this disease have a wide range. Precautionary measures are especially required in the nursing of the tuberculous patient. His sputum should always be received in a cup or spittoon containing a disinfectant liquid, and this vessel when emptied should be cleansed with boiling water or a disinfectant. Sputum should never be received upon a handkerchief or cloth and allowed to dry. Towels and handkerchiefs should be moist when used, and immediately afterward placed in boiling water or a disinfectant. We have seen what disastrous results occur from the dried sputum. Whatever may be said of the innocuousness of the breath of the phthisical patient based on the supposition that the tubercle baciilus has so great a specific gravity in its moist state that it is not exhaled in ordinary respiration, nevertheless the sad experience of the midwife related at the commencement of this paper should teach us to avoid his breath, so far as is compatible with proper ministrations to him. The floors and walls of his apartment should occasionally be washed with a disinfectant liquid, and the bedding, clothing, rugs and mats should never be shaken in the apartment, but outside the house. Ventilation of the apartment should be allowed to the full extent compatible with the safety of the patient. The remedies which we will hereafter recommend in the treatment of the patient, are destructive to the bacillus, and, therefore, whenever employed have also a prophylactic action.

No physician who has read in the medical journals of the last decade the many reports of cases in which milk has been the vehicle of pathogenic organisms has failed to see the urgent need of obtaining this indispensable article from healthy dairies. Families should insist on the inspection at regular intervals of the dairies that furnish them milk, and the exclusion of such animals as exhibit the least sickness. Moreover, no one with a chronic cough should be employed in milking or in the subsequent handling of the milk But with the utmost endeavor, on the part of families living at a distance, to obtain milk free from impurities, no one can state positively that it will not sooner or later contain pathogenic organisms, as those of diphtheria, scarlet fever, typhoid fever, or tuberculosis, so many and unsuspected are the modes of infection. Fortunately, heat at or near the boiling point is an effectual sterilizing agent, and it can be employed without diminishing the nutritive properties of milk or rendering it more indigestible. I do not forget the interesting experiments which have been made to determine the tenacity of life of the tubercle bacillus, when subjected to heat and cold. In experiments made it is said to outlive most of the microbes associated with it. Schill and Fischer state that dried and pulverized tubercular matter not subjected to treatment retains its virulence six months, and Pietro states that tubercular sputum well-dried and maintained at 77°, retains its virulence nine or ten months. But what concerns us most at present is the remarkable statement made by Max Voelsch (*Centralb. für klin. Med.*, June 30, 1888), that twice boiling does not entirely destroy the virulence of the tubercle bacillus. I habitually direct that the morning supply of milk designed for children shall be immediately placed in a steamer and subjected, two hours, to a temperature of 190° to 200°. No pathogenic microbe can probably survive if subjected so long a time to so high a degree of heat. The flesh of the tubercular animal, which it is believed is often purchased by unsuspecting families, evidently requires similar treatment—that is, thorough cooking—in order to be rendered innocuous. A competent meat inspector should be employed at each slaughter-house, and all di eased meats be rejected, but in the present management of the meat market, the only sure method of preventing the presence of living and active bacilli in the meat foods appears to be by thorough cooking.

Outdoor life, residence in elevated localities, where the air is not only pure but rarefied, the occupancy of sunlit and well-ventilated rooms, the avoidance of rooms or localities where the air is contaminated by the preseuce of others, as in crowded schools or factories, or by unwholesome occupations, and all measures which promote the appetite and general health, are prophylactic, as they are also to a certain extent curative, of tuberculosis. It is evident from what has been stated above, that caseous substance occurring in any part of the system, inasmuch as it sustains a close causal relation to tuberculosis, should, if practicable, be removed by surgical measures. Moreover, since cheesy degeneration results for the most part from

inflammations occurring in the scrofulous, measures designed to prevent or cure such inflammations, or to cure scrofula, have a prophylactic effect as regards tuberculosis. The strumous child should be watched with great care, and such measures be employed as are calculated to invigorate his system. He should receive anti-strumous treatment, both hygienic and medicinal. Especially should glandular hyperplasia and the products of inflammation, whether occurring in the lungs or elsewhere, be, if possible, removed before caseation occurs. For this purpose the old remedies, like cod-liver oil and syrup of the iodide of iron, given internally, and for hyperplasia of the subcutaneous glands, ointments like iodide of potassium in lanolin, may be advantageously employed. Finally, one having an abrasion or sore of the cutaneous or mucous surface, or catarrh of the air passages, as indicated by discharge from the nostrils, sore throat, or a cough, should not attend as nurse or otherwise a phthisical patient until his local ailment is cured, since the tubercle bacillus is believed to enter the system more readily through a diseased than a healthy surface. We will next consider the treatment of tuberculosis, which is undergoing a marked change since the microbic nature of the disease has been discovered, the antiseptic and germicide remedies coming more and more into use, so that there is reason to think that, at a time not distant, this malady, instead of causing one-seventh part of the deaths of the human race, will be somewhat less frequent and fatal.

(*To be continued.*)

ON THE TREATMENT OF SCARLET FEVER BY CHLORAL HYDRATE.

By J. C. WILSON, M.D.,
PHYSICIAN TO THE HOSPITAL OF JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

It is my wish to bring to the notice of the profession an efficient method of treating scarlet fever not hitherto described. My account of this method is based upon a personal experience now extending over seven years. It therefore relates to cases and epidemics of every degree of intensity.

The most cursory review of the history of the treatment of this disease enables us to divide it, in common with that of the other acute infectious diseases, into three periods:

First, a period in which treatment was based upon the idea of depletion by means of general or local bloodletting, emetics, purgatives, and diaphoretics. It is needless to say that neither experience nor an enlightened pathology support this plan.

Second, a period in which the treatment was based upon the administration of so-called specific remedies—a method which, having its origin at a time when not only, as now, our knowledge of the specific cause of scarlatina was most indefinite, but when even the germ theory of the infectious diseases in general still rested upon pure hypothesis—was wholly without scientific basis. The treatment of this period, earnestly advocated by different observers, as its various plans were, resulted in disappointment and failure, and has of recent years fallen largely into desuetude.

As a consequence of the reaction from the disappointed enthusiasm in regard to the second plan, a third method of treating scarlet fever came into vogue. This may be described as the rational, or expectant-symptomatic plan. It is advocated in the greater number of the recent text-books upon practice. The principles upon which it is based are familiar. They depend upon our knowledge of the self-limitation of the acute infectious diseases, and our ability, the result of the accumulated experience of the profession, to modify, within somewhat narrow limits, the intensity and the disastrous effects of particular symptoms.

The general adoption of this method of treatment at the present time, when a more exact knowledge of the causation of certain of the acute infections inspires the hope that the true methods of specific treatment may yet be discovered, is not so much a manifestation of theoretical disbelief in specific treatment as it is an indication of our inability, up to the present time, to realize our expectations in this direction.

A plan of treatment which at once relieves the more urgent symptoms of the disease, and anticipates their development, fulfils, in a high degree, the more important therapeutic indications. If any such plan realizes to some extent the requirement of a specific medication, its value is proportionately enhanced.

Such is the plan under consideration.

It consists chiefly in the administration, from the outbreak of the attack of scarlet fever until defervescence, of small and frequently repeated doses of chloral hydrate. The administration of this drug in acute disease for the relief of restlessness and for the promotion of sleep is familiar. It is, in fact, a matter of every-day occurrence, especially in the treatment of diseases of children, who bear chloral remarkably well. Simply to advocate its use for these purposes would be to occupy unnecessarily the attention of the readers of this journal. The use of chloral which I am about to describe is not only different, but is based upon a wholly different view of its effects in this disease. Chloral, under this method, constitutes the drug employed from the beginning to the end of the febrile stage. If other medicaments are used, it is for the purpose of meeting special indications not fulfilled by the

chloral, or to counteract certain effects of the chloral, which, when exaggerated, are unfavorable.

The plan is as follows: So soon as the patient is suspected or known to be developing scarlatina, a laxative dose of calomel, proportionate to the age and general condition, is administered. Shortly thereafter chloral is given, in moderate doses, at intervals of two or three hours, or longer, throughout the attack. The dose varies with the age of the child; the frequency of its administration depends largely upon its effect. To infants of two or three years, a dose of from one to two grains may be given, the dosage being gradually increased with older children; that for adolescents reaching five grains. The tranquillizing and sleep-producing effects of the drug are in most instances promptly realized, the patient falling into a condition of quietude or somnolence, in striking contrast to the discomfort and jactitation which are so distressing in the well-developed disease.

The repetition of the dose should not be more frequent than is necessary to maintain this condition of quietude, a condition from which the patient may be easily aroused, and into which he quickly relapses when disturbed. It is neither necessary nor desirable to push the drug to the establishment of a deeper sleep. Profound narcotism is, of course, to be avoided. The patient may thus be kept in a condition of light repose throughout the whole duration of the fever. By this means, not only is there obtained relief from the restlessness and distress of the active period of the disease, but much wear and tear of the nervous system and some exhaustion from muscular effort are prevented. Delirium is controlled; the itching and burning of the skin due to the eruption are allayed; in a word, the greater number of the distressing symptoms of the disease are favorably influenced by the cautious and prolonged administration of chloral hydrate in efficient doses.

As a rule, the drug is easy of administration and well borne by the stomach. I have found its acrid after-taste best masked by the administration in Aubergier's syrup of lactucarium diluted, thus:

℞.—Chloralis . . . . . gr. xxx.
Syrup. lactucarii (Aubergier) } āā
Aquæ . . . . . } ℥jss.—M.

SIG.—A teaspoonful in iced water every two, three, or four hours.

The administration of nourishment immediately after the medicine is desirable. The sleep-inducing properties of the drug manifest themselves rapidly, but are not prolonged; therefore, its repetition at intervals of two or three hours is called for.

The elimination of the drug takes place chiefly by the kidneys, and to a large extent as chloral. Decomposition with the formation of chloroform does not, as Liebreich anticipated, take place within the organism. This fact is of some theoretical importance, in view of the well-recognized antiseptic properties of chloral. Chloral acts, then, as a local antiseptic upon two tissue areas that are especially prone to the pernicious effects of the infecting principle of scarlatina. These are the throat and the kidneys. It cannot be claimed that chloral, in such doses as are safe, exercises to any great degree a specific antiseptic effect upon the fluids of the organism at large. Nevertheless, the continual presence of even small amounts of chloral in those fluids may be held to exert to some extent an influence upon them unfavorable, so far as it goes, to the development of bacteria.

The local action of chloral in these doses upon the throat in ingestion, and upon the kidney in elimination, is direct and efficacious, as shown by the lower grade of intensity of the inflammation of the palatine arches and tonsils, on the one hand, and by the almost constant absence of albuminuria on the other. The diuretic action of chloral is almost invariably manifested, the urine being much increased in quantity, of lower specific gravity, light-colored, and faintly acid. The diuresis is sometimes enormous, reaching from fifty to eighty fluid-ounces in the course of twenty-four hours. In a large number of cases intercurrent abuminuria was rarely encountered, and post-scarlatinal nephritis was not observed, although the cases were kept under observation for prolonged periods.

Chloral in the doses given appears to exercise no influence upon the primary temperature curve of the disease, defervescence taking place between the seventh and ninth days by rapid lysis as is usual.

Otitis media, extensive adenopathy of the cervical lymphatics, the collar of brawn, and abscesses, under this treatment do not occur. Hence, troublesome secondary fever, by which the febrile movement of scarlatina is often prolonged indefinitely, is prevented.

In the above doses chloral does not appear to be a cardiac depressant, exerting, in the earlier periods of the disease, simply a favorable influence upon the excited heart, similar to that of small and frequently repeated doses of aconite. If during the course of the disease, especially at the beginning of defervescence, the heart flags, alcohol must be given. As a matter of fact, alcohol in the form of milk punches, wine whey, or egg-nog, forms a useful addition to the dietary throughout the course of disease.

From the beginning of the attack the nasal passages and the throat are systematically treated by antiseptic sprays, such as weak dilutions of Labar-

raque's solution, Dobell's solution, Listerine, or the antiseptic tablets devised by Dr. Seiler. This is done from the beginning in all cases. I regard it as a prophylactic measure of great importance, preventing the accumulation and retention of the morbid products of the inflamed mucous membrane and diminishing the risks of secondary mixed local infection, the cause of the throat and ear inflammations which constitute occasional complications.

From the time of the appearance of the eruption inunction is practised. For this purpose freshly washed lard is employed.

If the arrangements are such as to secure thorough disinfection of the clothing before it is washed, frequent changes are permitted; otherwise, to avoid risk of contagion, the patient is allowed to wear the same night-clothes throughout the attack. After the child leaves the room, thorough disinfection is to be practised by sulphur fumigation in the presence of moisture.

During the convalescence, quinine, nux vomica, and iron are indicated.

Whether or not other hypnotics, administered upon the same principles, would yield equally favorable results in the treatment of this disease, I cannot say. Chloralamid, among the recent synthetic narcotics, appears to be more efficient as a sleep-producer than chloral, and less dangerous; but we have yet no experience with it, nor does it possess the antiseptic qualities of chloral.

In conclusion, the following propositions are affirmed:

1. The treatment of scarlet fever by chloral hydrate without the use of other drugs has yielded satisfactory results.

2. The chief *rôle* of chloral in the treatment of scarlet fever is that of a sedative to the cerebral centres. It appears to antagonize certain exciting toxic principles formed within the organism during the course of the disease.

3. Chloral is also useful on account of its antiseptic properties, (*a*) upon the throat; (*b*) upon the kidneys; (*c*) to a slight extent upon the fluids of the organism at large.

It is necessary in this connection to bear in mind the difference between the germicide and the antiseptic influences of drugs. No amount of chloral compatible with the maintenance of life can act within the organism as a germicide. It is assumed that medicinal doses may *tend* to render the fluids of the body antiseptic, that is to say, may *tend* to impair to some extent, their fitness as culture media for pathogenic bacteria.

4. The elimination of chloral by the kidneys and its diuretic effect render it especially useful in the treatment of scarlet fever.

A CONTRIBUTION TO THE THERAPEUTICS OF TYPHOID FEVER.[1]

BY GEORGE L. PEABODY, M.D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE results in the treatment of typhoid fever continue to be so bad in general in this country as to constitute a chronic opprobrium to the art of medicine here. We do not seem to be capable of approaching, at least in New York, the low rate of mortality which has rewarded the efforts of the medical profession in many cities of Europe. While we endeavor to explain our relatively higher death-rate by various differences which, without doubt, exist in the manner of collating and recording statistics in different countries, and while we may have to deal with a larger percentage of *bad cases*, cases which come under treatment in hospitals late in the disease—too late, indeed, to allow of anything like active therapeutic procedures—still, after making every allowance for local differences of these descriptions, it must be admitted that our death-rate in this disease is far higher than it should be. I believe, too, that the fact that we have not as yet arrived at anything at all resembling a general consensus of opinion regarding its treatment is in itself evidence that many cases must be improperly treated, and that in this way much of our high mortality is to be accounted for.

Those who still adhere to the expectant plan of treatment are still in the large majority here. The expectant plan seems in a general way to make us quite content with our bad results, and to lead us to expect the patient to die if he becomes gravely ill. In this plan of treatment practically nothing is done unless symptoms in themselves very disturbing or grave, or even threatening, develop; and then much is often done that is likely to be pernicious in its effects. Doctors of this class seem to be pretty well in accord as to the proper plan of procedure, and to believe that a simple *symptomatic treatment* is the rational one. If a patient have a headache he receives the bromides, or an ice cap, or both, depending upon its severity; if he develop a bronchitis he is given opium, or cough mixtures, or inhalations; if he suffer from tympanites he is given turpentine, or turpentine stupes are applied; if he have a diarrhœa he is given opium and astringents; if hemorrhage from the bowel occur, to the opium is added tannic acid or gallic acid, or some other equally useless and disturbing drug; if he become delirious, the dose of the opium is increased, or he is physically restrained; and, most pernicious of all, if his temperature reach what is considered a dangerous height, an elevation which, long continued,

[1] Read before the Practitioners' Society of New York, December 6, 1889.

would become incompatible with life, he is given a *large dose* of some antipyretic drug, and his temperature is suddenly reduced to a level which may be several degrees below the normal. Often this objectionable procedure is repeated in an almost rhythmical way for several days or weeks; and if, accompanying the fall of temperature thus produced there be a degree of prostration and feebleness of the heart which is alarming in itself, then, to counteract this bad symptom for which the drug and the doctor are responsible, alcoholic and other stimulants are given in large amount. This method of treatment, if it be proper to call that a *method* which seems to lack all true system—is often dignified by its advocates by the appellation *rational*. In fact, however, it would be difficult to devise a more irrational method than the symptomatic method, carried to its logical issue. It would be quite as proper to treat perityphlitis symptomatically as to treat typhoid fever so; and yet who would think of treating the constipation of perityphlitis by purgatives? Who would now think of withholding food or drink of proper kinds from a fever patient merely because he may prefer, having no appetite, to be left undisturbed rather than to take an adequate supply of nourishment at definite intervals? And yet, if we are to be guided simply by *symptoms* in the treatment of this disease, the presence of anorexia should lead us sometimes greatly to diminish, and sometimes totally to withhold, the supply of food.

Unfortuately, those of us, on the other hand, who believe in treating the disease upon some other and more definite system, are still very far from being in accord as to the best method to pursue in the average case.

In the uncertainty which still prevails in this branch of therapeutics, it would seem that any one possessed of any facts bearing upon the subject need offer no apology for presenting them to his brethren.

During the past year it has fallen to my lot to treat about fifty of these patients, chiefly in the New York Hospital and the Bellevue Hospital. It would be premature to say that results were due to treatment, inasmuch as this number of cases is very small, and also because the same method of treatment was not pursued in each case; but that the results followed the treatment, and that, all things considered, the results have been in the main satisfactory, seem to justify a brief publication of the general plans adopted.

That the severity of the type of fever prevailing in one year may differ greatly from the severity of the type of the next year, has often been noted. As the fever prevailed here last year it seemed to me to be of much less severe type than is usual in New York; and this year it seems to me to be fully up to the average degree of severity. It may, therefore, well be that good results, which in numerous cases attended the plan of treatment by intestinal antisepsis last year, are really to be explained by the fact that the disease which prevailed at that time was of an unusually mild type. The antiseptics which I used last year in the New York Hospital were *resorcin* and *beta-naphthol*. When patients entered the hospital sufficiently early in the disease, that is to say, within the first ten days, the routine method was to administer a calomel purge of ten grains, and then immediately to follow this drug by a dose of one of these antiseptics, which was repeated at varying intervals, day and night, as a rule, until the temperature became normal, and remained so.

When resorcin was used, it was given in the dose of five grains every four hours; when beta-naphthol was used, its dose was two grains, given every two, three, or four hours, depending upon its effects. These drugs were administered in pill form, and each pill was carefully coated with keratine, to insure it against changes to which it might have been subjected in the stomach. Thirty-three well-marked cases of this disease came under my care in this hospital last year, and of these, twenty-seven were treated antiseptically in one of the ways indicated.

But little use was made of any of the newer antipyretic drugs, though in some cases occasional doses of phenacetine were administered. This formed no part of the *plan of treatment*, and was ordinarily given only a few times when the temperature remained persistently high.

The effects of the antiseptics upon Ehrlich's reaction were interesting. This reaction, even though it might have been ever so plainly present when the patients began treatment (and it was so almost invariably), usually disappeared after the first few doses, and remained constantly absent while the drugs were given. In several cases, for experimental purposes, the drugs were stopped, and the reaction promptly returned, to disappear again when the administration of the drugs was resumed. Of unpleasant consequences of these drugs, I have to record the occurrence of blood, albumin, and casts in the urine in a few patients who took beta-naphthol. These symptoms were always looked upon as positive indications to discontinue the drug, and they disappeared promptly when it was stopped. Resorcin produced absolutely no unpleasant effects.

The effects upon the temperature and duration of the disease seemed sometimes quite unmistakable, and to be about the same in the cases of those who were taking either drug. In six cases the fever lasted seventeen days or less, in three it lasted only two weeks, and in nine cases the fever ceased entirely in just three weeks—all from the date of its commencement. In the other cases it lasted generally about four weeks, though in a few instances

it continued over four weeks and did not seem to be materially influenced by the treatment. In two of these it lasted five and six weeks respectively. Among this latter class, however, are included two cases which can hardly be said to have been subjected to this plan of treatment, for they died in one and two days respectively after the treatment was begun.

Of these twenty-seven patients five died; but of these one was under this treatment only one day, two others only two days, and a fourth only six days. Of these deaths, one was due to extensive ulceration of the colon with profuse and wasting diarrhœa; one to profuse hemorrhage; one to lobar pneumonia; and two to parenchymatous nephritis. These two latter were treated by beta-naphthol and resorcin, respectively one and six days. In consequence of its short duration the treatment could hardly be considered the cause of this grave symptom. The height of the fever seemed to be even more markedly affected than its duration, and the comfort of the patients was proportionately promoted. In most cases it did not rise above 103° F. after treatment was begun, and it ranged usually between 100° and 102°.

Twenty-two of the patients were males and five were females. All but seven were twenty-one years of age or older, and these seven were aged respectively eight, eleven, fourteen, sixteen, seventeen, eighteen, and nineteen years. The fatal cases were aged respectively seventeen, twenty-four, twenty-five, twenty-six, and thirty-five.

Milk was always the chief, and, usually, the only food, until the patients became *very hungry* shortly before the temperature became normal, at which time eggs, chops, or steak were allowed.

Excepting the complications mentioned in relation to those who died, but very few and chiefly insignificant complications occurred. There were but two relapses, and these were not serious.

Diarrhœa was present among the early symptoms in a majority of these patients, and it was usually well influenced by the drugs given without opium or other astringents.

The eruption was nearly always present, and was not affected by treatment.

Albuminuria was often present, but never became an alarming symptom, except in the cases of the two patients who died of nephritis after having been under treatment one and six days respectively.

Estimated by mortality percentage alone, this record cannot be claimed as a brilliant showing for intestinal antisepsis; and it may well be that further experience will lead us to abandon the hope of being able to attack this disease at the site of its most marked lesion; but, all things considered, the results are certainly better than those which have followed the expectant plan of treatment in any year in this hospital.

I desire to say that I have been greatly aided in the tabulation of these and other statistics of these cases by Drs. G. H. Cobb and H. A. Griffin, of the house staff.

It would be a source of great regret to me to give the impression that I consider this method of treatment as to be compared with the antipyretic method, *i. e.*, the antipyretic effect of cold water applied to the surface of the body.

It seems to me that any one at all open to conviction by statistics cannot but admit that the recent statistics of Brandt, as quoted by Professor H. C. Wood, of Philadelphia, in the recent edition of his text-book on *Therapeutics*, make a marvellously good showing for the cold water treatment. After reading these statistics it would seem as if all other plans of treatment were of insignificant value when compared with this one.

Unfortunately, however, two factors of vital importance in the treatment by cold baths seem likely always to be lacking here. The absence of these will probably always prevent our being able to save as large a proportion of patients ill with this disease as is now saved in Germany, and must reconcile us to our higher morality, although I firmly believe that our death-rate, even under existing unfavorable conditions, is needlessly high. I allude primarily to the fact, to which reference has already been made, that patients habitually come under observation and treatment later in the disease than is the case in Germany. It is well known that in Germany and Austria many patients are received into hospitals with various trifling maladies that would not be supposed to justify them in seeking hospital treatment here. Thus people acquire the habit of going to hospital upon comparatively slight provocation in general, and do not wait, as is so commonly the case here, until their illnesses become pronounced and severe. It is, I think, exceptional for us to see in hospital a patient in the prodromal stage of a typhoid fever, or even in the first few days of the pyretic period, except when we give him the disease in the hospital, as sometimes happens. This coming under treatment late deprives them of *some* chances of recovery, no matter what plan of treatment be adopted. The second misfortune which militates against our success in the treatment of this grave disease, is the unsatisfactory manner in which our hospitals are conducted. The shifting attendance of several doctors, each for a few months only in every year; the rapid changes by rotation in the house staff; the constant changes in the nursing force, and often the unsatisfactory character of the nursing; all these evils render it impossible for most physicians to carry out promptly,

efficiently, and with due regard to the exigencies of each case and on a large scale, any such thorough and systematic method as the cold water treatment of fevers. We cannot ourselves become thoroughly familiar with the method, and cannot, of course, properly train and discipline a shifting and temporary body of assistants and nurses.

In the face of these discouraging facts, I have lately been trying to accomplish the principle of Brandt to a certain extent by other means than the cold bath. We receive into Bellevue Hospital a considerable number of patients suffering from this disease. But they are recruited largely from the poorly fed, badly nourished, and intemperate classes, and they usually come under treatment late in the disease. Many of these patients do not bear the cold full-bath well. The depression which it causes seems to be too profound, and the reaction from it very slow.

Accordingly, I have been trying to keep the temperature of the patient constantly at or below 102° F. without the use of cold baths. This is often well accomplished by the *cold pack*, administered whenever the temperature rises above 102°, no matter how frequently it may need to be applied. Few even of this unpromising material do not bear this procedure well, and only occasionally is one encountered in whom the pack when properly applied is not capable of causing a prompt reduction of temperature. Occasionally a patient is met with whose temperature shows such a tendency to rise immediately after the pack as to render the repetition of the procedure necessary after but a brief interval. Under these circumstances I have found it desirable to combine the wet pack with the administration of a small dose of an antipyretic.

It is never desirable in this disease to give these drugs in the large doses which were in vogue when we first began to use them. Moreover, it is well to bear in mind that they are rapidly eliminated from the body, and that to be of continuing effect they must be given in small and frequent doses. No good is likely to result from an occasional large dose of them.

If, however, we use them in *small and frequent doses to supplement the effects of the cold pack*, I believe that they become of distinct value in the treatment of this disease.

Many patients whose fever is not controllable by cold packs alone respond promptly to a cold-pack *plus* five grains of antipyrin, the latter given as often as *every hour*. Both these should indeed be repeated as often as this while the tenperature continues above 102°.

It soon ceases to be necessary to repeat either at very short intervals, and after a few days the drug can usually be discontinued entirely and the frequency of the cold pack greatly diminished. The latter is rarely necessary oftener than four or five times in twenty-four hours.

Once in a while it happens that the packs are not well borne at the commencement, and the fall of temperature caused by them may be then not sufficient to justify their continuance.

In such cases I have found that a few doses of an antipyretic drug, just enough to cause the temperature to fall a few degrees, can be well followed by the combination of the packs and antipyrin, as already described.

This endeavor to carry out the principle of Brandt, in so far as it relates to keeping the temperature continuously low throughout the disease, is certainly worth a trial, and can be recommended to those whose clinical material and resources do not allow of the use of the cold full-bath. This is probably the most important principle involved in the antipyretic treatment of fevers, and experience has led me to believe that it will commend itself to all who apply it consistently *in any way* to a considerable number of cases. I have treated a few cases throughout their period of fever by the administration of five grains of antipyrin every hour, and a few others by giving small doses of sulphate of thallin every hour in the same way as long as the temperature remained above 102°. The elimination of these drugs is so rapid that there is no danger of a cumulative effect in using doses like these, and therefore no liability to sudden or great fall of temperature with cardiac depression.

At the same time, the increased heat diffusion is very great, and the general principle of Brandt of keeping the temperature continuously low can thus be carried out.

The cold-pack, however, for the average case that will not stand the cold bath is doubtless decidedly preferable to this plan.

In the past few weeks I have subjected eleven cases in Bellevue Hospital to treatment by the cold-pack, and with very gratifying results. The house physician, Dr. Painter, has kindly supplied me with data of these cases, taken from the hospital records. These patients all got well. They were all adults, only one as young as twenty years, and most of them made of the very poor material which seeks admission to our public hospitals in this city. In most of them the temperature was persistently high, and they came under treatment late in the disease —*i. e.*, after it had lasted between one and three weeks.

In a few instances the pack was kept up for fifty minutes, and ice was occasionally rubbed over the surface of the wet sheet which covered the patient. If, however, the method be persisted in, the patient being treated otherwise with care and discretion, it

is usually not long, not more than a few days, before the temperature will remain habitually below 102° in response to a single pack in a day, and that of only a few minutes' duration.

It is a matter of greater importance than is commonly supposed that these patients should not be kept too warmly covered in the intervals between the packs. It should be borne in mind that we wish to increase heat diffusion as much as possible, and that this is to be promoted directly in proportion to the thinness and conductivity of the patient's covering. Under no circumstances should a fever patient have any more covering than due regard to his comfort renders necessary; and his unaided sensations are not always a safe guide. In his obtuse condition he often thinks that he wants several blankets, when a little gentle persuasion will lead him to believe that he really needs but one.

On the whole, the method of treatment by the cold-pack has been more gratifying to me than that by the internal use of antiseptics: but I wish again to emphasize the importance of using it systematically and so frequently as to keep the temperature always below 102°.

CLINICAL MEMORANDA.

SURGICAL.

Two Cases of Excision of the Wrist-joint.—The comparative rarity of the operation of excision in cases of disease of the wrist-joint so extensive that a removal of the entire articulation is necessary, the prevalent idea as to the danger entailed by the operation, and the scepticism with which many surgeons regard the possibility of preserving a useful hand after a complete resection of the wrist, have induced me to place on record the following cases upon whom I performed this operation.

CASE I.—B. P., widow, æt. forty-eight, a cook by occupation. Both parents, four sisters, three uncles, husband, and one child died of pulmonary consumption. Has always been remarkably well and strong with the exception of an attack of rheumatism of the knees and ankle ten years ago; from this she suffered much pain for several weeks but was not disabled. Three years ago, when much fatigued and overheated, she wrung out a number of towels which had been soaking in ice-cold water. Her right wrist pained her through the night and was stiff next morning. This stiffness shortly wore away with use, but returned again at night together with sharp cutting pains which disturbed her sleep. In three months her hand became so stiff, painful, and weak that she had to give up work. Since that time the local condition has gradually become worse, there has been a progressive swelling of the joint, the pains at night have been intolerable, the hand has become absolutely useless, and there has been a serious deterioration in her general health.

Admitted to Philadelphia Hospital, July 16, 1889. The hand was held rigidly between flexion and extension; the fingers were extended, swollen and stiff; the thumb could be moved slightly. The muscles of the forearm were greatly atrophied and the anatomical points of the wrist were marked by an obscurely fluctuating, very tender, fusiform swelling, most marked upon the dorsal aspect of the joint. The styloid process of the ulna was prominent, the corresponding bony point of the radius could be found with difficulty.

Tonics, splints, pressure, and extension, together with local applications, were tried for one month, but produced no effect upon either the pain or swelling. The patient was willing to submit to any measure which would afford her a chance of relief.

August 16th, the joint was excised; a single long dorso-radial incision, beginning an inch and a half from the articular extremity of the radius and running obliquely downward to the middle of the metacarpal bone of the index finger was made into the joint. Caries and suppuration had already begun, and had involved the articulation so extensively that complete excision was necessary. All the carpal bones were removed, and the diseased articular surfaces of the radius, ulna, and metacarpal bones were cut away by means of the metacarpal saw and bone- forceps, and the diseased synovial membrane was carefully dissected out with knife and scissors. A tourniquet was not used; the tendon of the extensor carpi radialis was the only one divided, and but a single vessel required ligation. A counter-opening was made in front of the wrist, a drainage-tube was pushed through, the large cavity left by the removal of so much bone was packed with iodoform gauze, and after a careful antiseptic dressing the hand was placed on a Bond splint.

The operation lasted nearly an hour, and at its close the patient's temperature was 96.4°. She reacted quickly and pursued a typical apyretic course to complete healing. Passive motion of the fingers was begun the day following the operation. In two weeks the Bond splint was replaced by a light metal splint allowing more freedom of motion, the arm was rubbed and faradized daily, and the patient was encouraged to use the hand as much as possible.

At the present writing, three months from the time of operation, this patient has a useful hand and one entirely free from pain. She can pronate and supinate, slightly flex and extend all the fingers, oppose the thumb, and has resumed her sewing. A great part of her remaining disability is due to the pronounced muscular atrophy, which, in time, will probably disappear.

CASE II.—M., æt. twenty-eight, housewife, of dissolute habits. Was bitten in the hand while fighting with a woman. Very violent inflammation followed, involving the tissues beneath the palmar fascia. Fearing that she would be "cut" she refused to see a doctor for two weeks, when the extension of the swelling of the forearm induced her to apply to the Howard Hospital for relief. An examination showed that there was a purulent infiltration not only of the sub-palmar structures, but also of the wrist-joint. The parts were freely incised, irrigated and drained, and the hand was put upon a palmar splint. This promised well for a time, but the patient persisting in the free use of alcohol, suppuration became very profuse, the pus showed a tendency to infiltrate the forearm, and marked symptoms of absorption developed. Amputation was strongly advised but absolutely rejected by the patient. Excision was

then suggested, and to this she consented. The radial and ulnar incisions of Lister were made, and the extremities of the radius and ulna, all the carpal bones, the necrosed metacarpal bone of the thumb, half the metacarpal bone of the index finger, and the articulating extremities of the remaining metacarpal bones were removed. All the suppurating area which could be reached was curetted, the wounds were freely drained, and antiseptic dressings and a Bond splint were applied. The night following this operation the patient was intoxicated; the following night she had some difficulty with her friends, and rising from her bed cleared the room of them, using her splinted arm as a weapon. Suppuration followed this, and amputation being still refused, bichloride irrigation 1:1000 was continued for three weeks, vent being given to the pus by frequent incisions. At the end of this time an opening made in the palm for the evacuation of a fresh collection of purulent matter showed that the flexor tendons of the index and middle fingers were sloughing, and the patient at last consented to an amputation. She subsequently regained her health completely. An examination of the amputated hand and wrist showed that the seat of excision was filled in with newly formed fibrous tissue, and that a continuance of the suppurative process was caused by necrosis of the second and third metacarpal bones.

In the first case the stiff and useless hand held in very slight extension with fingers straight, the tender, obscurely fluctuating, fusiform swelling, not accompanied by obvious heat or redness and of several years' duration, the steady progress of all bad symptoms in spite of very careful and long-continued treatment, and the distinct tubercular element in the family of the patient on both the mother's and father's side, made the diagnosis of tubercular arthritis almost positive.

For three years before her entrance to the Philadelphia Hospital she had been under almost constant medical treatment. She had taken large doses of anti-rheumatics for long periods of time, had been frequently blistered and counter-irritated locally, the wrist had been thoroughly manipulated (a most dangerous practice in these cases) mercury and belladonna ointments, equal parts of each, iodoform ointment, splints, pressure bandage, and finally ichthyol ointment, 50 per cent. in lard, extension, and the plaster-of-Paris bandage, had all been tried. The constant and wearing pain, the impairment in general health, the failure of palliative measures, and the tubercular family history were the factors which called for a prompt operation. The family history was of especial importance in the case, since the fact that wrist-joint tuberculosis is particularly liable to become disseminated is well recognized. The excision was accomplished through a single incision, but not so readily or quickly as in the case where the two incisions of Lister were employed. There is no objection to be urged against the additional opening over the inner and anterior aspect of the joint. The packing of the cavity with iodoform gauze is, in view of the antitubercular effect of iodoform, to be particularly commended; and a most important factor in the favorable treatment of this case was, I think, the persistent passive motion which was begun the day following the operation.

The second case is illustrative of a class to which resection is not adapted: the bone disease was so extensive that entire removal down to healthy tissue would necessarily have left a flail-like hand. Since several of the metacarpals were involved along the greater part of their shafts, the inflammatory action in the hand had already been so widespread that nothing better than absolute fixation of all the flexor tendons could be looked for. The joint was removed in this case simply as a means of lessening the suppurating area.

The operation of wrist excision is tedious but not difficult; no important bloodvessels and but one tendon are cut. To diminish the space between the metacarpals and the forearm bones after the operation, I should in another case be inclined to adopt the method of Lauenstein, who, after operating in the usual way through the long dorso-radial cut, sutures his wound transversely, thus not only bringing the hand and forearm nearer together, but also placing the latter in the position of extension, a very distinct advantage from the standpoint of future utility. EDWARD MARTIN, M.D.

An Analysis of Nine Cases of Penetrating Stab-wounds of the Abdomen Treated by Laparotomy.—Laparotomy for traumatism is daily becoming such an important factor and such a universally recognized method of procedure in modern surgical operations that it needs neither eulogy nor defence. The rule seems well established, that in cases in which penetration of the peritoneal cavity has occurred abdominal incision should be promptly done, and the viscera carefully examined. If the intestines or stomach be wounded, rectal injections of hydrogen usually demonstrate the existence of the lesion prior to operation; but that cannot always be relied upon, unless used with great skill, for I have seen it fail from want of skilful manipulation, and that too in a case which, upon subsequent section, disclosed a large ragged wound extending directly through the stomach. Should hydrogen injections give assurance of no intestinal injury, an "exploratory" incision may be necessary to determine the existence of other visceral lesions or internal hemorrhage. By this means the latter can be checked, and foreign substances, as clothing and clots, washed out. Nor does this seriously complicate an already grave state.

The conditions existing in a case in which operation is necessitated as the result of traumatism are usually the most unfavorable, and exactly the contrary to those present when disease compels surgical interference. In a series of nine cases of penetrating stab-wounds of the abdomen treated in the Pennsylvania Hospital during a portion of my term as surgical resident, an analysis reveals the following conditions: Six of the patients were intoxicated upon admission. Seven received their wounds in fights, and five of this seven had various other injuries accompanying the stab. Three had more than one penetration, and eight had more or less visceral injury. Shock, generally profound, sometimes amounting to collapse, was present in all but one case, and was undoubtedly in a great measure due to internal hemorrhage in six patients at least. Death supervened in six cases from shock, exhaustion, or delirium tremens. Operation was promptly performed in all cases, four hours being the longest time between the reception of the wound and operation.

The *modus operandi* adopted in the treatment was practically the same throughout. Intestinal wounds were sutured with fine silk or catgut. Hot distilled water irrigation, with glass-drains, was commonly employed.

Peritoneum, muscles, and skin were included in each suture, and full antiseptic dressings finally applied. Drainage-tubes were kept clean by frequent emptying with a hard-rubber syringe and a stilette armed with absorbent cotton. Liquids were given sparingly by the mouth, stimulants being administered hypodermatically. Opium was but rarely used.

The large percentage of deaths was due, it seems to me, to several causes. Most of the patients admitted that they were steady, hard drinkers. Several were Italians, whose physical condition was by no means the best, nor were they, as a rule, able to bear with any degree of fortitude the pain necessarily entailed. All were in a condition of shock, from which some did not react before the time when it was deemed best to operate. In several great handling and exposure of the intestines were necessary, both to locate perforations and bleeding points. Ether nausea was common, and at times persistent. Tympany was usually an obstinate symptom. The complications were wounds of the bladder, the liver, the kidney, and the lung.

In a series of such severe cases we naturally expect a high mortality, but I cannot conceive that *any* of the above could have recovered without operation, and do not believe that the operation in itself contributed to the number of deaths. WALTER D. GREEN, M.D.

A Case of Strangulated Inguinal Hernia, the Protrusion being Epiploic Appendices—Radical Operation—Recovery.—The following case, although not unique, presents, I think, one or two points of interest, for which reason it is placed on record.

F. C., aged forty-four, a glass-blower, the subject of a left inguinal hernia, for which he had worn a truss for some years, was admitted to my wards in the Episcopal Hospital at midnight on the 8th of July, his rupture having come down about twenty-four hours previously and having resisted his usual manipulations to reduce it. At the time of admission the hernial tumor was found by the resident physician, Dr. B. B. Reath, Jr., to be tensely swollen, and efforts at taxis tried to the limit of safety were unsuccessful. There was no general or constitutional sign of strangulation, although there was considerable local pain. The patient was put to bed, a dose of opium given, the thigh placed in the position most favorable to relax the part, and an ice-bag laid upon the swelling. When I first saw the patient, at my visit at noon on the 9th of July, or twelve hours after his admission, the local tenderness had increased somewhat, and there was general abdominal pain, the features were becoming pinched and the countenance anxious. There was no vomiting, and there had been an evacuation of the bowels since the rupture had come down. A gentle trial of taxis convinced me that nothing could be accomplished in that way, and I decided to operate at once, and obtained the patient's ready consent. Making an incision the full length of the tumor, the upper angle being over the position of the internal abdominal ring, where the constriction could plainly be felt through the tissues, the sac was speedily exposed, and, my intention being to make the operation radical, I carefully separated it from the spermatic cord—a task that was far from easy, not only because of numerous adhesions but also because the sac was irregular, or sacculated in shape. The separation accomplished, I carefully opened the sac, giving exit to a considerable amount of blood-stained serum, and investigated the nature and condition of the contents. At first I supposed what I saw to be a small portion of the great omentum—an epiplocele—but I afterward discovered that it was two epiploic appendices, deeply congested and firmly matted together. The colon to which the appendices were attached was held firmly at, and was partly pinched by the mouth of the sac. Ligatures were applied to the two appendices, and they were cut off, and a third one which came into view within the ring was similarly treated. A strong silk ligature was applied to the neck of the sac, my finger being within it and guarding the ring while the knots were tied. The sac was then cut off, and the stump secured by stitches to the muscular tissue above the internal ring. Drainage was provided for by several strands of catgut brought out at the upper angle of the wound, and a small drainage-tube at the lower angle. Stitches were then carried through the muscles and the aponeurosis above, and Poupart's ligament below, and the canal so closed, and the lips of the wound brought together with superficial sutures.

The progress of the case was excellent, save for a rise of temperature in the evenings of the fourth and fifth days, to 103°, due to constipation, on relief of which it fell to normal and so remained throughout. On the eighth day the drain-tube and the superficial silk stitches were removed, and healing appeared to be about established. At the end of the second week the upper angle of the incision broke down and gave exit to a few drops of pus, and in a few days the ligature which had surrounded the neck of the sac came away, a deep ulcer being left over the position of the internal ring, and communicating with a sinus running beneath the superficial fascia nearly the whole length of the inguinal canal. Healing took place gradually, by granulation, the patient being kept in bed until it was complete, altogether about eight weeks. At the end of ten weeks he was discharged with a firm cicatrix.

This is the second case in which I have been disappointed by failure to secure thorough and rapid healing after closing the wound in the manner above described. In both, the integument healed speedily but soon broke down, and, after all, cicatrization by granulation took place. I am now inclined to look upon this as desirable, and as leading to a firmer cicatrix than that which results from primary union. The operation of McBurney is, I am satisfied, the most rational, and holds out the best promise of permanent cure.

The length of time the patient should be kept in the recumbent posture is a point of the first importance. He should not be allowed to get up until healing is *complete*, nor in any case in less than six weeks. This is the rule I follow.

THOMAS R. NEILSON, M.D.

A London Polyclinic.—A system of post-graduate instruction has, for the first time, been inaugurated in London, under the presidency of Mr. Jonathan Hutchinson. The secretary of the first course may be addressed at No. 60 Welbeck Street, West. An abundance of clinical opportunities, hitherto unused, will be available to those associated with the new school.

HOSPITAL NOTES.

THE TREATMENT OF SIMPLE PYLORIC STENOSIS BY GASTRO-ENTEROSTOMY (BY ABBE'S RINGS), RATHER THAN BY LORETA'S STRETCHING OPERATION.

Abstract of a Clinical Lecture, Delivered at the New York Hospital, December 5, 1889.

BY ROBERT F. WEIR, M.D.,
ATTENDING SURGEON.

DR. WEIR, at his clinic at the New York Hospital, performed the above operation by means of Abbe's catgut rings, on a patient aged forty-one, whose symptoms of vomiting and emaciation had lasted nearly two years. Only once had blood been vomited, and this, with the duration of the case and the absence of a perceptible tumor even when examined under anæsthesia, together with the continuance of hydrochloric acid in tested meals, led to the conclusion that the stenosis was non-malignant, and that it was possibly due to the contraction of an ulcer. The distention of the stomach was great; it held eight pints of fluid, at which time it could be felt three inches below the umbilicus. Ewald's salol test revealed the decisive discoloration only one and a half hours after ingestion of the drug. The patient's weight was 104 pounds.

The operator presented to the class, at some length, his reasons for the choice of gastro-enterostomy on the patient then before them, and gave a rapid review of the various methods resorted to in the treatment of pyloric disease by operation. He cited the fact that in the eighty-one cases of pyloric resection with sixty-one deaths collected by Winslow, there were reported six cases in which this operation was performed for non-malignant disease of the pylorus—in three of these cases, however, death resulted. The mortality of resection alone must throw it out of consideration, and resection of the pylorus, as at present conducted, is an operation without much future, unless intestinal anastomosis done with plates or rings may so far shorten the operation as to diminish its risk. An allusion was here made to Billroth's celebrated case of resection of a cancerous pylorus with turning in the ends of the duodenum and stomach, making them thus blind cul-de-sacs and the opening between the two being subsequently effected by a gastro-enterostomy. This operation appeared to him, with the use of anastomostic plates or rings, to be better than the one now in vogue. Heinecke's pyloroplasty was described, but was not considered as applicable in this instance, being more fitted for ulceration with hemorrhage. Loreta's operation of incising the stomach and stretching the pylorus was then detailed, and the cases collected by Drs. Bull and Barton, who have each recently reported a success in the operation, were analyzed. Out of the twenty-five operations of this kind that have been collected, there were ten deaths or forty per cent. of mortality, a rate not altogether due, as some might justly think, to the inexperience of the operator—for Loreta himself, in 1887 and 1888, resorted to this procedure seven times with two deaths. This mortality was very high, and even though brought down in the last twelve published cases to 25 per cent., it presented such a risk, that if another way of accomplishing the same thing could be found it should, of course, be used. The re-contraction that follows or may follow the operation of stretching, though much less than was expected from the analogy of strictures thus treated elsewhere, must not be cast entirely aside from the consideration of this part of the subject. Loreta himself had encountered the re-contraction three times, in two of which a second operation was resorted to. However, it may be said in behalf of the stretching operation that one of the causes of death, to wit, hemorrhage, and, perhaps, others, can be avoided not only by more gradually conducting the dilatation, but also by refraining from stretching the pylorus as far as Loreta directs, as it is becoming apparent that this has been carried to a too great degree, and that a separation of two inches attained by the surgeon will suffice, instead of three inches, as Loreta advised. The fact of this stenosis being sometimes a prodrome of malignancy should also be borne in mind.

Reverting, however, to the mortality of the operation itself, an investigation of the results of gastro-enterostomy in the non-malignant strictures of the pylorus has shown sufficient evidence of the superiority of this operation in the latter respect to warrant its further adoption. Rockwitz, for instance, has given in his collection of 29 gastro-enterostomies 7 cases (to which can be added 1 of Mikulicz's and 1 of Hahn's, or 9 in all) where this operation was resorted to, in non-malignant stenosis, with but 1 death—that is to say, with but 11 per cent. of mortality. These operations were done under the old method, requiring on an average from two to two and one-half hours for their performance and the insertion of sixty to eighty stitches. It was also proven by these operations that the nutritive conditions were amply preserved in a successful gastro-enterostomy, and that the necessary interference with the flow of food material from the stomach to the point where the small intestine had been tapped resulted in no evil. The mortality of gastro-enterostomy for cancerous stenosis was then presented to lend proper force to the clinching of the argument brought forward. It amounted in twenty-four cases to 42 per cent.

Since Senn, of Milwaukee, has taught the use of decalcified bone-plates to secure, with the least amount of suturing, the apposed peritoneal surfaces when an opening is to be made between two portions of an intestine, or, as now in point, between the stomach and the intestine, time, so largely important in abdominal operations, is greatly saved. Under this method, or some modification of its technique, and notably in the material with which the opposing plates have been made, eleven cases of gastro-enterostomy for cancer have been reported, and with the remarkable result of but one death (McBurney's case), where the operation was resorted to when the patient was nearly moribund, or a mortality a little over 9 per cent Remarkable, because it is to be contrasted with the 42 per cent. from the old operation. Even a better result is to be expected in the less deteriorated condition of a patient suffering from starvation alone, as in a simple stenosis, and not starvation and disease combined, as in a cancerous stenosis.

Dr. Weir's operation was done under ether, the stomach having been previously, and for several days, washed

out with a boro-salicylic solution, and the peritoneum opened by a four inch median incision running from the umbilicus upward. As soon as the peritoneal cavity was reached, the finger and thumb of the right hand were introduced, the omentum and large intestine pushed up out of the way, and the vertebral column felt for, which guided to the pancreas, and thence passing from right to left, the end of the jejunum was hoped to have been seized as Hahn suggests. But this endeavor was not crowned by success, which apparently justified the statement of Luca, based on his experience of eight cases, that it was more often missed than secured by this procedure. So the advice of the last-named surgeon was followed, not to delay long in searching for the required portion of the bowel, but to draw out a loop of intestine, and either by comparing the two ends of the same and following the smaller portion, or by applying Nothnagel's salt test with its ascending peristalsis, and acting accordingly. Both the methods failed, and the predetermined intent of the operator not to spend much time in this search, nor to disturb the parts to any great extent, was carried out, and the plan practised with success (of eight cases and one death) by the same surgeon, of seizing any loop of small intestine with a long enough mesentery, to allow of easy apposition to the wall of the stomach, was followed. The loop was withdrawn from the peritoneal cavity, and also a portion of the stomach close to the gastro-colic fold. The two peritoneal surfaces were first sewn together by a continued silk suture, to correspond to the posterior edge of the catgut rings when inserted, as after the application of the rings this suturing would be more difficult to accomplish. The small intestine was then opened opposite the mesenteric attachment for a distance of two inches, the hemorrhage was arrested by temporary clamp pressure, and an elongated Abbe's ring inserted and held *in situ* by six sutures carried through the wall of the bowel about one-quarter of an inch from the incised edge. The stomach was then opened to a corresponding extent, nearly four inches from the pylorus (a little further from this point than was intended), and its ring similarly introduced and fixed *in situ*, and the various sutures tied in pairs, beginning with those on the deepest side and alongside the first applied row of peritoneal sutures. Finally, a continued suture, beginning where the last one left off, was carried around the anterior surface, and secured everything tight and snug.

This secondary suture was of value in two ways. At one place the rings failed to hold in the inverted peritoneum and showed the divided mucous membrane, which condition has been occasionally noticed in the use of the broader decalcified bone plates. The outer stitching remedied this at once. Furthermore, the stitching was carried some distance beyond the line of the included rings, especially toward the pylorus in order to aid in preventing the formation of a spur in the small intestine as it dragged downward. The opening was made purposely large to avoid ill effects should such a spur be formed. The examination made outside the stomach during the rapid search for the pancreas showed a moderately enlarged hard pylorus and from within the viscus its opening was about the size of a lead-pencil and of a gristly feeling. The operation from the opening to the closing of the peritoneum took thirty-five minutes. Total time forty-five minutes—from skin incision to closure of the same. At the end of the operation patient was in good condition. During the operation only the loop of intestine and the portion of stomach were outside the abdominal wall, the peritoneal cavity being shut off by antiseptic compresses and sponges.

NOTE BY DR. WEIR.—December 10th—five days after the operation—the patient's progress has been very satisfactory, only disturbed for a few hours at the end of first day by the appearance of albumin and sugar in large quantities in the urine. Neither had been found at various testings prior to the operation. These disappeared, the sugar first, in the next twenty-four hours. This may have been due to the anæsthesia, which I strongly doubt, or to the handling of the pancreas and left kidney, or possibly of the solar plexus. He began on the third day drinking water and beef-tea freely, the nourishment being aided by rectal enemata of peptonized milk and whiskey. Since then peptonized milk and raw eggs well beaten have been allowed him. A recovery seems assured.

MEDICAL PROGRESS.

Hypodermatic Injections of Salt Solution in Hemorrhage.—In the Dresden Lying-in Hospital the plan of introducing a large quantity of a solution of common salt under the skin has been employed with success in several cases of severe post-partum hemorrhage. The solution is of the strength of 0.6 per cent. (sixteen grains in a pint), and the quantity injected is somewhat less than a quart. The spots selected for the injection are the infra-clavicular and the infra-scapular regions. During the operation the swelling produced under the skin must be manipulated by a shampooing movement so as to disperse the liquid as much as possible. The water with which the solution is made must be sterilized by being well boiled. The advantage of the plan is that it can be easily carried out by any medical man, as it is far less difficult than transfusion and less dangerous. DR. MÜNCHMEYER considers the plan so suitable for private midwifery practice that he suggests that a little apparatus, which is made on purpose for it, should always be carried in the obstetric bag, together with the proper quantity of common salt. Boiled water can always be procured, and this, when cooled down to the temperature of the body, 98.6° F., will do very well, though in the hospital he employs a more carefully sterilized solution.—*Lancet*, November 16, 1889.

Removal of Gunpowder Stains.—According to the *Peoria Medical Monthly*, stains produced by the explosion of gunpowder may be removed by first painting the skin with a solution of biniodide of ammonium in an equal part of distilled water, then with dilute hydrochloric acid.

Insufflation for Whooping-cough.—

Pulverized benzoin	. . .	10 grains.
Salicylate of bismuth	. . .	10 "
Sulphate of quinine	. . .	2 " —M.

A pinch of this may be insufflated into the nasal cavities every few hours.—*Lyon Médicale.*

Pills for Metrorrhagia.—

Pulverized ergot	75 grains.
Subcarbonate of iron	75 "
Sulphate of quinine	15 "
Extract of digitalis	7 "

Mix and make into fifty pills, of which two may be taken three times daily.—*L' Union Médicale*, Nov. 7, 1889.

Parasiticide Ointment.—

Salicylate of mercury	16 grains.
Vaseline	1 ounce.—M.

This makes not only an excellent ointment against the parasitic skin diseases, but against eczema, pityriasis, and syphilitic vegetations.—*L' Union Médicale*, Nov. 7, 1889.

Prescription for Toothache.—

Arsenious acid	15 grains.
Muriate of cocaine	15 "
Crystallized menthol	3½ "
Glycerin	2 drachms.—M.

A pledget of cotton moistened with this and placed in the cavity of the tooth will quickly check the pain.—*L' Union Médicale.*

Treatment of the Acute Stage of Eczema.—In the *Practitioner*, DR. MACKINTOSH makes some valuable suggestions on the treatment of eczema in the earlier stages. The first thing to insist upon is that the patient must not wash the affected part at all, though in eczema of the head and face the corners of the eyes and angles of the mouth may be touched lightly with a small piece of soft sponge made damp with cold water and immediately dabbed dry. Coffee, strong tea, and alcoholic drinks should be forbidden. The second essential is to keep the bowels freely open. In the case of children, mercury with chalk, rhubarb, and bicarbonate of sodium, a grain of each, taken as required every second or third night, will answer every purpose. In adults, salines hold the first rank, and sulphate of magnesium is by far the best of all purgatives. Three drachms should be taken an hour before breakfast, though it often acts as well if taken one hour before any other meal. The great desideratum is an appropriate external application, and the following acts in many cases with marked rapidity:

Subnitrate of bismuth	℥ij.
Oxide of zinc	℥ss.
Carbolic acid	♏ xij.
Glycerin	℥jss.
White vaseline	℥vj.—M.

If there are much tingling and irritation at night, the following will be found useful, applied with a camel's-hair brush:

Subnitrate of bismuth	℥j.
Carbolic acid	♏xij.
Glycerin	℥iv.
Rose water	℥iv.—M.

—*London Medical Recorder*, November 20, 1889.

The Treatment of Herpes Zoster.—DR. DUPAS, of Lille, recommends, for the abortive treatment of herpes, the application of ninety per cent. alcohol, or a solution either of two parts of resorcin, one part of thymol, three parts of menthol, or two parts of tannin, in one hundred parts of ninety per cent. alcohol. A compress should be saturated with one of the solutions, bound upon the diseased part, and covered with an impermeable material. The dressing should be frequently renewed. If either of the above solutions is painful, cocaine may be added. Under these applications the element of pain is diminished often in a few hours. If the disease has already reached the stage of suppuration, the vesico-pustules and pustules dry up rapidly, and no new ones appear.—*Journal of Cutaneous and Genito-Urinary Diseases*, December, 1889.

Solution for Blepharitis.—

Sulphate of zinc	15 grains.
Rose water	2 fluidounces.
Distilled water	5 " —M.

A compress of soft linen or a small sponge is to be soaked in this solution and placed over the affected eye. —*L' Union Médicale.*

Prescription for Acne.—

Naphthol	10 parts.
Precipitated sulphur	50 "
Lanolin	25 "
Green soap	25 " —M.

This should be thinly spread upon the skin, rubbed off in fifteen minutes, and the part dusted with talc.—*London Medical Recorder*, November 20, 1889.

Prescription for Scabies.—The following mixture is recommended as an efficient application in scabies:

Creolin	1 part.
Peruvian balsam	20 parts.

—*London Medical Recorder*, November 20, 1889.

The Treatment of Endometritis.—The local treatment usually adopted by Dr. Mundé in endometritis without hyperplasia of the mucous membrane is as follows: If necessary, the os is dilated; the cavity of the uterus is then thoroughly mopped with a 50 per cent. solution of chloride of zinc, the applicator being introduced several times in order that no portion of the endometrium may escape cauterization. A cotton plug covered with vaseline is then inserted into the uterine cavity, and an iodoform tampon placed over the cervix. After this the patient is put to bed, with an ice-bag upon the hypogastrium. In two days she is allowed to get up, the tampons are removed from the uterus and vagina, and lukewarm douches of a 2 per cent. carbolic solution given twice daily. In a week or ten days, the sloughs having separated from the endometrium, an application of chloride of zinc solution, 20 grains to the ounce, is again made to the cavity. The carbolized douches are continued, and when the discharge decreases in amount, gelatine-coated pencils, containing 5 grains each of iodoform and alum, are inserted into the uterus.—*Annals of Gynæcology*, November, 1889.

Iodoform Gauze in Post-partum Hemorrhage.—Dr. O. Piering, assistant in Prof. Schauta's obstetric clinic in Prague, has published his experience in the employment of Dührssen's plan of plugging the uterus with iodoform gauze for post-partum hemorrhage due to an atonic condition of the organ. Dührssen recommends that, when

post-partum hemorrhage comes on, the bladder should be emptied, and forcible friction, intra-uterine irrigation with hot or cold water, and hypodermatics of ergotin employed; that if the hemorrhage still continues, the cavity of the uterus should be filled with iodoform gauze, the irritation produced by this setting up active and permanent contraction. The method has, according to Dührssen, the advantages of great certainty, complete harmlessness and facility in its performance. Olshausen, Veit, and Tehling, however, say that the contraction set up is not always permanent, and that the method is not so free from danger as Dührssen believes. In consequence of these conflicting views, Dr. Piering resolved to give the method a trial, and he has recently detailed several cases in which it was employed with complete success. In no case was harm done by it. He advises that resort to the plug should not be too long delayed, and prophesies an important future for iodoform gauze in post-partum hemorrhage.—*Lancet*, Nov. 9, 1889.

Treatment of Tuberculosis of the Testicle.—DR. VERNEUIL, in the *Annales d' Orthopèdie*, states his belief that iodoform inhibits the development of tuberculosis, and his experience leads him to think that the removal of one testicle often gives an impetus to the disease, and causes it immediately to attack the other. He therefore reserves the extirpation of the testicles for cases in which the lesions are in an advanced stage. In less severe cases he prefers interstitial cauterizations, and searches for the nodules, which he pierces with a pointed thermo-cautery. Into the cavities thus produced he inserts a pencil of iodoform which is allowed to remain. He considers that this method of treatment gives satisfactory results, and rarely excites any increase of the diseased action. It also saves the testicle, or at least appears to do so, and many patients attach great importance to the preservation of their sexual organs. It is not uncommon for castration to be followed by suicidal ideas.—*Provincial Medical Journal*, November, 1889.

Bromoform in Whooping-cough.—DR. STEPP, of Nürnburg, publishes in the *Deutsche medizinische Wochenschrift* his results in the treatment of pertussis with bromoform. The drug has, according to the author, no ill effects, and his numerous observations have proved that, as used by him, it is non-poisonous, and that the pulse and temperature remain unaffected by it. Children are ordered from five to twenty drops during the twenty-four hours in very frequent doses. The solubility of bromoform in water being very slight, the mixture requires the addition of alcohol. Stepp has administered bromoform in about sixty-five cases of whooping-cough, the children ranging in age from six months to seven years. The longest time required for a complete cure was four weeks. Symptoms of pulmonary catarrh in all these cases were entirely absent, or else were slight and soon disappeared. No complications existed in any of the cases observed by the author, but Dr. Goldschmidt has treated several serious cases of whooping-cough complicated with pneumonia, completely curing them in a fortnight by the daily administration of bromoform. Dr. Stepp concludes from his observations that under bromoform treatment bronchial catarrh and lobular pneumonia do not generally occur, and that where they exist at the commencement of the treatment, resolution takes place at an earlier period than under other methods of treatment. His observations show also that the dose of bromoform must be in direct proportion to the severity of the affection and the age of the patient. The system does not seem to become accustomed to the drug, which has, moreover, considerable prophylactic power, so that the other children of a family in which whooping-cough in an advanced stage already exists can be shielded from the disease by being given bromoform. *Therapeutic Gazette*, November 15, 1889.

The Staining of Gonococci.—A useful method of staining gonococci, as described in the *Medical Press and Circular*, is as follows: "After the cover-glass is spread with a thin layer of the suspected substance, it is passed three times through a flame. It is then allowed to remain from five to ten minutes in a saturated solution of methyl-blue in carbolized water, after which it is washed in pure water, and dipped for a moment in a weak solution of acetic acid (dilute acetic acid five minims; distilled water five and a half drachms), and again washed in water. As the acetic-acid solution decolorizes other organisms more rapidly than the gonococci, the latter will remain a distinct blue.—*Medical Record*, November 23, 1889.

Chloroform Water in Whooping-cough.—DR. SCHILLING has recently treated sixty-one cases of whooping-cough with inhalations of chloroform water, after the method of Salkowski, his results being excellent. The patients varied in age from ten weeks to twelve years. His methods and results are thus described: Into the boiler of a steam atomizer is placed one tablespoonful of water to which are added two drops of pure chloroform for each year of the child's age. The inhalations are practised four times daily, each inhalation being continued until the solution is entirely vaporized. If there is no improvement by the eighth day, the chloroform is increased to three drops for each year of the patient. In most cases the disease ceases to progress after a few days of treatment, and by the eighth day the patient begins to improve. Nearly one-half of his cases lost the convulsive element of the disease in about two weeks, or, more accurately, four cases terminated favorably in one week, twenty-eight in two weeks, twenty-one in three weeks, and eight in four weeks. His former experiments with inhalations of carbolic acid gave much less satisfactory results. Antipyrin he has found of use in some cases but valueless in many more.—*Therap. Monatshefte*, October, 1889.

Explosive Mixtures.—PROFESSOR ROBERT calls attention to the following explosive mixtures: Chlorate of potash mixed with charcoal dentifrice powder may explode, even in the mouth. Chlorate of potash mixed with catechu, or with tannin, explodes with friction, even if glycerin is added. Chlorate of potash and phosphate of sodium explode while mixing the powder. One part of chromic acid mixed with two parts of glycerin explodes immediately. Iodine and ammonia should never be mixed together, as they are extremely apt to explode. Bromine and alcohol, forming the bromide of ethyl, often explode. Picric acid, reduced to powder, explodes when mixed with any other substance.—*Weekly Medical Review*, November 16, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

THE CO-EDUCATION OF THE SEXES.

WE present to our readers in the present number of THE NEWS the carefully thought-out opinions of several eminent gynecologists and neurologists upon this important subject. These expressions of opinion have been obtained in response to a series of questions; they therefore contain the views of the writers arranged in a systematic manner, and nearly in parallel lines of treatment. But the conclusions are strangely at variance. They represent, in point of fact, every shade of opinion from a reasonable advocacy, through hesitating and qualified endorsement, to strenuous opposition. As the subject is, in its present phase and notwithstanding much tentative work already done, a new one to many earnest thinkers, this want of agreement among men well qualified by professional training and broad experience to discuss it, is of peculiar value as indicating the necessity for deliberate consideration on the part of those now active in the movement in favor of co-education in institutions devoted to the higher general and technical training. It shows that there is much to be honestly said upon both sides of the question. Bitter partisanship in a cause like this is, on the one hand, a waste of energy; while, on the other, a narrow conservatism cannot long retard, much less arrest, the progress of that social evolution which to-day leads the van of civilization. What is now most needed, is reform within educational institutions; the elimination of injurious traditional methods, such as the cramming system, competitive examination, grinding routine which neither recognizes nor makes allowances for differences of capacity and temperament among students, and the bettering of the means by which the student and the instructor may be brought into closer personal relationship, with the advantage to the former of having that which is best in him developed, and that which is wrong set right, and to the latter the advantage of doing work of a high order, instead of perfunctory drudgery. This means education as a fine art. It is coming to take the place of older methods at higher levels, just as at the lower the kindergarten system has replaced the *a, b, ab's* and the dunce-cap, and technical schools for artisans the apprentice system. The education which makes allowance is not so hard for women as compared with men, as the present system is for the feebler man as compared with his sturdier and more phlegmatic fellow. Our experience in the higher education of woman is, as yet, too limited to warrant positive conclusions as to its effects upon the mental and bodily health. It is, however, increasing steadily, and the facts now appear to be in favor of the view that there is nothing in thorough training, properly conducted, that is of itself adverse to the highest physical well-being of either sex. If that training is to be given women side by side with men, it will necessitate numerous readjustments of existing educational methods, readjustments that will rebound to the advantage of all concerned.

SPECIAL ARTICLE.

CO-EDUCATION AND THE HIGHER EDUCATION OF WOMEN.

A Symposium.

BY PROFESSORS WILLIAM GOODELL, M.D., T. GAILLARD THOMAS, M.D., JAMES R. CHADWICK, M.D., S. WEIR MITCHELL, M.D., M. ALLEN STARR, M.D., AND J. J. PUTNAM, M.D.

THE subject of co-education and the higher education of women is just at present attracting so much attention in this country and abroad from a purely educational point of view but with utter disregard to the physical side of the question and the systemic influences exerted thereby, that we have thought a symposium of the opinions of medical men, eminent in their special lines of work, of importance and interest. Importance because of the effects upon

the well-being of the community both moral and physical, and interesting because the experiment is being so widely tried at present at Harvard, Columbia College, the University of Pennsylvania, and other centres of learning, as well as those institutions especially devoted to the female sex, such as the Vassar, Wellesley, and Smith colleges.

The opinions given have been based upon the following outlines:

Gynecologists.—In your opinion, does the higher education of women produce changes in the general or generative system of sufficient frequency or magnitude to lead you to disapprove of movements looking to improved mental training in females?

Do you think that co-education is worse for women than separate teaching methods, either by reason of the danger of excessive competition or other causes?

Do you think that far advanced intellectual training interferes with childbearing, directly or indirectly?

What troubles have you found produced, so far as the uterus and ovaries are concerned, in women from such endeavors?

Man for woman, do you think the average girl going to college will come out as mentally and physically active as the average man?

Neurologists.—In your opinion, does the higher education of woman, that is, a college training, produce changes in the nervous system of sufficient gravity to make the general application of such a course a procedure in any way productive of evil results to the sex?

Do you think women are qualified to imbibe the same amount of knowledge as men with no more expenditure of nerve force than men?

What maladies have you seen more frequently in females, as a result of hard study, than you have in males?

Do you think that co-education is advisable from the standpoint of a neurologist?

Man for woman, do you think the average girl going to college will come out as mentally and physically active as the average man?

Mr. Editor: Your five questions, short as they are, need for answers at least as many essays, and long ones, too; but as you ask merely for "opinions," I shall try to give mine categorically, and as briefly as possible:

1st. There is no question that many women, perhaps, indeed, most women, are intellectually fully as capable as men for higher mental culture. But such advanced education means prolonged education, and herein lies the danger. In young women prolonged confinement, prolonged brain-work, and prolonged intellectual rivalry are, in my experience, injurious to physical and sexual development.

The chief strain of reproducing the species falls on woman, and her share in this cardinal matter is complex, while man's share is single and simple. To this end she ovulates, she menstruates, and she conceives. For this end she bears the burden of gestation, of parturition, of lactation, and of maternity. For this great end she needs the utmost perfection of physical development. Therefore the growth and the well-being of her body should be, at least, as carefully looked after as the growth and well-being of her mind. It should be a co-education of body and mind, the one helpful to the other. But this *junctura callida*, this important harmony, is not well observed in female education, and our boarding-schools, public schools and female colleges are liable to become the hotbeds of forced and sickly girls. As a result, the chief skill of the milliner seems to be directed toward concealing the lack of organs needful alike to beauty and to maternity, and the cultured girl of to-day becomes the invalid mother or the barren wife of to-morrow, or she has all the natural human instincts partly, or indeed wholly, educated out of her. So commonly do I find ill health associated with brilliant scholarship, so often that she who wins an honor is a "victor who hath lost in gain," that one of the first questions I put to a young lady seeking my advice is: "Did you stand high at school?" At the present moment I have in my private hospital one such example: a girl of brilliant mind, whose previously rude health has been grievously injured by overtaxing her brain at one of our best female colleges. Nor is this case a single one. I have had many such; at one time, three ladies from the same college were in my hands.

Whether the fault lies more in the mode of education than in its quality, is yet to me in a measure an open question. But I cannot withhold the opinion that woman's dress must also play an important part in this result. Given one hundred young men "cribbed, cabined and confined" in corsets, or in the tightly fitting clothing which women ordinarily wear; to say nothing of several skirts hanging from the waist; and given one hundred young men clad in the every-day masculine attire, which is a blouse when compared with a lady's dress; which hundred, think you, Mr. Editor, would pass the less unscathed in health through a four years' curriculum at college, supplemented by a three years' professional curriculum?

Of course the monthly drain upon the system, together with its accompanying pains and lassitude, must also have its effect upon the female student. But I shall touch more at length on this factor a little later.

2d. For reasons which, perhaps, may be more sentimental than sound, I, personally, am opposed to the co-education of the sexes. Yet I am bound to confess that it seems to work well in those Quaker institutions with which I am familiar. It certainly does succeed in bringing about close attachments between the sexes, which often end in early marriages.

3d. I believe that in young, developing women, "far advanced intellectual training," as it is now imparted, does interfere not only with conception, but also with childbearing. For, of course, if I am right in my first answer, whatever stunts and enfeebles the frame, must interfere with one of the chief requirements of that fame. To the present system of education do I attribute much of the sterility and the infecundity of women, the absence of sexual feeling, the aversion to maternity, the too often lingering convalescence from a first labor, which is frequently the only one, and the very common inability to suckle their offspring.

I have sometimes been led to think that over brain-work tends not only to stunt the body and to contract the pelvis, but, by the law of evolution, to develop bigger headed offspring, or at least offspring with heads relatively disproportioned to the pelvis of the mother. But perhaps this opinion belongs to the domain of transcendental medicine, and has no sound empirical basis for its support. I merely throw it out as a hint for others to work out.

4th. Before you, Mr. Editor, had asked me to answer your five questions I wrote a paper which appeared in the last issue of your journal. In it are remarks so pat to this, your fourth question, that I shall take the liberty of quoting them:

"By breaking down the nervous system the brain-cramming, the intellectual rivalry, the buckram, proprieties, and the unwholesome confinement of our boarding-schools and public schools, breed a host of sickly girls, who swarm in every class of society. Manifold diseases, both functional and structural, date from the recitation room. They are mostly of a uterine complexion, for at that time of life the sexual sphere dominates, and the brunt of the nervous and the vascular disturbances which form the essence of nerve-exhaustion, falls on the most exacting organs—the reproductive. Hence these suffer from neuralgic pains, or from congestion and the lesions coming from prolonged congestion." . . . . "So common is it for girls in boarding-schools to suffer either from amenorrhœa or from irregular menstruation, as to create a general impression in the community that in these schools some drug is secretly given in the food in order to lessen the laundry work. In one school of great repute so many girls missed their monthly periods, that the family physician of several of them wrote to me asking whether it were possible, as his patients averred, 'that, as their clothes were laundried in the building, something was given in their food or in their drink to produce the effect, for the purpose of saving the laundress the disagreeable task of washing the napkins.' My reply was that if laundresses were acquainted with a drug that could arrest menstruation they knew more than the profession, and that his patients had lost their monthly periods—not from secret drugs, but—from loss of health, due to an unwholesome system of education."

In fact, the most common sexual disorders which I find in female students are menstrual derangements—viz., suppressed, irregular, or scant menstruation; occasionally profuse, and very frequently painful menstruation.

The next most frequent sexual troubles are spinal irritation, leucorrhœa, irritable bladder, pruritus vulvæ, painful ovaries, a bearing-down feeling, and various pelvic aches and congestions. But most of the so-called uterine symptoms are the protean ones of nerve-exhaustion, which is, after all, the bottom factor of the ill health of these girls, the uterine lesions being secondary.

5th. My previous remarks, Mr. Editor, should cover your fifth question. But, since you ask for a categorical answer, let me give you one: Without wishing to wear an illustration threadbare, let us compare the average male student with the average female student. Let us consider that in addition to the clogs and trammels of her dress she has, for several days in every lunar month, to forego her daily bath, to curtail her customary exercise, and to lose some ounces of blood, because she is "*unwell*"—as women from their feelings and sensations aptly call themselves at such times. She, then, will be nervous and irritable, perhaps hysterical, and, most probably, worn out by headache, backache, or groinaches, and oppressed with great lassitude. Yet, for all that, if she has a spark of ambition—and I take it that the average girl has—she must go on with her studies to keep up with her class. Now, I leave it to your common sense, Mr. Editor, and to the common sense of the many readers of your excellent journal, which one would come out of a four years' curriculum the more "mentally and physically active." Would it be the female student, handicapped by her dress and her monthly periods? or the male student, unhampered by female panoply or by monthly flux?

Yours truly,

WILLIAM GOODELL, M. D.

Gynecologists.—In regard to the first question my reply is: No, it does not, by any means. A certain number of women are so organized, physically and mentally, as to render them incapable of undergoing

the training which attaches to the higher order of education exactly as a certain number of race-horses are incapable of undergoing the training to fit them for their work; or as a certain number of prize-fighters are incapable of undergoing the training which would make them able to perform the antics of the prize ring. As a general rule, I would answer the question in this way: I do not think that the higher education of women produces changes in the general or generative systems of sufficient frequency or magnitude to lead me to disapprove of movements looking to improved mental training in females.

I see no great danger connected with co-education, when properly conducted, either for women or for men.

No. In very exceptional cases far advanced intellectual training might do so. As a general rule, I feel sure that it does not.

In the exceptional cases mentioned I find a tendency to irregular ovulation; to painful menstruation, to nervous disorder, and to consequent blood impoverishment; but, as before stated, such results are very exceptional. T. GAILLARD THOMAS.

It is my opinion that the highest education of women tends to improve their general health, and consequently their capacity for childbearing, in that it develops the reasoning powers at the expense of the emotions, and thus gives them greater power to keep the latter in proper subjection. It matures their judgment, thus rendering them more reasonable and prudent in the various relations of life.

It gives them—especially if the higher education leads, as it should, to definite careers in life other than matrimony—spheres of interest extraneous to their own bodies or personal affairs.

These opinions, based upon *à priori* considerations and personal experience in a medical practice exclusively among women, receive partial corroboration from the meagre health statistics of women graduates as yet available. Carroll D. Wright has shown[1] that among 705 female graduates of colleges "20 per cent. show a deterioration in health, 60 per cent. no change, and 20 per cent. an improvement." From these and other figures he concludes that they "do not seem to show, as the result of their college studies and duties, any marked difference in general health from the average health likely to be reported by an equal number of women engaged in other kinds of work."

So far as I know, there are no sufficient statistics as to the health of women after graduation, but if knowledge and trained understanding are of any value to men in fitting them to lead more healthful lives, as is universally admitted, how much more important is it likely to be to women! A development of the reasoning powers in women will, I believe, make women healthier through life, render them wiser in the care and education of their children, and fit them more fully to be in companionship with husbands and with men generally.

I see no great danger of excessive competition between the sexes in colleges conducting co-education, but if it were to arise, I think it would be averted by the skilled supervision now exercised over the health of students in many colleges, which should be introduced in all.

As Dr. Mary Putnam Jacobi shows[1] "that in our existing social conditions, 46 per cent. of women suffer more or less at menstruation," it is evident that in a system of co-education women are handicapped by the manifest necessity of abstaining from severe or sustained mental work for several days in every month. How provision can be made to meet this physical necessity without overtaxing girls during the rest of the month is not clear. Yet no evidence of this detriment to girls in any of the colleges, in which co-education prevails, has yet been made public, and it is evident that the same or even greater danger exists in the last two or three years of the course in the preparatory schools, when the menstrual function is being established.[2]

For these reasons I am in doubt as to the expediency of co-education in colleges.

I have no conclusive evidence that a specially intellectual training has any influence upon childbearing, either directly or indirectly, but my impressions are that it is rather favorable than otherwise.

I have not found any prejudicial influences exerted directly upon the uterus or ovaries by study, and only indirectly, in participation with the derangements of the general system, where the study has been irrational or excessive.

I think it fairly established by experience, so far as it has accumulated, that the average girl, on graduating, is as active, mentally and physically, as the average man, though not as strong muscularly.

JAMES R. CHADWICK.

Neurologists.—I beg leave to answer these questions without reference to their order. I merely state, without defence, what I think on this weighty subject. Elsewhere, in three books,[3] I have said my

[1] Sixteenth Annual Report of the Massachusetts Bureau of Statistics of Labor.

[1] The Question of Rest for Women during Menstruation. New York, 1877, p. 232.

[2] I have shown in the North American Review for December, 1882, that the average age of first menstruation in Americans is fourteen years, four months, and five days.

[3] Wear and Tear, or Hints for the Overworked. Lectures on Nervous Diseases; Doctor and Patient.

say, and, save as to one point, have said it in full. As to this one, I can in a medical journal speak with frankness and ease; in secular journals no one can do justice to this subject.

I think that women would be better in many ways for the higher education, if it come late enough. I believe that they have a right to it, if they ask for it, just as they have the human right to study medicine or law, irrespective of what men may think of their fitness to practise either.

I do *not* believe that constant hard study is as free from evil for the woman as for the man. She is less fit for competitions than man, and her more emotional nature, which qualifies in some directions, in a measure disqualifies in others. I speak now of the average woman. I believe that selected women will stand the stress of continuous intellectual work; for the mass it is dangerous, and, probably, in the long run, sexually incapacitative to a varying amount. The male, overworked and worried, suffers a variety of neurasthenic breakdowns; the woman overworked, or too continuously worked, with the addition of the emotional distresses or excitements to which her nature more largely subjects her, is more liable than he to hysteria, or hysterical hypochondriasis, as well as to neurasthenia.

Your final question is difficult. I believe that of one hundred boys who study hard and well and live the average college life, fewer will be hurt than will be of one hundred women of like age and under like conditions. The reasons for this belief I have given elsewhere.

It is fair to say, however, that at many of the girl-colleges, of late years, a fortunate proportion idle along, or, like many boys, take it easy. Then the statistics are worthless. All concerned are tacitly pledged to accept and defend the man standard of work, and so it is hard to know the full truth. What I believe rests on cases I have seen and what they have told me, and concerning these I have long since said my say.

I reserve No. 4 for the last. I do not believe in co-education, and would abolish it if I could.

The sexes run along in childhood intellectually, not very far apart. At from thirteen to sixteen the girl becomes more decisively the woman than does the boy become a man; more serious, more conscientious, and more suddenly a complete being. The female, for reasons moral and developmental, up to a certain time, surpasses him in intellectual quickness and in power to acquire knowledge. I speak now of groups of either sex who are in reasonable earnest. Somewhere after twenty (no one can set an exact date) the average man increasingly surpasses the woman in persistent energy. Her defect as to this exists from puberty, but is emphasized in her contests with man when he acquires manhood's motives for constant labor, and puts out his strength. I think it unfair to both sexes to bring them into mental competition.

I believe co-education abominable for many reasons, but, for physiological reasons, I think it foolish and absurd; as for others, I think it needless. You put a woman—a girl—in a class with men—or lads. Her wants and her menstrual disabilities she is forced by modesty to hide, or control, or defy. If in women's colleges the silently accepted standard of health and endurance is that of man, how must it be where the groups are of both sexes, and the effects of shame are intensified by the fear of a masculine smile.

I have put all this tersely, as was needed. It is hard to do justice, however, in such brief compass. We speak from the standpoint of the male physiologist. We know the evil, but we do not enough see how painfully stringent are the motives which urge the woman into competitions she is unfit for. The higher education is her right, in some sense, and let us do all that is possible to relieve it of what makes it hurtful to so many.

As to co-education, it seems to me utterly wrong. If any one supposes the curve of endurance as to intellectual labor does not drop with the menstrual period below the continuity of the male capacity, they can know very little of women. If any one believes that ambitious girls put in competition with boys are not thus influenced to disregard in their eagerness the monthly reminder of possible motherhood, and, too, some other matters, they can know little of human nature.

We have been presumbly discussing sexual groups of healthy people, but it is a sad fact that the standard of health in young men and women, taken in the mass, is sadly different. Of 100 average girls between the ages of fourteen and twenty, far more will be ailing than is the case among 100 average lads of like years. This is a matter which the physican, at least, cannot disregard in discussing education in relation to health; but as to this I have also written much, and let those who doubt the conclusions reached read what I do not care to repeat here, or let them study the papers of Romanes, Mrs. Lynn Linton, and Dr. Edward Clarke.

S. WEIR MITCHELL, M.D.

A higher education, that is to say, a college training, if properly pursued, does not seem to me in any way productive of evil results to either sex. On the contrary, by stimulating mental activities; by opening up new intellectual interests; by broadening individual experiences and views of life, it is decidedly advantageous to both sexes equally. The demand everywhere made at present is that woman shall be companionable to man, and this can be

possible only when the range of mental activity in both is on a common plane, an end to be best attained by opening to both the same educational facilities, and encouraging their pursuit. Girls devote so little time to culture after leaving school that the better their education is at the outset the better for the girl in the end.

Given a man and woman of equal natural abilities, I think there will be very little difference in the amount of knowledge imbibed under the same circumstances with similar expenditures of nerve force. The rapidity of observation may be even greater in the case of woman, as has been shown by certain investigations regarding the personal equation. In respect to the kinds of knowledge which are derived from observation it is possible, therefore, that the woman would have the advantage. But in respect to the power of continuous attention it is my impression that man would have the advantage. Observations upon general audiences have shown that there is more apparent inattention on the part of women, even when interested in the subject being presented, whether music, play, lecture or sermon; and since for imbibing the highest kinds of knowledge close attention is requisite, man might have the advantage here.

I do not think that hard study is a frequent cause of disease. It is the anxiety attendant upon close competition. It is the emotional strain in connection with efforts to attain success, rather than the study alone, which is the usual cause of nervous prostration. If competition can be eliminated in education the process could never be accused of producing disease. Fear of failure in examinations, eager desire to excel in competing for honors or position, or prizes, and the attendant emotional strain, is, in my opinion, the chief cause of maladies usually ascribed to over-study. Under such emotional strain I think women give out more quickly than men, and from the effects they recover more slowly. This I should not be willing to ascribe entirely to inherent weakness on the part of the nervous system of women, but, in part, to their very common neglect of the many precautions which prevent such a break-down. I refer to proper diet, sufficient exercise, a careful regulation of digestion, and the relaxation from continuous work which should be enforced at certain periods.

I do not think co-education is advisable, because it increases the amount of competition in study. Some women can compete successfully with men, but in every college where co-education exists the number of men is much larger than that of women, and hence the probability is that there will be several men of talent for every woman of talent. In all these colleges the competition will be greater for the women than in the colleges limited to her own sex. The stimulus to competition will also be greater than in a woman's college, for a talented, ambitious girl will try the harder to surpass her competitors if they are men. Hence, for the girls of ability, the nervous strain of co-education is likely to be too great for their good. For girls of no special ability, who have to be forced to study, the opportunities for social diversion in a college for both sexes are so great as to interfere to some extent with their study and tend to distract their attention from their work. Lastly, in a girl's college, allowances for illness will be more readily made and more freely demanded by the girls than in a co-educational institution. While I believe, therefore, in opening a college education for women, I believe it should not be on the co-educational plan.

I see no reason whatever why mental and physical activity should be impaired in a girl's college, and I think the college girl will come out as strong as the average man in these and other respects.

M. ALLEN STARR, M.D.

I interpret the first question as asking whether the injurious effects of college life, as regards health, overbalance the beneficial effects, and in replying shall consider: 1, to what influences women who seek a higher education are exposed, for good and for evil; 2, how women may be classified in relation to these influences; and what would be the effect of the "general application" of such an education.

Statistics as to the effects of a collegiate course upon the health of women, based on sufficient numbers to be of value, exist, so far as I know, only in the report of the Special Committee of the Association of Collegiate Alumnæ,[1] adopted as a part of the Sixteenth Annual Report of the Massachusetts Bureau of Statistics of Labor.

This gives information concerning the health of 705 students before, during, and for a number of years after their college course.

It appears that the majority of the students kept the good or fair health with which they entered college, and that almost the entire 705 had led active and useful lives since graduation; the greater part being engaged in the exacting labor of teaching.

I believe the principal causes of ill-health met with in women's colleges, to be, anxiety about outside matters, mainly concerning home affairs; emotional excitement attending severe or prolonged study of competition for honors; and the physical strain of overwork.

Another unfavorable influence is, that the students—who have thus far been almost entirely of a peculiarly zealous and ambitious type—often stimu-

[1] Boston, 1885.

late each other to a degree that creates an atmosphere of nervous tension.

As regards this danger, the colleges would doubtless gain by the admission of more pupils of the class who would go rather as a matter of course, and who would not feel that they had so much at stake, as do the more serious and over-eager students of the earlier and present days.

For similar reasons, women in co-educational colleges gain through contact with their more phlegmatic associates.

Lastly, inattention to hygienic matters is an important cause of ill-health, but in this respect women's colleges are steadily improving and are likely to reach a high standard of excellence.

At many of them, as at Wellesley, a certain amount of physical exercise is prescribed, and at one college[1] an examination in this branch is required for a degree.

In deciding to what extent these influences are liable to be injurious, it is advantageous to classify the students.

There is one large class who are amply strong enough to perform their college duties, and as well equipped as their male colleagues for receiving and transmitting further the many ennobling influences of college life.

Then, there is a smaller class who are so handicapped by constitutional weakness or external conditions, that they are very likely to lose their health in attempting to do college work.

Finally, there is a large number who are liable to break down under college strains, just as they are liable to break down from hosts of other strains. Quick and ambitious, but over-sensitive and introspective, they form the neurasthenic class, and the study of the effects of college life upon them is of especial interest to the physician.

I believe that there are many young women of this temperament, and, also, many who would otherwise lead aimless lives at home, who would be safer, both at the time and afterward, for the sobering and bracing effect of a well-governed, wide-awake college, where they might be trained in such a way that they would be enabled to take an effective part in the world outside, or the world of their own homes.

Every physician who has to give advice to neurasthenic patients often seeks for them many of the very influences that the college should, and to a considerable extent does offer—a well-ordered routine as a substitute for an irregular series of fatiguing and listless efforts, mental and practical work to offset emotional excitability, respect for industry and accomplishment, belief in the power of training, a safe introduction to a broadening circle of interests.

It is a noteworthy fact that the question is rarely asked, except *apropos* of athletics, how the health of men is affected by their college life. It is taken for granted (and I believe correctly), that the four college years are, what they were intended to be, a period peculiarly favorable to the orderly, systematic development of mind and body, and those who fall out are assumed to have been weakly at the start, or to have acted with unusual folly.

I believe that when the idea becomes more familiar, a similar training, properly adapted to their needs, will be considered equally good for women.

Women are constantly doing more and better work in education, in the public charities, in certain of the professions, and even in municipal politics, and the alternative for them is to exercise faculties which have been strengthened by prolonged and systematic training, or, for the lack of such training, to work under a pressure that is a serious strain upon the health.

In regard to the question, "Do you think that co-education is advisable from the standpoint of a neurologist?" I may state that while I am not prepared to advocate collegiate co-education as a general system, yet I think it presents more advantages and fewer objections than are generally recognized. It has the merit of economy, simplicity, and accordance with American habits of social life, which, in most respects, have proved to work so well.

J. J. PUTNAM, M.D.

REVIEWS.

A CLINICAL ATLAS OF VENEREAL AND SKIN DISEASES. By ROBERT W. TAYLOR, A.M., M.D., Surgeon to Charity Hospital, New York; Late President of the American Dermatological Association, etc. Illustrated with 192 Figures and 48 beautifully colored Plates, etc. Parts VII., VIII. Philadelphia: Lea Brothers & Co., 1889.

THE completion of this monumental work is a subject of congratulation, not only to the author and publishers, but to the profession at large; indeed, it is to the latter that it directly appeals as a wonderfully clear exposition of a confessedly difficult branch of medicine. It sometimes happens in such enterprises that there is a glaring disproportion between the component parts of the work; that is to say, the text may be good and the illustrations poor, or the reverse may occur. In this instance, however, good literature has joined hands with good art with highly satisfactory results for both. It is scarcely necessary to make any extended review of the Atlas as a whole, since the separate parts have been duly noticed at the time of publication, but for the benefit of those who may be unaware of the general scope of the work some idea of the plan pursued in its composition may not be unwelcome.

There are altogether one hundred and ninety-two figures, many of which are life-size, and representing the highest perfection of the chromo-lithographic art, and scattered throughout the text are innumerable engravings. Quite a proportion of these illustrations are from the author's own collection, while on the other hand the best atlases of the world have been drawn upon for the most typical and successful pictures of the many different types of skin and venereal disease. We think we may say without undue exaggeration that the reproductions, both in color and in black and white, are almost invariably successful.

The text is practical, full of therapeutical suggestions, and the clinical accounts of disease are clear and incisive. We remember once to have read an article in the *American Journal of the Medical Sciences*, by the late Dr. Bumstead, in which he stated that the syphilographer was never a good dermatologist and *vice versa*, and we believe that he himself made little claim to a knowledge of cutaneous medicine. His own immediate successor and co-laborer is, however, an apt illustration to the contrary. Dr. Taylor is, happily, an eminent authority in both departments, and we find as a consequence that the two divisions of this work possess an equal scientific and literary merit. The last two, and concluding, parts illustrate skin diseases. The two most notable subjects treated of are xeroderma pigmentosum and lichen ruber and planus, both of which embody pictorially and otherwise a large amount of original work of permanent value and interest. The investigations of the author on the subject of xeroderma pigmentosum have long been known to dermatologists, and here, after a series of years spent in the observation of certain cases, we are finally presented with his completed and matured conclusions. The identity or non-identity of lichen planus and ruber has been and is a *questio vexata* among the best authorities, and we are glad to be able to say that in the pages before us, rich in illustration and comment, a considerable step has been taken toward its solution. We must certainly stand with the author in his belief that the two affections are entirely dissimilar.

We have already passed the limits allotted to a notice of this kind, and while we have nothing but praise for this admirable atlas, it must be said in justification that it is more than warranted by the merits of the work itself.

CORRESPONDENCE.

NEW YORK.

(*From our Special Correspondent.*)

To the Editor of The Medical News,

Sir: The Sanitary Aid Society of this city, which during the last few years has been engaged in excellent practical philanthropy, has just opened a new night lodging-house on Division Street, in the heart of a crowded down-town tenement-house district, which is a model structure of its kind, unsurpassed by any similar institution in the country. It is five stories in height, four stories being devoted to dormitories, and offers every necessary comfort to lodgers. It can accommodate 110 inmates nightly, and for the sum of ten cents it furnishes each one with a clean bed, a night-shirt, a bath, a separate locker for clothing, and, if desired, a cup of coffee and a roll in the morning. The building has all the modern improvements in plumbing, ventilation, and closets, and is provided with iron stairs and fire-escapes, both front and rear.

The Sanitary Aid Society has been in existence only since 1885, but during that time it has furnished lodgings to more than 130,000 people, while it now has accommodations for 50,000 per annum. At the time of its organization it was deemed best to concentrate its efforts on some special district, as, with the limited pecuniary resources at its command, it would have been useless to attempt sanitary reforms in every part of the city; accordingly, it selected as the field where such reforms were most needed the Tenth Ward, where there was a population of 50,000 souls to but 1859 houses. The Society undertook an exhaustive investigation of the condition of these houses, and as an instance of the over-crowding discovered, it was ascertained that 258 human beings continuously resided on one lot twenty-five by ninety-five feet, containing a front and rear building. A campaign of reform was instituted, and a canvass from house to house, and from room to room, was made. The result was, that, by the following May, 300 of the worst houses had been cleaned out, a systematic work of cleansing, repairing, and drainage had been organized among landlords, lessees, and tenants, and twenty additional sanitary inspectors had been added by the Board of Health to its working force. In addition, a night lodging-house was built on sanitary principles, which for the past four years has been doing excellent work. In order to appreciate the benefits of these model institutions provided by the Sanitary Aid Society, it is only necessary to compare them with the ordinary cheap lodging-houses in the lower part of the city, among which, notwithstanding the strict surveillance maintained by the health authorities, several outbreaks of typhus fever have occurred in recent years.

Diphtheria is becoming increasingly prevalent in Brooklyn, and the records show that during the eleven weeks ending November 9th, there were 192 deaths from the disease, as against 118 during the corresponding period last year, and that with the exception of the last week in October, there has been a weekly increase in mortality over that of 1888. No special cause has been assigned for the prevalence of the disease, but there can be little doubt that it is very often contracted by children coming in contact at school with light cases of diphtheria, or with other children from infected houses. There is also good ground for the opinion held by some authorities, among whom is Dr. J. Lewis Smith, that the germs of diphtheria, having once been introduced into the sewers of large cities, meet there with conditions favorable to their development and multiplication, independent of the human subject; so that wherever the emanations from the sewers enter a dwelling they are liable to carry the specific virus of this disease.

Dr. Henry H. Duncan, a ship-surgeon in the service of the Pacific Mail Company, has brought suit to recover $60,000 damages from the city of Brooklyn. While on board the steamer "Colon," on his way to this port in June last, he was taken with remittent fever, and after arrival went to stay at the house of a friend, Captain Thompson, in Brooklyn. He claims that when already recovering, the report having been circulated that he was suffering

from yellow fever, the Brooklyn health officials decided that he had this disease, notwithstanding that Dr. Cyrus Edson, Chief of the Bureau of Contagious Diseases, New York Board of Health; Dr. Smith, Health Officer of the Port, and others, expressed a contrary opinion. Consequently, he was taken from the house at midnight, and sent on a tugboat to Swinburne Island, in the harbor. His treatment, he says in his complaint, was rough and unskilful, and would, if he had really been suffering from yellow fever, have caused his death. The vehicle which carried him to the dock was not an ambulance, but an old patrol wagon without springs; and while on the way to Swinburne Island he was kept on deck and exposed to the damp air. At the Island he was kept practically in solitary confinement, without proper food or treatment. Moreover, Dr. Bogart, his attending physician at the time of removal, was detained by force in Captain Thompson's house for several days.

The necessity for greater care in the examination of "drunk" patients than is usually observed at our hospitals is well illustrated in the case of a man who was recently found intoxicated on Broadway and arrested. At the station-house he told a story of having been stabbed in the eye with an umbrella. The wound was not regarded by the police as sufficiently serious to call for medical attendance, but the next morning his condition was such that he was sent to the New York Hospital, where he was treated for acute alcoholism and lacerated wound of the face. The next day he was transferred to Bellevue Hospital, where he improved for a number of days, but subsequently developed symptoms of cerebral inflammation and died. Autopsy showed that some instrument had been thrust through the inner angle of the eye to the base of the skull, injuring the optic nerve and fracturing the sella turcica.

The Hon. Andrew D. Smith, ex-president of Cornell University, who has just returned from an extended foreign tour, makes a comparison of Constantinople with New York, which is not very flattering to the citizens of the latter place. "Constantinople, throned upon the most magnificent site for a city on the globe," he says, "is in all its recent civic buildings and its general municipal system vile. I know of but one other city which can be classed with it in these respects. As I went through its muddy, badly paved lower streets, saw the evidence of bad sewerage everywhere, and looked upon its tumble-down quays, it all fairly made me homesick—they resembled so strongly those of our own city of New York. As a simple matter of fact, those districts in New York, somewhat remote from the main avenues and centres, have the vilest arrangements I have ever seen in any part of the world, with the possible exception of Constantinople." That there is unfortunately a great deal of truth in these remarks, is attested by the fact that only during the past week a committee of the State Senate has been making a personal investigation of the Twenty-third and Twenty-fourth Wards, in the annexed district beyond the Harlem, and listening to complaints and evidence as to bad streets, drainage and sewerage.

The seventh congress of the American Ornithologists' Union has recently been in session at the building of the American Museum of Natural History, and the proceedings were often of considerable general interest. A number of physicians from different parts of the country were in attendance, and reports on the Migration and Geographical Distribution of Birds, and on the Anatomy of Birds, were read respectively by Dr. C. H. Merriam, Chief of the Division of Ornithology and Mammalogy in the Department of Agriculture, and Dr. Robert Shufelt, U. S. A., of Fort Wingate, New Mexico. Among other papers read was one on the Avifauna of Arizona, by Dr. E. A. Mearns, U. S. A., of Fort Snelling, Minnesota.

Last season the College of Physicians and Surgeons sustained the loss of its president, Dr. Dalton, and a number of its faculty, Drs. Sands, Sabine, and Agnew; all these distinguished members of the profession dying within a comparatively few months of each other. This season it is Bellevue College that suffers the loss of its president and founder, Dr. Isaac E. Taylor, which has followed rapidly upon the death of Professor Alexander B. Mott.

The report of the president of the trustees of the House of Rest for Consumptives, presented at the annual meeting of the board, which was held November 15, shows that one hundred and sixty-four patients have been treated in the institution during the past year, of whom eight were discharged cured and thirty-one improved. The gratifying results thus reported are due in a measure to the improved methods now employed in the treatment of phthisis, and the trustees hope soon to increase further the facilities for scientific management.

The new Christ Hospital, of Jersey City, erected under the auspices of the Abercrombie Guild of St. Matthew's Episcopal Church, was formally dedicated on the 12th of November, and on this occasion addresses were made by Bishop Starkey, of New Jersey, Bishop Quintard, of Tennessee, Governor Green, and Governor-elect Abbett. The ground and buildings cost $60,000. The hospital was founded many years ago by the late Dr. Abercrombie, rector of St. Matthew's, and the new building was greatly needed in order to carry on successfully the work thus begun.

BOSTON.

To the Editor of THE MEDICAL NEWS,

SIR: As it is the best of which there is the least heard, so let us hope it is with medicine in Boston. At all events, medicine seems to be very quiet at present and nothing of special interest has come up at the meetings.

The Medical School continues as of old, but this year is deprived of the services of Professor Bowditch, who is spending his vacation in Europe. Every seventh year the professors are given a year's leave in order that they may travel and gather facts to dispense again to the less fortunate obliged to stay at home. Dr. J. W. Warren presides over the department of physiology, while Dr. Whitney fills Dr. Bowditch's place as Dean; both are guarantees that the school will not suffer.

The laboratories contain rather more than the usual number of physicians engaged in investigating special points, from whom, doubtless, we shall hear in due time. Dr. Ernst is still continuing his study of the milk of tuberculous cows of which a preliminary notice appeared in *The American Journal of the Medical Sciences*. Besides the work being done in the laboratories of the Harvard Medical School, the writer is cognizant of a considerable amount which is being conducted privately by men whose names assure valuable results.

The amount of outside work being done is a clear sign of the useful field that awaits Scar's new laboratory for pathology and bacteriology if it ever be built and conducted on liberal principles. As yet, no start has been made on this building, which is to contain ample animal rooms, which is a great want, even teachers in the school being now forced to keep their guinea-pigs and rabbits for experimental purposes at home. The bacteriological department will offer certain peculiarities, as besides general rooms for autopsies, cultures, and the like, each worker will be provided with a small room or cell, where he can work in peace.

The two larger hospitals continue to offer a large amount of material, both surgical and medical. Perhaps the tendency of the staff of the Massachusetts General Hospital to the adoption of Brand's method in the treatment of typhoid fever may be of interest to the profession. The expense appears to be the chief stumbling-block. The City Hospital staff, on the other hand, use the antipyretics more freely, incline to the wet sheet, and are not as favorable to Brand's method.

NEWS ITEMS.

THE following letter received from Dr. Abraham Jacobi, of New York, in regard to Dr. Goodell's article in THE MEDICAL NEWS of December 7th, is of interest:

DEAR SIR: I offer twenty-five dollars as a contribution to an edition of ten thousand reprints of your article in the last number of THE MEDICAL NEWS. It is the best and probably most useful paper published in a medical journal these many years. If anything can do so, it will prevent untold cases of malpractice and numberless cases of ailing and demoralization.

Very sincerely yours, A. JACOBI.

110 WEST THIRTY-FOURTH STREET, N. Y.

Insane Asylum Burned.—The Insane Asylum of Idaho was destroyed by fire on November 25th, with the loss of eight lives.

Sir Morell Mackenzie.—It is stated that although Sir Morell Mackenzie was condemned by the Council of the Royal College of Surgeons for his publications on the case of the Emperor Frederick, at a general meeting of the body he had but one accuser.

Dr. Billings and the University of Pennsylvania.—Dr. John S. Billings has accepted the position of Medical Director of the Hospital of the University of Pennsylvania. The duties of this position have been arranged so that they will not in any way conflict with his important duties at Washington. It is understood that the Board of Trustees of the University have also in contemplation the erection of an important building for a complete School of Hygiene. It is expected that, at some future time, Dr. Billings will assume the position of Director of this department.

The Manhattan Eye and Ear Hospital.—The Manhattan Eye and Ear Hospital, of New York, has just completed its twentieth year of active work. It was opened for the reception of patients in a house hastily altered from an ordinary dwelling to the purposes of a hospital on October 15, 1869. Since then over 108,000 patients have received treatment. As a fitting memorial to the late Dr. Cornelius R. Agnew, who was the chief agent in founding the Hospital, an endowment fund is being established, and has already reached the sum of over $8000.

Dr. Northrup's Article in Scribner's Magazine.—Dr. William Perry Northrup, who wrote the articles on "Spasmodic Laryngitis," "Pseudo-membranous Laryngitis," and "Intubation," in Keating's *Cyclopædia of the Diseases of Children*, has written a very interesting article entitled "The Pardon of Ste. Anne d'Auray and other Breton Pictures," for the December issue of *Scribner's Magazine*, in which the habits of the people are portrayed in a way which carries the reader from the beginning of the article to the end without a desire to stop.

Obituary.—Dr. Rudolph Tausky, who died at the Bloomingdale Asylum, November 22d, was a man of fine natural ability and an indefatigable worker. It is supposed that excessive application to his profession unhinged his intellect, so that about four years ago in a sudden access of insanity he attempted to take his own and his wife's life. Both recovered from the pistol-shot wounds in the head, but Dr. Tausky's mind was gone, and for four years he has been in the asylum, suffering from paresis. He was a native of Bohemia and but fifty-three years old. He had had numerous hospital and dispensary positions.

An American Hospital in Persia.—The United States Minister to the court of the Shah of Persia laid, at Teheran, the corner-stone of a hospital, which has largely been promoted by American influence. An American physician of Teheran, Dr. W. W. Torrence, was the originator of the undertaking, and a portion of the funds was subscribed in this country; a larger portion was raised in Persia.

Association of American Anatomists.—The second meeting of the Association of American Anatomists will take place in the Biological Department of the University of Pennsylvania, December 26th, 27th, and 28th. The profession is cordially invited to attend the meetings.

Association of Life Insurance Directors.—Twenty medical directors of life insurance companies met in New York on December 6th, and formed a permanent organization by adopting a constitution and electing the following officers: President, J. M. Keating, of the Penn Mutual; vice-presidents, G. W. Russell, of the Aetna, and Lewis McKnight, of the Northwestern; secretary, Frank Wells, of the John Hancock; treasurer, J. W. Brannan, of the Washington. The object of the association is the promotion of medical science as applied to life insurance.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

PARALYSIS OF THE TRIFACIAL NERVE, INVOLVING THE INFERIOR AND SUPERIOR MAXILLARY BRANCHES—SPINAL IRRITATION.

A Clinical Lecture
Delivered at the Rush Medical College, Chicago, Ill.

BY DANIEL R. BROWER, M.D.,

PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM, DIDACTIC AND CLINICAL IN THE WOMAN'S MEDICAL COLLEGE; PROFESSOR OF MENTAL DISEASES AND LECTURER ON THE PRACTICE OF MEDICINE, RUSH MEDICAL COLLEGE.

GENTLEMEN: We have before us to-day a patient who complains of loss of sensation in the right half of the face, with the exception of a small part around the angle of the jaw. We touch him in various parts of the face with the æsthesiometer and find no evidence of tactile or of pain sense. On moving the jaw as in mastication, you will notice that on the right side of the face the muscles concerned in mastication do not move to the extent that they do on the left side. This, then, is a case of paralysis of the inferior and superior maxillary and ophthalmic branches of the trifacial nerve, involving the sensory and the motor functions.

On smelling this bottle of vinegar you see he does not recognize the substance. There is, therefore, an impairment of the sense of smell. This results not from the trifacial nerve being a nerve of smell, but from the fact that it is the nerve which presides over the nutrition of the nasal mucous membrane, and by examining this membrane you will find that it is very dry. Its nutrition is impaired because of the paralysis of the trifacial nerve.

In order to test his sense of taste, we have here *bitters*, *sweets*, and *sours*. The bitters are tasted by the posterior part of the tongue; sweets by the anterior, and sours by the sides. Applying these three kinds of material to the sides of the tongue, we find that on the right there is no recognition of any of them.

The sense of taste can also be tested by electricity. We have here an electrode, the points of which can be brought close together. I will fix them at a distance of about one-fourth of an inch, and will put into the circuit two cells of the galvanic battery and apply the electrode to various parts of the tongue. You see that on the right side there is no appreciation of the galvanic current, but that on the left there is.

There is no conjunctivitis, no disease of the skin, nor any impairment of its nutrition. This, then, is a case of paralysis of the trifacial nerve, with the unusual features of involvement of both the sensory and motor functions of the nerve in all three of the branches. Paralysis of the trifacial involving a single branch is not very uncommon. The trifacial nerve is frequently the seat of neuralgia, the opposite condition to that which we find here. Neuralgia of the inferior maxillary nerve is toothache. Neuralgia of the superior maxillary branch gives us toothache of the upper jaw. Neuralgia of the ophthalmic branch of the nerve in its supra-orbital distribution is brow ague, a form of neuralgia that is very common.

Having made the diagnosis of the disease it is necessary to determine its seat, and for this purpose we must look for associated phenomena. As all the functions of the fifth nerve are involved in this case, the seat of the disease must be either at the Gasserian ganglion, at the base of the brain, or at the centres within the medulla. Now, if the disease were in the medulla, we should have associated with the paralysis disease of the nerves that supply the eyeball, because these cranial nerves in their origin and the first part of their course are in close and intimate relation with the fifth nerve. But in this case we observe that all the movements of the eyeball are well performed, so that the lesion cannot be in the pons, and there is no involvement of any other part of the body; that is, no paralysis of the arm or the leg which would reasonably be the case if the lesion was located in the pons. The lesion cannot be exterior to the ganglion of Gasser, because the three divisions of the nerve are involved, so that the probability is that the disease is located at the Gasserian ganglion.

The next point to determine is the cause of the condition. The probability is that it is syphilitic, and that it is either a disease of the bone or of the membrane. The man tells us that the affection was gradual in its development. It is probable, therefore, that it is a tumor which, by gradual growth, has encroached upon the nerve, making pressure, first upon the inferior division, then upon the middle, and finally upon the ophthalmic branch. An inflammatory disturbance might produce the same results, but it would be more apt to involve the entire structure of the ganglion at once. It would not be so gradual in its development as he tells us this was.

The treatment in this case must be by large doses of the iodide of potassium. The system will tolerate large doses of the iodide of potassium if it is administered in an alkaline solution. We will begin with 10 or 15 grains, increasing, if possible, to 40, 50, or even 60 grains, pushing it to the utmost extent that the patient's digestive system will tolerate.

Then the paralyzed side should be treated by galvanism, stimulating by means of this current the several branches of the nerve, the negative pole being placed at the back of the neck and the positive over the three several branches. The skin of the paralyzed side should be stimulated by the application of the faradic brush or a dry sponge electrode. It will be well also to guard this alterative treatment by the use of tonics—iron, quinine, and strychnine—in addition to the iodide of potassium.

SPINAL IRRITATION.

This female patient is twenty-eight years of age, married, has had one child, now three years old, who

during lactation was seriously sick and caused her mother much anxiety. She complains now of headache; pains of an uncertain character throughout the body; depression of spirits; palpitation of the heart; feels weak and tired; and you notice that she has a peculiar respiration, frequently giving a deep sigh. She says she has considerable distress after eating, and that her bowels are constipated.

We find, upon examining over her spine, that there are certain points of tenderness; pressure in the cervical region produces a considerable amount of pain throughout the entire cervical region and in the lumbar region. Listening over her neck with the stethoscope we hear the anæmic murmur, a peculiar roaring sound, which is an evidence of anæmia, poverty of the blood, and especially of a deficiency of iron. You notice, notwithstanding this anæmic murmur is so pronounced, that she looks fairly well nourished. In amount of adipose tissue, she is far above the average; so that we may have in a person who is fatter than usual marked anæmia.

Now, this is a case of spinal irritation, especially of the cervical portion of the cord, and the headache, the sighing respiration, the palpitation of the heart, the indigestion, the depression of spirits, have their origin in this depressed condition of the cervical cord, which contains the mechanism by which the blood-supply of the brain is in part regulated, and if this regulating apparatus is out of order, the functions of the brain must be disturbed. There is also a close connection with the pneumogastric nerve, the nerve that regulates to a certain extent the action of the heart, and which is the great nerve of respiration. Upon examining her pulse we find it 115 per minute.

The tenderness in the upper lumbar portion of the spinal cord gives rise also to the symptoms of which she complains—derangement of the menstrual function, irregularity and pain, a certain amount of leucorrhœa, and a variable condition of the urinary function.

The causes that produced this spinal irritation were lactation, anxiety of mind, and the attention that the sick child required.

We will order for this patient Blaud's mass, a combination of the sulphate of iron and the carbonate of potash, giving it in gradually increasing doses beginning with 2½ grains of each, and increasing the dose to at least three times this amount. We will also administer this mild laxative pill: aloin, $\frac{1}{8}$th of a grain; strychnia, $\frac{1}{60}$th of a grain; extract of belladonna, $\frac{1}{8}$th of a grain, every night at bedtime. And we will also direct general galvanization, passing a current of one to three milliampères through the head, the positive pole in front; a current of about the same intensity through the neck, the negative pole in front; and a current of four or five milliampères through the spine, the negative pole being over the epigastrium, and will direct her to take the most nutritious food that she is capable of digesting.

Mechanical Treatment of Pleurisy.—DR. RICHARD OTTO asserts that pleurisy in an early stage can often be aborted, and that the symptoms of pain can always be diminished by a bandage passed tightly around the chest at the level of the painful area.—*Centralblatt für Therapie*, November, 1889.

CARTWRIGHT LECTURES.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, November 21, 1889.

BY JOHN S. BILLINGS, M D.,
U. S. ARMY.

LECTURE II.

ON VITAL AND MEDICAL STATISTICS.

THE term "expectation of life" is used by different writers in different senses, and hence has often given rise to confusion and misunderstanding. It should be used only in the sense of the mean after-lifetime—that is, the average number of years which persons at any given age, in a given place, may expect to live. In a stationary population, where there is no migration, and where the births are exactly equal in number to the deaths, the expectation of life at any age would be found by dividing the sum of the number of years which the whole population lived after that age by the number actually living at that age.

The term "expectation of lite" is often confused with the "probable duration of life," which is the age at which a certain number of newborn children will be reduced one-half, so that for any one of these children it is an equal chance as to whether it will die before or after that age. The difference between the probable duration of life and the expectation of life may be understood from the following example: Suppose that of 100 children born, 30 live one year, 20 live five years, 30 live forty years, and 20 live sixty years. Then the probable duration of life is five years, because at the end of five years just one-half of these children will be dead; so that at the beginning it is an even chance for any one child as to whether it will die before or after the age of five years. But the expectation of life of any one of these children is 25.3 years, because these 100 children will, in all, live 25,300 years of life. In like manner, if 10 of these children were to die at the end of every five years, the probable duration of life would be 25 years, and the expectation of life would be 27.5.

Another phrase sometimes used in vital statistics is "specific intensity of life." This is the quotient of the dividend of the number of persons living at any age by the number dying at that age—that is, $\frac{Px}{Dx}$, being the reverse of the ordinary mortality ratio.

The chief source of error in an approximate life table constructed directly from the census figures and a registration of deaths, without correction or adjustment, is due to the fact that there is a very considerable error in the number given of the living population in the first six or seven years of life. Usually the census figures show that the number of children two years old is greater than the number one year old, and that the number four years old is greater than the number two years old, owing to a tendency to report erroneously a child at these ages as being older than it is. If we undertake to adjust or correct these figures so as truly to represent the number living at each year, we usually have to make some assumptions as to the law governing the mortality, or as to what is sometimes called the "law of life." This expression—the law of life—refers to the

hypothesis that variations in mortality at successive ages take place in regular succession which may be geometrically represented by a curve, and that, therefore, if we know the mortality at certain ages in a given community, we can, if we know this curve, and if the number of observations were sufficient, deduce the mortality at other ages. Numerous formulas have been proposed for this purpose, from that of De Moivre in 1727, which is $Y = 86 - x$, x being the age and Y the corresponding number of the living, to the latest and most generally accepted formula of Gompertz, as modified by Mr. Makeham. This last is based on the assumption that a person's power of resisting death decreases as his years increase, so that at the end of infinitely small periods of time he loses infinitely small portions of his remaining power to resist destruction, death being considered as the consequence of two generally existing causes—the one a progressive, necessary deterioration, the other chance. If, for instance, there were a number of diseases to which young and old were equally liable and which were equally destructive at any age, the number of deaths among the young and the old by such diseases would evidently be in the proportion of the number of the young to that of the old. If there were no other causes of death but these diseases, the number of living and dying would decrease in a geometrical progression as the age increases. But if the liability to death is constantly increasing in a given ratio as the man grows older, then the number of the living will decrease in a greater ratio than a geometrical progression would indicate.

This line of human life—which in some respects is not unlike the line in the palm of the human hand, which the ancient teachers of cheiroscopy also called the line of life—is that of the healthy and normal individual. Many persons do not at any time possess the amount of vital force which it represents; many infants at birth have but the capacity for a few hours or a few days of existence. Some men begin to grow old at forty; the atheromatous degeneration invades their arteries, the heart becomes fatty, and at fifty they are in extreme old age as regards the processes of retrograde metamorphosis and the ability to resist death. Calculations and corrections based on such formulæ as these give interesting results and are useful to life-insurance work, but they are unnecessary to the purposes of the sanitary statistician. Even the fundamental hypothesis upon which Gompertz's law is based—that the proportion of deaths at a given age is constant—is always untrue for any given age, as the prevalence of infectious and contagious diseases of various kinds, and of various lethality, varies with different years; and for this reason it is desirable to have the records of deaths for a considerable period of time—at least three years, and, better, ten to twenty years—in order to correct these variations.

It is impossible to calculate a life table for the United States as a whole, for we have no accurate information as to the total number of deaths occurring in any given period of time in the United States, and still less as to the number of deaths occurring at each group of ages. But even if such a table could be prepared, it would be of very little interest or use, for the conditions of the various sections of the country as to climate, occupations, prevailing diseases, character of inhabitants, etc., are so widely diverse that the average or mean would scarcely be applicable anywhere. The most useful life tables for sanitary purposes are those which relate to certain circumscribed localities, such as a single city, or even a single ward of a city; but for scientific and medical purposes the most useful are those which relate to particular classes of people, particular occupations, etc. There is a special difficulty in preparing an accurate life table for a city, due to the effect of migration into and out of the city from and to the surrounding country, which disturbs very much the rates of death at different ages. The mortality in a great city is almost always reported as less than that which the actually existing causes of death and disease tend to produce, because domestic servants, shop-girls, and others who have come from the country, go back to their rural homes when their health begins to fail after a year or two of city life, and there die. This is especially the case in regard to deaths from consumption and diseases of that class. The groups of ages which are thus specially affected are those between fifteen and twenty-five years; and, therefore, the mortality at this group of ages in the large cities, as calculated from the number of deaths, is too small to represent properly the causes of death acting on the population at those ages. On the other hand, the mortality at the same ages in the rural districts near the city will be correspondingly unduly increased.

The data necessary for the construction of life tables are comparatively rarely available for the purposes of the sanitarian. Hence, while admitting that these furnish the only true measure of public health, registrars of vital statistics and sanitarians have sought for other standards for such measurement, the data for which could be more readily obtained and more easily applied. Especially has the search been made for some means of measuring sanitary conditions and progress from the data furnished by deaths alone, without reference to population. One of the most common of these is the use of the period of infancy from 0 to 5 years, by comparing the number of deaths at this period with the total number of deaths. It is very certain that the period of infancy gives the most sensitive test of sanitary conditions; but the comparison must be made, not with the total number of deaths at all ages, but with the number of the living population furnishing such deaths.

Another method, which we can only use for a census year, is the use of the ratio which exists between the total number of births during the year and the number dying during the year out of this number of births. This is not the same as taking the total number of those dying under one year of age. For example, in the city of Brooklyn during the last census year there were 8805 births, and of these 1408 died, leaving on the date of the census 7397 living children under one year of age, putting aside the effects of migration; but the total number of deaths of white male children under one year of age in Brooklyn was 2059; hence, 159.9 per 1000 of those born within the year died within the year, while the deaths of children under one year were 278.4 per 1000 living at the end of the year, with a still higher rate for the year.

The test of sanitary condition which is most generally

employed in this country is the proportion of the number of deaths which occur in children under five years of age to the whole number of deaths reported. This does fairly well in comparing the rates of the same city, in which it may be presumed that the general ratio of age distribution is nearly uniform at different times, but it is a very fallacious method of comparing rates of different cities or localities.

Much the same may be said of comparison of deaths at a given age-group to total number of deaths, which is apt to give very misleading conclusions. For example, suppose in a given city the total number of deaths of children under five years of age was 30 per cent. of the total deaths, while in a given class of people in the same city they were only 10 per cent. of the total deaths. It would be by no means safe to infer that this special class was in a better sanitary condition, because among the poorer classes the proportion of children is always relatively large, which implies a large population exposed to these special diseases, and, consequently, a larger number of deaths under five years of age, without reference to the sanitary condition.

Another test which has been proposed is that of the mean age at death, which is the quotient of the sum of the ages of different individuals at death, divided by the total number of deaths. This is only useful in comparing the conditions of two populations when the age and sex constitutions of these populations are the same. It is out of the question to apply the test to different occupations, as, for example, to compare the mean age at death of major-generals with that of second lieutenants. The chief use of this test is in its application to different causes of death, but even for this purpose the death-rate in relation to population is much better.

A considerable part of the errors to which one is liable in comparing the mean age of different occupations at death may be avoided by excluding from the computation all deaths of children under five years of age.

Although the expectation of life, or mean after-lifetime, is the standard of comparison almost universally accepted by statisticians, it is, in some respects, not a very satisfactory one, since it is often misunderstood by the public, which is apt to use the word "mean" in the sense of usual or ordinary—that which occurs most frequently. But the ordinary lifetime, or, as Bertillon calls it, the *vie normal*, is a very different matter. After the perils of childhood are passed the greatest number of deaths cluster about the age-period of seventy years, and the popular phrase here would be that it was a premature death which occurred in a man under sixty years of age.

The great majority of the mortality statistics prior to the present century are necessarily incorrect and unreliable, because they are based, for the most part, on the data of deaths alone. The deaths can only be taken as a measure of probable duration of life for any community when the births and deaths are equal and there is no migration, a state of matters which must very rarely happen and be of very brief existence.

Among the many expedients which used to be employed for estimating population was that of multiplying the number of living in which one death was supposed to occur, by the number of deaths. That is to say, by guessing at a factor which could only be ascertained by comparing the annual deaths with the number living. Take, for example, the estimates of the population in London made by Graunt in 1662, on the basis of one death occurring out of every 32 living, which made the population to be 403,000. In 1683, Petty, taking the mortality to be 1 to 30 persons living, made the population to be 669,930.

One peculiar thing about this method is, that it is liable to make the population seem the largest at those periods when it was in reality the smallest; for when the number of deaths was unusually large by reason of an epidemic, which would actually lessen the number living, it would show an apparent increase in the population for the same period.

It may, perhaps, be asked why it is, if the nature of the data which are required to make mortality statistics reliable and satisfactory is so well known, that more of them are not provided by the municipal and State officers charged with the registration of vital statistics. For example, New York City has a very perfect system of registration of deaths, which is in competent hands and is well executed. Why, then, has New York City published no separate mortality report since 1883, and why, in the reports which it has published, does it not give the data with minuteness of grouping, so that we might know the number of deaths at each age, of each sex, and of each race and occupation in each ward from each cause of death, instead of giving, as it gave in its last report, the number of deaths from each of a few causes of death for each of a few groups of ages, and separately for each sex, and for natives of the United States, natives of foreign countries, and colored, to which is added a statement of the deaths from zymotic diseases in each ward?

In order to understand the answer to this it is necessary to have a clear conception of the difference in cost of tabulation and publication according to the mode of grouping of the data. If, for example, the deaths are given by 20 groups of ages and by sex and by color for each of the 24 wards, and for the city as a whole, it will require 49 columns to do this. If we make the distinction for, say, 100 different causes of death, allowing 50 lines to the page horizontally, and 20 columns vertically, giving 1000 places per page, we should get all this information for the city on 4 pages; but if we wish to show the number of cases of death from each cause at each group of ages, of each sex and each color in each ward, we shall have to have 2000 columns, which will make about 200 pages. If it be desired to estimate the influence of seasons in connection with all these things, we must have a similar table for each month, or 2400 pages large octavo.

Again, let us suppose that we wish to have the data fully presented in order to estimate the influence of occupation upon health. We will only ask for details of 100 occupations in males. But we should like to know the number of deaths in each of these occupations for each of, say, 10 groups of ages, in each of at least 5 races, in the married and single, in each of 12 months, for each of the 24 wards, for each of, say, 100 different causes of death, giving 288,000,000 possible places, making 288,000 pages large octavo.

It is, of course, out of the question to present the data

in any such detail as this, and it is therefore necessary to make a selection of combinations which will indicate the most interesting relations of the several points under discussion.

It is, however, often very difficult and even impossible to tell precisely what combinations it will be necessary to make to get at the probable explanation of an especially high or low death-rate in a given group; and hence we sometimes have to make a very considerable number of tentative combinations and tabulations, from which we may select only a few as really throwing light on the matter, and therefore as worth publication.

When we have to tabulate data in such a way that the individual items are to be distributed through a thousand columns or more, and each of these to be summed up for different localities, a vast amount of clerical labor is required. For distributing in 1000 spaces the various items assigned in each death certificate, if it be done by the old-fashioned system of tallying on a large sheet, an expert clerk will not be able to tally off more than 1000 records of death per day; so that for, say, 30,000 deaths, which is less than the average number of annual deaths in New York City for the last ten years, it would require the labor of a clerk thirty days to produce a single-page table—about one per cent. of what is needed.

By the use of cards or slips, tallying machines, adding machines and sorting boxes of various kinds, this labor may be much reduced. One of the latest methods of doing this is by the use of cards of a uniform size in which holes punched in certain parts of the card correspond to the various divisions of locality, time of death, sex, age, occupation, cause of death, marital condition, etc. These cards may then be passed through a machine which registers on a series of dials such combinations of the data as the dials may be adjusted for, by means of electrical connections established between a metal plate below and a series of metal rods above, wherever there is a hole in the card.

Death-rates, even when derived from complete and accurate data and compiled in the most satisfactory manner in the form of life tables, necessarily give only an imperfect view of the prevalence of disease in a community, or of the relative amount of disability among the people, requiring extra labor by the productive class, due to the recurrence of sickness. Many forms of disease which render life more or less of a burden, and some of which totally disable the individual from earning his subsistence, seldom or never appear in the registers as a cause of death; while even of those diseases which are reported as causes of a considerable proportion of deaths, we can rarely at present indicate any definite or certain relation between the number of cases of the disease and the number of deaths reported. For example, it is well known to all practising physicians that the mortality varies greatly in different epidemics of such diseases as scarlet fever, measles, smallpox, whooping-cough, yellow fever, etc., the variations appearing to depend principally upon the particular conditions of the environment as to temperature, moisture, winds, density of the population, etc., at the time of the outbreak, and also upon particular conditions of the specific virus or microörganisms causing diseases of this kind.

Take, for example, the spread of yellow fever in Texas and along the Gulf Coast during the year 1867. Here the specific cause of this disease appears to have entered the United States by two distinct routes, one coming from Vera Cruz, Mexico, and the other coming from the usual source, Havana. At that time the United States had a comparatively large number of troops along the southern border of the country, and hence we have a series of returns showing not merely the number of deaths but also the number of cases of sickness from this disease occurring in a given population.

Now, in those places where the disease was of Mexican origin the cases were more fatal than those of Cuban origin, "two out of every five cases of the former dying, while the mortality of the latter was only two out of seven. The ratio of deaths was 400 per 1000 cases for the first of these groups, 284 per 1000 for the second."[1]

For the great majority of diseases it is not possible to obtain statistics as to their prevalence among a general population. The only sources to which we can look for information of this kind are the records of the Army and Navy, of the police force in certain cities, of the employés of railroads, and of the members of certain societies having insurance against sickness. The records of the Army and Navy are especially valuable in this point of view, but they relate only to males of certain groups of ages and of a carefully selected class of population.

In the last United States Census an attempt was made to obtain on the schedules of the living population the number of those who on the first day of June, 1880, were so sick or disabled as to be unable to pursue their ordinary occupations. This was the first attempt of the kind which has been made in this country, but similar attempts were made in two censuses in Ireland, in a census of the Australian Colonies, and in a census of Hungary.

The first examination of the United States schedules seemed to show that the returns of the sick were too imperfect and too inaccurate to permit of drawing any conclusions from them. But subsequently it turned out that they were really more complete than had been supposed, and a sufficient number were compiled for different parts of the country to obtain a fair sample of the general results. This compilation showed that for the total population over fifteen years of age the number found sick out of every 1000 living varied from 7.17 to 22.7 for males, and from 8.1 to 17.5 for females, or about 1⅓ per cent. of males and 1½ per cent. of females. These do not include the blind, deaf and dumb, insane, and idiots, and it is probable that the figures do represent very fairly the different proportions of sickness occurring in males and females and in certain groups of ages at the time the Census was taken, which, it must be remembered, was at a period when there is probably the least amount of sickness and disability among adults.

From the results of data derived from mutual benefit societies in England, it has been estimated that for every case of death in a community there are two persons constantly sick; that is to say, there is an average of two years' sickness to each death, or that, if the annual death-rate is 18 per 1000, the average number constantly sick is about 36 per 1000.

Mr. T. R. Edwards (London *Lancet*, 1835–36, i. p. 855), from the study of a series of returns from friendly

[1] War Department, Surgeon-General's Office, Washington, 1886; Circular No. 1, p. xviii.

assurance societies, claimed that, for large numbers of people, there is a constant ratio of sickness peculiar to each age, and that the duration of each case of sickness at any age is in proportion to the mortality at that age. His theory is that the mortality at any year of age exceeds that of the preceding year by 2.999 per cent., or that the mortality during any decennial interval of age exceeds that of the preceding decennial by one-third part; or that the mortality rate doubles in twenty-three and a half years.

According to his theory, if a physician loses by death double the proportion of patients at the age of forty-three that he does at the age of twenty, the effect of his remedies in each case is the same.

By the Census reports the proportion of sick to 1000 of population of different ages was as follows:

Age.	Males.	Females.
15 to 25	6.9	6.8
25 to 35	8.6	9.7
35 to 45	12.2	11.5
45 to 55	16.8	14.4
55 to 65	25.5	20.4
65 and over	44.5	35.3

This corresponds in a general way to the conclusions of Mr. A. G. Finlayson relative to the amount of sickness in members of friendly societies, printed in 1854.[1]

He found that taking the whole mass of male members of friendly societies from the age of fifteen to that of eighty-five, about five years of sickness occur to each man during this seventy years; but during the period of labor from the commencement of the sixteenth year of age to the close of the sixty-sixth, there are in this fifty-one years but seventy-eight weeks of sickness, or about one and a half weeks per annum; and the sickness occurring from forty-two to sixty-six is almost double that occurring in the first half from fifteen to forty-one. Hence he concludes that the sickness of the first twenty-five years of working life is almost exactly one-half that that of the second twenty-five years. In the class devoted to heavy labor the sickness is almost a year more, or in the proportion of eleven to nine as compared with the sickness undergone in the class engaged in light labor.

It is also to be observed that during the early years of life—say from twenty-one to forty-one—the number of persons withdrawing, or excluded from such societies, is very large, being nearly five times the number of deaths. As the age of the members increases the departures become fewer, because it becomes more of an object to remain connected with the society, since the rate of annual payments is the same for all ages, while the proportion of sickness steadily increases, as we have seen, with advancing age.

Several attempts have been made to induce physicians to keep a record of all the cases they treat, but with very little result, and it is very improbable that anything like complete returns of sickness will ever be obtained for any large body of the civil population. Such registration will always be confined to infectious and spreading diseases; in other words, those which are known or supposed to be preventable. In order to make a registration of this kind of any great practical value it must be continuous and compulsory. The plan of endeavoring to get the medical men of a locality to contribute voluntarily this information, even when accompanied by the offer of the payment of a fee, has produced partial and incomplete results, which become more and more incomplete as time goes on and the first enthusiasm in favor of the new plan dies away.

The various systems of compulsory notification which have been tried are, first, to require the medical attendant only to furnish the returns to the Health Office; second, to require the householder or head of the family to make such returns; third, to require both the doctor and the householder to make such returns; and fourth, to require the doctor to certify to the householder and the latter to notify the health authorities.

On the part of some members of the medical profession, both in Great Britain and in this country, strong objections are urged against compulsory notification of disease, and, especially, against that form which requires the doctor to furnish such notification direct to the sanitary authorities. It is urged that such notification is a violation of professional secrecy; that it leads to concealment of disease and to the refraining from calling in a medical attendant, and that it tends to throw the treatment of such cases into the hands of a lower class of practitioners, who are willing to run the risks of violation of the law, or even to make false returns for the sake of securing an increased practice. There is, however, little difficulty in keeping the information furnished strictly confidential, provided the health officer is a man of tact and discretion, and provided, also, that the press does not insist upon being too inquisitive with regard to matters of this kind.

Any system of compulsary notification, however, which has to be continuously successful, involves two things: First, that the health officer shall not be in any way engaged in, or connected with private practice; so as to do away with all reluctance on the part of general practitioners reporting their private cases.

The second is, that to obtain any benefit from notification, special hospital accommodations for such forms of diseases as are reported must be provided by the community, and there must be a power of compulsory removal of patients to such hospitals in certain cases.

Undoubtedly, valuable statistical data might be obtained by the simple notification alone; but the desire to obtain statistical information will never be accepted as a sufficient ground for legislation requiring compulsory notification.

We hear very much in recent years of the proportion of deaths from zymotic diseases as a test of the salubrity or sanitary condition of a place; but as there is no general agreement as to what is and what is not a zymotic disease, and as the term rests on a theory of causation of disease which is now definitely abandoned, it should no longer be made use of. It is much better to select the mortality from certain forms of disease, and specify these, in order that we may know exactly what we are talking about and be sure that the matters compared between the two localities are the same. English health officers often use the term "seven principal zymotic diseases," by which they mean smallpox, measles, scarlet fever, diphtheria, whooping-cough, typhus fever, and enteric fever. If this is the selection it is not a good one, for it

[1] See Insurance Cyclopædia, vol. v. p. 83.

omits the diarrhœal diseases. Forty years ago, near the commencement of the speculations of Dr. Farr and Mr. Simon as to the causation of disease, nearly all of the contagious diseases were grouped together as zymotic diseases and were supposed to be more or less connected with filth. At present we know that the cleanliness of the surroundings has little or nothing to do with the prevalence of smallpox, measles, scarlet fever, or whooping-cough; so that these, which are typical zymotic diseases, are of very little interest in connection with the question as to local causes of diseases in a place, connected with uncleanliness, and to be remedied by sanitary effort.

Their relative prevalence, and the mortality due to them, are of interest in a totally different connection, and their separation involves an entirely different field of sanitary work. Such diseases as phthisis, diphtheria, and the various forms of diarrhœal disease, including cholera infantum, or the summer diarrhœa of children, of England, are of especial interest as regards the field of local sanitary work in relation to sewerage, drainage, and cleanliness.

The influence of habitation upon death-rates and on the prevalence of certain forms of disease is indicated by statistics given by Dr. Korosi[1] for the city of Buda-Pest, where the deaths are reported with the following classification, viz.:

1. Persons in a habitation where, at most, two persons dwell in one room.

2. Persons dwelling where from two to five persons dwell in one room.

3. Where there are from five to ten in a room.

4. Where there are more than ten in a room.

The first class includes the rich and well-to-do. The others present increasing grades of overcrowding. Of each 10,000 deaths reported, 1,941 belong to the first; 5,759 to the second; 2,167 to the third, and 133 to the fourth; and these ratios may be used to compare with the proportions of deaths from any disease, or group of diseases, as occurring in the different classes.

Comparisons thus made indicate that contagious diseases, with the exception of scarlatina and typhus, are more frequent and more fatal in the crowded houses, and that the same is true of congenital debility and diarrhœa, while tuberculosis and pneumonia do not seem to be specifically influenced by this cause. (?!) As the figures of death in these categories are not comparable with those of the living population, the results have not much value.

Suppose, now, that we are studying the death-rates of a city for a series of years, in order to determine whether its sanitary condition is, upon the whole, improving; whether work which has been done in the way of introducing sewerage, or improved water supply, or special precautions in dealing with contagious diseases, have had an evident good effect, and have produced results which are on the whole satisfactory in proportion to their cost. It is very evident that we must have something more than the mere gross death-rates for the whole population in order to form an intelligent opinion on these points. A gross death-rate may, it is true, give a correct answer to the question as to whether the sanitary condition is improving, but we can never be sure of the correctness of this answer until we have made detailed comparisons of the mortality by age and sex, and of that due to certain great classes of disease.

What has been the influence of modern civilization upon the average duration of human life—upon rate of increase of population—upon the average health and vitality of the races which it has affected? The present population of the world is between 1500 and 1600 millions, of which there are in Europe over 350 millions, and of European stock in other countries 100 millions—in all, say 450 millions, as against 150 millions in 1788. (See Giffen, *Jubilee Volume of Statistics*, 1885, p. 99.)

Evidently the birth- and death-rates now prevailing in Europe and the United States cannot have long continued, for if we suppose a population to double itself only once in a century, a million of people living 1200 years ago would have developed into a population of over 4000 millions by this time.

What, then, is the difference between the expectation of life in New York, at the present day, and that in European cities one, three, five, ten, or twenty centuries ago? This question has been asked in various shapes many times, and many attempts have been made to answer it; the general conclusion being that there has been a very great increase in the average longevity of man in civilized countries not only within the last thousand years, but within the last century. Notwithstanding, it must be confessed that the statistical records bearing on this point are very incomplete, vague and unsatisfactory, and that it is only for the last forty or fifty years that we can speak with anything like scientific precision as to the amount of progress made.

So far as what is termed potential longevity, that is to say, the maximum duration of life possible in an individual of the race, is concerned, there is no evidence that this has changed for at least 2000 years, being, for man, generally taken as 100 years. You will remember the Scriptural declaration that "the years of a man are three score years and ten, and though by reason of strength they be four score years, yet is their strength labor and sorrow;" notwithstanding, there are sufficient records to prove that even in those days the potential longevity of man was as great as it is at present.

But when we come to the average longevity and expectation of life at birth, there is sufficient evidence to indicate that it has increased; but whether this is due to the preservation of more infant lives for a few years although they may still die before the productive period is reached, or to an increase of the number of those who live into and share the working period of life, is still uncertain, for this question can only be settled by comparative life tables, and I have already explained that we have no reliable life tables that are much over fifty years old.

I have already referred to the average duration of life among the better class of Roman citizens, as fixed by Ulpian, being equal to thirty years. Among the oldest data which we possess, from which we can attempt to compare death-rates of past centuries with those of the present, are the records[1] of Geneva in Switzerland, which

[1] Korosi: Influence des Habitations sur les Causes des Décès, etc. Paris, 1877.

[1] Malet: Annales d'Hygiène, 1837, vol. xvii. p. 5.

date from 1551. The average annual death-rate per 1000 was as follows:

From 1551 to 1600	40
" 1601 to 1650	37
" 1651 to 1700	35
" 1701 to 1750	33
" 1751 to 1800	29

From 1801 to 1813 the mean duration of life was thirty-six years and six months.

From this, the probable duration of life is given as follows:

Periods.	Probable duration of life			Proportionate increase.
	Years	Months.	Days.	
End of the 16th century	8	7	20	100
17th century	13	3	16	153
1701 to 1750	27	9	13	321
1751 to 1800	31	3	5	361
1801 to 1813	40	8	0	470
1814 to 1833	45	0	29	521

The figures are not sufficiently full or accurate to justify the conclusion that the probable duration of life in this place has been increased five times in three centuries, but they do indicate a very marked and progressive increase.

In the sixteenth and seventeenth centuries Geneva had a small population, frequently exposed to fatal pestilence, and produced a comparatively large number of infants, of whom but a very small proportion reached the age of puberty. In the early part of the eighteenth century the average mortality of all European countries, taking towns and villages together, is estimated by Sussmilch as 1 in 30, or 27.778 per 1000.

The most important contributions to our knowledge of the increase in the duration of life in recent years is contained in a paper on "The Decline in the English Death-rate," by Noel Humphreys, published in the *Journal of the Statistical Society* in 1883: and in a report by Dr. William Ogle in a supplement to the Forty-fifth Annual Report of the Registrar-General of England, published in 1885.

The conclusions, as based upon English life tables, comparing periods from 1838 to 1854, and from 1871 to 1880, are as follows:

The mean after-lifetime of a male at birth was for the first period 35.91 years, for the second 41.35, showing an average gain of nearly a year and a half. The mean after-lifetime continues longer in the second period than in the first for each year of life until the nineteenth. At the close of the nineteenth year the expectation of life was exactly the same in each period, viz., 40.17 years. From that time onward the after-lifetime is shorter in the recent period than in the older one; that is to say, the individual male in England lives on an average a shorter time after he is nineteen years old than he did forty years ago; but the number of males, out of equal numbers at the start, who survive to live these shorter lives, is very much greater than it was formerly, so that the aggregate life of the whole is considerably increased. The gain is greater in females than in males. Thus, in the first period, the expectation of life in females was 41.85, while in the second period it was 44.62, being a gain of 2.77 years, on an average, for each female. The after-lifetime continues longer in the new period down to the completion of the forty-fifth year, when the expectation of life becomes the same, viz., 24.06.

Taking a million males and a million females the following table shows the additional years gained at each age-group, for each sex, during the recent period:

Age-periods.	Males	Females
0 to 15	255,340	288,226
15 to 25	281,872	339,933
25 to 35	344,906	453,221
35 to 45	310,746	490,471
45 to 55	211,040	474,009
55 to 65	86,920	385,257
65 to 75	10,464	239,617
75 to 85	27,770	82,568
85 and upward	13,451	8,282
Total years gained,	1,439,139	2,777,584

This table plainly shows how erroneous is the conclusion sometimes drawn that because the death-rates have fallen only in the earlier age-periods, while they have risen in the later age-periods, the aggregate gain to the community from the changes is confined to the unproductive years of life. We may fairly take the period which intervenes between twenty-five and sixty-five years of age to be the most valuable part of life, and of the aggregate years saved, 66 per cent. in the case of males and 65 per cent. in the case of females are lived in this period.

The earliest attempt to give vital statistics for the United States is probably a paper by Edward Wigglesworth, published in the *Memoirs of the American Academy of Arts and Sciences*, 1793, vol. ii. page 131, entitled, "A Table showing the probability of the duration, the decrement, and the expectation of life, in the States of Massachusetts and New Hampshire, formed from sixty-two bills of mortality on the files of the American Academy of Arts and Sciences, in the year 1789." The whole number of deaths reported on these bills was 4893. He had no data of population, but the reports indicated that the births in the locality sending the bills were twice as many as the deaths. As his calculations are based solely on the deaths alone at certain ages, the conclusions are evidently entirely unreliable.

Another paper is by J. E. Worcester, printed in the *Memoirs of the American Academy of Arts and Sciences*, Philadelphia, 1833, vol. i., new series, page 1, and entitled "Remarks on longevity and the expectation of life in the United States, relating more particularly to the State of New Hampshire." Taking the bills of mortality of thirty-two townships in New Hampshire, for an average length of time of twenty-one years, he found that the death-rate was 1 in 83, or 12.04 in 1000. He wisely remarks that the ratio is so small as to excite suspicion concerning the accuracy of the bills.

One of the most frequent fallacies in the use of statistical data is to mistake an effect or a coincidence for a cause. For example, it is common to speak of rapid growth in population of a locality or country, as if it were in itself a good and desirable thing, a cause of prosperity and well-being; and when this growth lessens or ceases we find some philosophers trying to devise ways and means to increase it. This, for example, has been the case in France for a number of years, and

various plans have been proposed for increasing the birth-rate and diminishing the death-rate, in order to produce prosperity and strength in the country. The fact is, that rapid increase of population in a country is an indication that things are going on well there; that there is a demand for labor; and that men find that they can increase their comfort by going, or staying, there. But it may, or may not, be a cause of prosperity at a given time, and sometimes it may cause hardship, weakness, and suffering.

You are all, no doubt, familiar with what is known as the Malthusian theory, which is, essentially, that population is limited by the means of subsistence available; that population increases in a geometrical proportion, while the means of subsistence do not increase in a faster ratio than arithmetical progression; that, therefore, the growth of population is checked by want of means of subsistence, and, therefore, that the increase of mankind may be considered as the chief source of misery, which misery, together with moral restraint to a limited extent, and vice, check the superior growth of population, keeping it at a level with the means of subsistence.

If this doctrine be applied to the lower animals, or to an extremely savage and ignorant set of men, it is very nearly correct; for, in this case, the term "means of subsistence" applies almost exclusively to the natural produce of the earth. As soon, however, as man applies his intelligence to the increase of the means of subsistence by improvements in agriculture, by manufactures, etc., it is no longer true that the means of subsistence increase in an arithmetical proportion. They may increase, and for the last fifty years have, throughout civilized regions of the world, actually increased in a ratio more rapid than geometrical proportion, and more rapid than the increase of population; and it is, therefore, substantially true that "the character of every race of men is the real limit to its numbers in the world, if allowance be made for accidents of position and time" (Farr, *Vital Statistics*, London, 1885, p. 15).

The uneducated and unskilled laboring classes, who are without capital, when gathered together in large masses, tend constantly to illustrate the theory of Malthus by increasing faster than they can provide means of subsistence for themselves and their families.

But this tendency is opposed by the advance in knowledge, increase in energy, and improvement in inventions in the educated classes, who, although it may be said that they are acting only from selfish interests, are, nevertheless, led by those interests to expand the fields of agriculture, manufactures, and commerce, and, thus, both to increase the means of subsistence and to lessen the price thereof.

Under favorable conditions a population is capable of doubling its number every 25 years. In the United States, between the years 1790 and 1860, the population doubled itself about once in 23½ years. But a proportion of this increase was due to immigration.[1]

[1] In estimating the progress of the population of the United States for the next century, if we assume a rate of 33.3 per cent. of increase in ten years, which is a little less than the mean rate for the last century, we find that the probable population in 1990 will be 1,206,562,248, giving a density of population of 399 to the square mile, approaching the present density of China, which is 420, or of Belgium, which is 434 per square mile.

Whether in the future a systematic attempt to maintain an equilibrium between subsistence and population will become a practical problem of national policy, is, at present, a purely theoretical speculation, for it is very easy to show, as has been done by Mr. Atkinson, that the means of subsistence at present at our command can easily be quadrupled, as the increase of the population occurs both to require and produce such increase.[1]

One of the most interesting and important questions in vital statistics in this country is that relating to the relative increase in the white and colored population in the Southern States, and the influence which has been, and will be, exerted upon this by the abolition of slavery. On the one hand, it is claimed that the large increase in the colored population between 1870 and 1880 indicates that in fifty, or at most a hundred, years more it will greatly predominate.[2] On the other, it is affirmed that the greater increase of the colored population is apparent rather than real.

We have little information of value relative to the vital statistics of the colored population in the South, previous to the abolition of slavery. The only two Southern States having registration laws which were to any extent enforced were Kentucky and South Carolina. The Kentucky reports relating to the registry and returns of births, marriages, and deaths are eight in number, commencing January 1, 1852, and extending to December 31, 1859, the last report being printed in the early part of 1861. The South Carolina annual reports of registration of births, deaths, and marriages begin with the year 1853 and end with the year 1859. In neither State was the registration of either births or deaths in any year sufficiently complete to permit of accurate comparisons with the number of living population, either for the whites or blacks.

The conclusions drawn by the registrars may be summed up in the statement that the birth-rate of the slaves was much greater than that of the whites in South Carolina, while the difference was not marked in Kentucky; that in both States the death-rate of the negro was decidedly greater than that of the whites, especially in infancy, and that the average age at death was decidedly higher in the whites.

I have already shown the fallacies connected with taking the average age at death as a means of judging either the healthfulness of a locality, or the expectation of life. Notwithstanding, this is practically the only ratio to which we can refer in regard to the question under consideration.

[1] Maria Mitchell, in a recent number of The Century, speaking of an interview with Sir John Herschel, says, that one morning at the breakfast table Herschel put the following question: Suppose that since the time of Cheops, 3000 years ago, man had only died from natural decay at about 90 years of age, and that the population doubled itself every 30 years; starting with a single pair at the time above referred to, would the present surface of the earth afford standing room to the entire progeny, if closely packed? The replies to this conundrum were various—one saying that they would occupy a layer three feet deep, another a layer fifty feet high, and so on, extending the guesses as he said "More, more," to the distance of the moon, to the sun, and, finally, to the planet Neptune; when his reply was, that they would have piled up upon the surface of the earth to a distance equal to a hundred times the distance of the earth from the planet Neptune.

[2] See paper by E. W. Gilliam, Pop. Sci. Monthly, xxii. 433.

The records of the statistics of 1880 show that the birth-rate for the year was greater in colored than in the whites, since in the ten groups in which distinction of color was made for this purpose, the birth-rate for the whites was 32 and for the colored 38.06 per 100 of aggregate population; or, for the whites, 127.1, and for the colored, 163.8 per 1000 of women between the ages of fifteen and forty-nine. The birth-rate is always higher among the poorer classes of a population, and it is doubtful whether the birth-rate of the negro is higher than that of the laboring classes among the whites. The mortality among the colored infants in the earlier months of life is much heavier than among the whites in the same localities. For example, in the ten grand groups just referred to, out of each 1000 infants born, the number which died under six years of age was, for the whites, 66.7, and for the colored, 71.4. This fact tends to increase the birth-rate among the colored, because, with the loss of the infant and the consequent cessation of nursing, the probabilities of a fresh pregnancy increase. The marked difference between the vital statistics of the white and colored in the South is much greater in the cities than in the rural districts.

The average mortality in a population of a little over 43,000,000 whites, was recorded as 14.74 per 1000; while in a population of 6,752,000 colored, the recorded mortality was 17.28 per 1000. It is known that each of these recorded death-rates is much lower than the actual one, owing to failure to record the whole number of deaths occurring during the census year; but it is also known that the proportion of failures to record was decidedly greater among the colored than among the whites, and hence the difference between the death-rates of the two races is even greater than that indicated by these figures.

How far is this excessive mortality in the colored population due to race characteristics? Is it due to peculiar susceptibility on the part of the negro to certain distinctive forms of disease, or to his having less vital force and capacity to resist disease and death? Undoubtedly the great mass of the colored population is poor and ignorant, lives in the dampest and dirtiest parts of cities, and in the midst of unhealthy surroundings, and is in other respects unusually exposed to well-recognized causes of disease.

The statistics of 1880 show that the colored race is peculiarly liable to fatal results from certain forms of disease, especially consumption, pneumonia, diarrhœal diseases, affections of pregnancy, scrofula, and venereal diseases; and that, on the other hand, it is much less liable than the white race to fatal results from cancer, diphtheria, diseases of the nervous system, scarlet fever, and suicide.

Notwithstanding the interest and importance of the question, we have, at present, no sufficient data to determine whether the negro, under the same circumstances as to poverty, etc., is or is not more prolific or short-lived than the whites, and absolutely no data of any value for determining the relative fecundity and mortality of the mixed bloods, including mulattoes, quadroons, octoroons, etc. An effort will be made in the coming census to supply this deficiency as far as possible. In the enumeration of the population, those of mixed blood will be recorded separate from the pure blacks and the pure whites, and an effort will be made to obtain corresponding records of death in order to determine the death-rates of these mixed bloods. An effort will also be made to determine the birth- and death-rates of certain classes of poor and ignorant whites, such as the tenement-house population in our northern cities, as distinguished from those of the mass of the white population, which will give us a better means of comparison of the mortality of the two races, under comparatively similar circumstances, than we now have.[1]

In studying the causes of disease and death in communities, a very important point to be considered is the relative poverty, ease, or luxury in which different parts of the population live, or the sickness and death-rates of so-called social classes.

That extreme poverty, producing inability to obtain the amount of food, clothing, and shelter requisite to preserve health, is a direct cause of high death-rates, especially in northern climates, is known to all; but the extent to which this factor of want influences the death-rates in different countries or communities is by no means easy to determine, and thus far we have, for the most part, only data bearing indirectly upon this subject. For the provident, and presumably well-to-do, classes we have the statistics of life insurance companies; but these are for selected lives, which fact tends to give a low death-rate during the early years of the policy-holders; while, on the other hand, the tendency to cease paying annual dues and to give up the insurance is greater in those who are well and strong than in those who have reason to suspect that they are diseased, so that the death-rates in the greater ages are higher in the insured than in those not insured. We can only draw some inferences from the vital statistics of occupations, from tenement-house statistics, etc.; but it is very difficult to distinguish between effects of density of population, occupation, race, intemperance, uncleanly habits, and actual want of the necessaries of life.

One of the latest systematic attempts to enumerate the population of a city by social classes, and to obtain corresponding reports of deaths so as to give death-rates, is that made in Dublin by Dr. Grimshaw.

In this connection may be mentioned the statistics collected by insurance companies among the Quakers, or Society of Friends, both in England and in this country.

In 1830 Mr. Robert Ranking published a table showing the probability of life among the Society of Friends in the city of Bristol, England.

The superior expectation of life shown in this city led to the establishment of a Friends' Provident Insurance

[1] Dr. Berenger-Feraud, in a note on the fecundity of the mulattoes of Senegal, published in Revue d'Anthropologie, 2d series, vol. ii., 1879, p. 577, gives the details with regard to the offspring of 118 females of mixed blood, and concludes, 1st, that the union of a white man with a negress in Senegal produces children apparently of good health; 2d, the offspring of these mulattoes between themselves, when there is no further intrusion of pure black or white blood in the descent, give children who are usually sterile; 3d, when there is a new addition of white blood after the first generation, the offspring are less vigorous, the number of the girls becomes greater than that of the boys, and the girls are often sterile, with a strong tendency to abortion.

The data are insufficient to bear out any definite conclusions, and the above can properly be put in the form of questions only.

Institution in the following year, due to the belief that the members of this society had a superior longevity; but the parties concerned, with their usual business sagacity, did not invest money on a mere belief. They set to work and collected all the registers of Friends in different parts of the kingdom, with births and deaths, from which a table was prepared showing that at birth the expectation of life was:[1]

At 5 years	. . . .	41.8 years.
" 10 "	. . . .	45.3 "
" 15 "	. . . .	42.1 "
" 20 "	. . . .	39.2 "
" 30 "	. . . .	33.3 "
" 50 "	. . . .	21.2 "
" 60 "	. . . .	14.7 "

The tendency now is to accumulate the best and the worst of the race in the cities. They draw to them the most enterprising, vigorous and prudent, whose tendency is to late marriages and few children, and thus tend after a time to lower the standard of the race. Where the tendency is to replace a feeble and lower race by a better one, there is progress; where the tendency is the reverse, there is decay. The hope that by increased knowledge, charity, and coöperation, the feeble, the sickly, and incompetent can be so cared for that they shall become strong and vigorous, is that held by most men of the present day, but there is nothing in the laws of heredity which gives any foundation for this hope.

What is to be the outcome of this modern civilization? "Its enemies are not without, but within; not savage nations on its borders, but dwellers in its own cities." The general tone of modern European literature is pessimistic as to the future, filled with doubts and fears as to what the coming supreme democracy will do. In this country it is more hopeful, and looks forward to progress in improvement in the physical conditions of the race, though admitting the dangers and difficulties which this very physical improvement tends to produce. But, whatever be the views of individual thinkers and writers, on one point all can agree, and that is as to the desirability of having at our command definite, positive information as to the character, amount, and set of currents of this stream of human life in different countries and localities. An important part of such knowledge is that which relates to the composition of, and changes in, the population in different countries, which is the special field of vital statistics.

ORIGINAL ARTICLES.

DIRECT HERNIOTOMY.

With Reports of Cases.[2]

BY W. O. ROBERTS, M.D.,
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY AT LOUISVILLE.

DIRECT herniotomy, done with the view of effecting a radical cure, is a subject of such importance that I venture to give a brief abstract of the work of this kind that I have done during the past fourteen months.

The number of cases I offer is small, comprising a total of but ten, in which I did eleven operations. Seven cases occurred in females and three in males. Three were cases of umbilical hernia, three inguinal, and one ventral. Six of the operations were done during strangulation, while five were performed for troublesome, irreducible hernias.

In the six cases of strangulated hernia the sexes were equally represented; three were inguinal, two femoral, and one umbilical. In five of them the operation for radical cure was done; the remaining case was one of strangulated hernia, where stercoraceous vomiting existed for eight hours before it was seen. General peritonitis was evident at the time of the operation. Much blood-stained fluid escaped when the contents of the sac were returned. Death followed in thirty-six hours. I have since thought that if, after returning the contents of the sac, I had done a low median laparotomy and washed out the peritoneal cavity, the result might have been different.

The four cases of irreducible hernia were all in females. Two were umbilical, one femoral, and one ventral. In one of the former a second operation was made necessary by the hernia recurring at the end of six months. The tumor also re-formed at the end of ninety days in the case of femoral hernia. A second operation was not done here, because the patient has been able to get along comfortably with the aid of a truss. The remaining eight cases continue well to the present date. I have already stated that one of the cases died. The patients were aged, respectively, twenty-four, twenty-six, forty, forty-six, forty-eight, fifty, fifty-five, sixty-two, seventy-six, and eighty-four years. In the patient aged eighty four years the hernia was inguinal and strangulated, and though presenting on the left side, both the cæcum and appendix were found in the sac.

The following is a very brief description of the different procedures practised in the several cases: In each the sac was first cleanly dissected out and not opened until hemorrhage was entirely checked. Both in the ventral and umbilical hernias the integument and fascia were divided by an elliptical incision. After opening the sac all adherent omentum was tied with catgut and excised. The remaining contents were then returned into the cavity. In one case of umbilical hernia the neck of the sac was tied close to the margins of the opening and cut away immediately in front of the ligature. The stump was then fastened tightly in the opening with silkworm-gut sutures, and the wound finally closed by interrupted sutures of the same material. In this case no suppuration occurred, but, as already mentioned, the hernia recurred at the end of six months. In

[1] See Insurance Cyclopedia, vol. v. p. 144; also, table on page 147, comparing expectation of life of Friends with those of the general population, and showing a decidedly higher average for the former.

[2] Read before the Southern Surgical and Gynecological Association, at Nashville, Tenn., November 12, 1889.

both the other umbilical and in the ventral hernias, the neck of the sac was excised on a level with the abdominal opening and sutured with catgut. The opening itself, after its edges were freshened, was closed with the continued suture of chromatized catgut in the ventral hernia and aseptic corded silk in the umbilical cases. The superficial tissues were brought together by silk sutures, which were continued down to the aponeurosis.

In the femoral hernias I adopted the practice of Mr. Mitchell Banks, which consists in freeing the sac up to the crural ring, tying it with strong catgut, and then cutting it away. No attempt was made here to sew up the ring.

In the cases of direct inguinal hernia, after tying the neck of the sac just within the ring, and removing everything in front of the ligature, the ring was closed with catgut sutures.

In the cases of oblique inguinal hernia I did Mr. Ball's operation, which, I hardly need say, consists in freeing the neck of the sac up to the internal opening, ligating it, cutting away everything in front of the ligature, then twisting the neck upon itself to effect closure of the peritoneal orifice, and finally stitching the stump to the pillars of the ring to guard the neck against untwisting itself.

Drainage by tube was secured in one case only. In the remaining operations drainage was effectually accomplished through the lower angle of the wound, this being left open for the purpose. Suppuration proper followed in no case. A small amount of pus, strictly limited to a suture puncture, was observed in two cases only—one an umbilical, the other a ventral tumor.

A detailed description of the several methods now employed for the radical cure of hernia is unnecessary and foreign to the object of this paper. Using the most general terms, however, I may say that in the operations for umbilical and ventral hernias, the difference, in any practical sense, is, after all, but little. Ligation of the neck of the sac, stitching it when excised, plugging the aponeurotic opening with the sac, closing the opening with sutures, really covering the several operations. The suture material itself is somewhat more varied, embracing chromatized catgut, kangaroo tendon, silk, and silver wire.

There is a greater diversity of practice when inguinal and femoral hernias are the subject of operation. Here, in order to close the internal opening, ligatures, sutures, twisting the neck of the sac, and tucking the sac into the orifice are used; while as to the sac itself, it is removed or left undisturbed after dividing it in front of the ligature, or sutured or quilted to the pillars of the external ring. The manner of dealing with the ring also varies. Some surgeons suture it, others leave it without sutures, while others split the entire canal and plug it with iodoform gauze, that it may close by granulation. Of one and all of these procedures it may truly be said that the prime object is to effect adequate closure of the abdominal orifice of the sac, and, by means of the needed plastic material, impart to it the strength and solidity necessary to keep it closed. The operation done and recovery effected, the question of whether the parts should be reinforced by a truss arises; and here again practice varies, some surgeons asserting that the pressure of the truss causes absorption of the inflammatory exudation, and thereby increases the probability of recurrence of the hernia; while others are equally positive that such is not the fact, but that a properly adjusted truss unquestionably tends to prevent the tumor re-forming. In a single word, however, it may be safely said that whatever operation selected, and however skilfully executed, a considerable percentage of relapses occur, and there is no procedure which is wholly devoid of danger.

I will now give an abstract of the several cases to which I have referred in the foregoing:

Case I.—Mrs. D., aged fifty-five years. Right femoral hernia for ten years. Became strangulated forty-eight hours before I saw her, vomiting from the beginning, and stercoraceous for the past eight hours. Great abdominal distention and tenderness. Temperature 101°; pulse 120; skin clammy. Herniotomy at 1 P.M., June 1, 1889; Drs. Clemmons and Chenowith assisting. Tumor small. Knuckle of intestine completely filled the sac and so adherent as to require great care in its separation. The knuckle, though quite dark in color, was not gangrenous. When it was returned a considerable quantity of reddish fluid escaped from the peritoneal cavity. This led me to leave the neck of the sac open and introduce a rubber drainage-tube into the peritoneal cavity. The vomiting soon ceased, but diarrhœa with copious green stools followed, and death occurred thirty-six hours later.

Case II.—Mrs. H., aged fifty years, suffered with a left femoral hernia for two years. Never wore a truss. Tumor descended only after violent straining, until now patient had been able to effect reduction without difficulty. Strangulation occurred June 10, 1888—thirty-six hours before I saw her; stercoraceous vomiting for the last six hours of the time. Slight abdominal distention; no tenderness. Temperature normal; pulse 112. On exposing the sac I found the condition of the hernial contents similar to those of the preceding case, though very little fluid escaped from the peritoneal cavity after the return of the hernia. The neck of the sac was ligated close to the femoral ring and the portion in front of the ligature excised. Recovery good. No recurrence up to date. Patient of Dr. Cox, of Cox's Creek, Ky.

Case III.—Mr. G., aged eighty-four years. Left inguinal hernia for past forty years; always used a truss. Hernia became strangulated June 30, 1888, twelve hours before I saw him. No stercoraceous

vomiting; temperature normal; pulse 78. Contents of sac: cæcum, appendix cæci, and a small knuckle of ileum. Patient still living, with no recurrence. Patient of Drs. Grant and Palmer.

CASE IV.—Mrs. I., aged sixty-three. Umbilical hernia of ten years' standing. Had been strangulated ten hours before I saw her. Contents of sac: intestine and omentum, the latter adherent to the sac. Recovery; no recurrence. Patient of Drs. Grant and Palmer.

CASE V.—Mrs. B., aged fifty-two years. Large irreducible right femoral hernia of five years' standing. The tumor had been increasing in size for two years, and was so painful as to incapacitate her for her household duties. Operated August 15, 1888; recovery. Recurrence of hernia the latter part of the following November. She declined a second operation, but has gotten along comfortably since with the aid of a truss. Patient of Dr. E. L. Pearce.

CASE VI.—Mrs. J., aged fifty-eight years. A small, irreducible umbilical hernia of one year's standing; very sensitive to touch. The patient had colicky pains whenever she attempted any kind of work. Operated December 19, 1888. Contents of hernia: omentum, which was adherent to the sac. Hernia returned eight months after. A second operation on July 3, 1889. No recurrence to date. Assisted by Drs. Pearce and Evans.

CASE VII.—Mr. M., aged twenty-four years, had a small, oblique, inguinal hernia occurring after a violent muscular effort in January, 1889. It was replaced and gave no further trouble until the following March; while he was straining at stool it descended. Three hours after the protrusion occurred he came to the University, being in great pain. He had not vomited. The tumor was about the size of a hen's egg and quite tense. Failing to reduce it under chloroform and aspiration, I operated. The sac contained a small quantity of reddish serum. Immediately after the operation the patient was taken in a conveyance three and a half miles, where he came under the care of another physician, who reported a quick recovery. The further history of the case I do not know.

CASE VIII.—Mrs. T., aged thirty-three years; weight 212 pounds; married, but no children. Had ovariotomy performed in 1883. At the lower end of the cicatrix a small hernial protrusion formed soon after the patient began going about. This steadily increased in size, in spite of many appliances. In April, 1889, the tumor had reached the size of a small cocoanut, and the abdominal cicatrix was stretched almost to the last degree. On April 15, 1889, I did herniotomy. I have previously told how the operation was done. Recovery complete; no recurrence to date. Assisted by Drs. Pearce and Evans.

CASE IX.—Mrs. M., aged sixty. An irreducible, umbilical hernia, of the size of a hen's egg, and of one year's standing; sensitive to touch, and quite painful when the patient did any manual labor. On September 29, 1889, I performed herniotomy. Contents of sac: omentum and knuckle of intestine, the former adherent to the sac. This operation has also been described. Uninterrupted recovery; no recurrence. Assisted by Drs. Pearce and Evans.

CASE X.—Mr. B., aged seventy-six; butcher by occupation. Had to give up business two years ago because of a troublesome right inguinal hernia. The hernia was strangulated in March last, but reduction was accomplished under chloroform six hours before I saw him. October 6, 1889, the hernia became strangulated. A faithful attempt at reduction under chloroform failing, an operation was urged, but declined. The following day the patient decided to have it performed. I did herniotomy forty hours after strangulation set in. Contents of sac: composed of a large knuckle of intestine, which was very deeply congested. There was about one-half an ounce of a reddish fluid and blood-clot in the sac. This operation I have described elsewhere. The patient, because of an enlarged prostate, could only urinate while standing; yet recovery took place without an untoward symptom. He made a quick recovery. No recurrence has yet taken place. Assisted by Drs. Rodman and Howard.

PRELIMINARY OBSERVATIONS ON THE MICRO-ORGANISM OF TEXAS FEVER.[1]

BY THEOBALD SMITH, M.D.,
OF THE BUREAU OF ANIMAL INDUSTRY, WASHINGTON, D C.

SOUTHERN cattle fever, or Texas fever, as it is more popularly known, is an infectious disease of the malarial type. The infectious agent, bound to a particular locality, is only temporarily transferred by cattle to places free from permanent infection. During the past summer healthy cattle brought from North Carolina, late in June, infected a small enclosed patch of pasture at the Experiment Station of the Bureau of Animal Industry. Of the native cattle placed in this enclosure at the same time, the first died late in August. Up to the last week in October, ten had succumbed to the fever and two recovered. The territory, even after the Southern cattle had been removed, was still capable of infecting fresh animals placed upon it. There was also a continual increase or accumulation of the virus in the enclosure, for the animals placed on the ground late in the season died after an exposure of but one-half or one-third the period which was necessary to destroy those exposed since early summer. The infection did not spread beyond the enclosure.

The first indication that the disease had entered the system and was there unfolding its destructive activity, was a continuous high temperature fluctuating very slightly and subsiding only when death or recovery ensued. The temperature rose from 101°–102° F., to 106°–107° F., and in the fatal cases remained high from four to fifteen days. After a variable number of days, the high temperature was accompanied by general weakness lasting but a few days, when death ensued. Had it not been for

[1] Read at the Brooklyn Meeting of the American Public Health Association, October 23, 1889.

the thermometer, the early stages of the disease would have remained unnoticed.

A few days before death, the urine became more or less deeply colored with hæmoglobin, and in nine out of ten cases the bladder after death contained deeply tinged urine. In the tenth case, hæmoglobinuria was present three days before death. The destruction of red globules causing this condition could be easily demonstrated by examining blood taken from an incision through the skin. In several cases, on the day before death,[1] the number of red globules had fallen to about one million in a cubic millimetre of blood, the normal being about five million. In one case, now recovered, the corpuscles were reduced in number nearly one-half several days before the temperature fell to normal, and a week later the number had not yet risen to three million. This enormous loss of red globules gave the blood an exceedingly thin, watery appearance.

At the autopsy, beside the condition of the blood as noted, it was found to coagulate rapidly and form clots of unusual firmness. Large clots in the ventricles of one animal which had died during the night cut like liver tissue. The following description of the most obvious lesions will apply with more or less emphasis to all ten cases:

The spleen is enlarged to several times its normal size. When incised, the tense capsule retracts and discloses a dark-red more or less disorganized pulp, occasionally running out as a semi-liquid mass. This engorgement is due chiefly to the presence of an enormous number of red globules. The liver is the seat of considerable disturbance. Its color is a yellowish-brown. The parenchyma is deeply bile-stained, and when examined under the microscope the finest bile canaliculi are found plugged in many cases with consistent, cylindrical masses of bile. We have, in fact, a complete pathological injection of the intra-lobular biliary system. The liver cells show more or less fatty degeneration. The bile in the gall-bladder is usually so thick that it scarcely flows. This is due to the presence of a large amount of solids in the form of minute yellow flakes. There is no obstruction to the flow of bile into the duodenum. The kidneys are in some cases suffused with the color of hæmoglobin, and the connective tissue around them distended with reddish serum. In some cases they are but slightly affected. The small quantity of albumin found in the urine may be accounted for by the hæmoglobin.

Lesions of the fourth stomach and intestines were either absent, or else did not differ much in degree from those observed in healthy cattle. In one case there were superficial ulcers in the fourth stomach. A more or less extensive ecchymosis of the duodenum is occasionally met with, more rarely in the cæcum. In none of the ten cases examined was there any appreciable jaundice.

I am fully aware that these facts, in much greater detail than my experience or my time will allow me to present them, have been before the public since 1868. My reason for bringing them up again is to connect the observations on the etiology to follow with certain definite characters of a definite outbreak, so that there may be no question raised in the future as to the nature of the disease from which the following facts were derived.

In investigations of this nature it is very desirable that all theories which may account for the disease process should be carefully tested. But the quantity of work to be done, if all are to be exploited at the same time, is so great that the work probably would end in a muddle. To the student of Texas fever several theories clamor for attention. First, it would not be out of place to do as some observers have done, and locate the cause of the disease in the organ most affected, such as the liver, and refer the destruction of the blood elements to the reabsorption of bile from that organ. This theory, however, does not seem tenable, because the visible sign of the reabsorption of bile, jaundice, is not constant in Texas fever and did not appear at all in the cases upon which our investigations are based.

If we make the destruction of the red corpuscles the starting-point of our theory, we have two alternatives before us. The specific germ may multiply in the digestive tract and there produce a ptomaine capable of dissolving red corpuscles when absorbed into the circulation. Those who are acquainted with the researches of Stadelmann, and more particularly Afanassiew, in Germany, will see the pertinence of this theory. These observers produced in dogs nearly all the lesions which I have mentioned as characteristic of Texas fever, by feeding varying doses of toluylene-diamine. The absorption of this poison caused rapid destruction of the red corpuscles followed by the injection of the bile canaliculi with thick bile, by jaundice and hæmoglobinuria. The other alternative would assume that the red corpuscles are destroyed by organisms in the blood itself. It will be seen on a little reflection, that to test the truth or falsity of these hypotheses would require diverging lines of research, especially when we bear in mind that there may be disease germs which can only be detected with the microscope.

In order to understand the results obtained from the investigations conducted in the laboratory of the Bureau of Animal Industry, it will be best to give a brief summary of the latter. In the summer of 1886, two spleens taken from animals which had died of Texas fever in Virginia came to the laboratory. Cultures from one gave a variety of bacteria.

[1] Several animals were killed in a dying condition.

From the other all media remained sterile. At the same time the following observations were recorded.

In or on many red corpuscles there are small round bodies, perhaps 1 μ in diameter, centrally or somewhat excentrically situated, which stain poorly in an aqueous solution of methyl-violet, very well in aniline-water methyl-violet. They then resemble micrococci in size and form. Unstained, they can be seen as mere transparent spaces in the corpuscles.

No opportunities were presented for the further study of the disease within reach of the laboratory until the summer of 1888, when an outbreak in Maryland, about fifty miles from Washington, furnished the material. Five cases were found in a condition fit for study, and various organs were taken to the laboratory in refrigerator cans designed especially for such a purpose.

From these, numerous cultures were made on different substrata, while the organisms of the intestinal tract likewise received due attention. In general, cultures from the spleen, kidneys, and urine remained sterile. From the digestive tract were obtained, almost pure, roll and plate cultures of a microbe probably identical with Escherich's *bacterium coli commune*. This organism was occasionally present in the liver and bile and very rarely penetrated into other organs in very small numbers.

During the outbreak studied this summer my time and attention were diverted into another channel. Cultures were made, however, from at least five cases upon such substrata as blood-serum, agar, glycerin agar, and bouillon peptone, with the same negative result. While cultivation demonstrated the absence of bacteria from the blood and internal organs, the microscopic examination was equally fruitless.

The negative outcome of bacteriological work in 1888, combined with a careful study of the pathological changes in the organs which came to the laboratory at that time, led to the inference that the disease must be due to a blood parasite which could only be detected by the microscope. It thus became essential to have the disease within reach of a laboratory, so that the blood could be carefully studied during the course of the disease, and the material from the internal organs obtained absolutely fresh. These conditions were fulfilled in an admirable manner, as you have seen, and the outcome has been the discovery of what we believe to be an organism within the red corpuscles of the blood. The intra-globular bodies observed in 1886 were found in all the ten fatal cases of Texas fever. It might be asked, Why was the organism not found in 1888? I would reply, that, owing to the condition of the material, I could place no reliance upon the studies of the blood elements, which even under the best conditions are very difficult. Hence no attention was paid to this subject, the time being devoted to bacteriological studies. In these days it is necessary first to demonstrate the absence of bacteria before other results are credited. I may say, however, that preparations from one of last year's cases, re-examined a few days ago, showed the intra-globular bodies as distinctly as could be desired, but in numbers too small to be detected by any but the forewarned. The observations thus far made upon the intra-globular bodies may be very briefly summarized.

In fresh spleen pulp they are visible as round or oval, nearly colorless spots from ½ to 2 μ in diameter on the disk of the red corpuscles, and always somewhat excentrically placed. Careful focussing leaves no doubt that they are within the body of the corpuscle. There may be but one, quite commonly two, and very rarely three, or four, in the same corpuscle. In organs kept in the cold for nearly two weeks they were still visible, but faintly, owing to the diffusion of the hæmoglobin around and perhaps into them.

When cover-glass preparations are dried, heated, and stained with the ordinary aniline dyes, these intra-globular bodies stain as readily as nuclei and bacteria, and hold the stain with a similar tenacity.

The smallest forms then appear like deeply stained cocci, about ½ to 1 μ in diameter, situated within the unstained circle of the corpuscle. Occasionally the bodies are nearer 2 μ in diameter, and then the staining may be less dense. Besides the spherical forms, ovoid forms are not uncommon. These usually occur in pairs within the same red corpuscle. A still rarer, pear-shaped form, is encountered in stained preparations of the blood. It is rounded at one pole, while the other is pointed and sometimes drawn out as a short filament. These forms quite invariably occurred in pairs, a corpuscle being occupied by a single pair. I am very much inclined to consider the pair as the result of a division of the single body within the globule. In one instance I saw the tapering ends of a pair apparently continuous. Each body was about 3 μ long; its greatest width, 1.5 μ. These are the largest I have encountered. This same pear-shaped form I have only seen in cover-glass preparations made from blood during life.

That these parasites have the power of changing their form I cannot affirm from direct observation. The following illustration seems to indicate that they may. In one of the animals attacked the disease ran a brief, acute course. It was killed when the rapidly falling temperature and the inability of the animal to rise indicated death before the next morning. The spleen and liver were flooded with the intraglobular bodies. Perhaps every fifth corpuscle contained a pair. Cover-glass preparations, dried at

the autopsy, showed the ovoid bodies very well. The kidney, for want of time, was placed in the cold. Twelve days later it was still in good preservation and preparations made at that time showed a large number of intra-globular bodies in pairs, but round. It is highly probable that they changed their form in the cold.

One other abnormal form found in the blood deserves mention. When dried cover-glass preparations are stained in Loeffler's alkaline methylene-blue, a few red corpuscles appear as if their surfaces had been dusted over with minute specks of coloring matter. Whether they are due to the anæmia, or whether they belong to the cycle of the parasite, remains to be determined experimentally.

As to the relative number of intra-globular bodies in the different organs of the same animal, the ten cases which have come under observation afford some noteworthy facts.

As a rule, there are very few in the circulating blood, whether taken from incisions through the skin before or during the death-agony, or from the heart after death. There are exceptions to this rule, however. In one case they were readily detected in the blood from a skin incision one day before the animal was killed. Blood from the right ventricle showed an enormous number of these bodies, in pairs, within the red globules.

As a rule, then, the circulating blood contains comparatively few parasites. They are filtered out by the spleen and the liver. They may be numerous in one or both of these organs, and practically absent in blood from the right ventricle. They are somewhat more numerous in the spleen than in the liver. This estimate may, however, be erroneous, owing to the larger number of corpuscles in the spleen pulp. I paid but little attention to the blood in the kidney. In two cases in which a very large number of parasites were found in spleen and liver, they were likewise very abundant in the kidneys. The red marrow of the ribs examined in four cases contained none.

There are also a few facts at hand concerning the relative number of parasites in different animals at the time of death. In perhaps one-half of the cases they were so few in number in the spleen that they might have easily escaped the attention of an observer searching for bacteria. In four out of ten cases the organisms were very numerous in spleen and liver, and could not well be overlooked. I found myself able to see them in a thin layer of fresh spleen pulp, with a dry apochromatic objective giving a magnification of not more than 250 diameters. In one case they were so few in number, even in spleen pulp, that a number of fields had to be scanned before any were detected. In this case the spleen was completely disintegrated. The urine, containing much hæmoglobin several days before death, was found of nearly normal color at the autopsy. The animal had evidently overpowered the parasites, but died from the havoc caused by them.

Concerning the transmission of the disease from cattle to other animals, we have only the following experiment to report: Spleen pulp from a steer just killed, and containing very many intra-globular bodies, was stirred up in sterile salt solution, and of this red liquid 1½ cubic centimetres were injected into the ear-vein of each of three rabbits. They remained permanently well.

The question now arises, What is this organism? We have seen it in but two recognizable forms, the sphere of slightly varying diameter, and the oval, pear-like form. I have already said that I believe these to be one and the same form, the latter a stage of division. This may or may not be true. The difficulties surrounding the direct observation of these minute bodies are very great, and we may have to rely upon indirect methods for more information. It might be argued that they belong to embryonic or degenerated red corpuscles. That they do not belong to embryonic forms I have been able to convince myself by examining the red marrow of the ribs, where the production of red corpuscles to take the place of the destroyed ones is very active. That they are not elements of degenerated corpuscles is too evident from what has been stated to require further discussion.

As to the true nature of the organism only conjectures are possible at this stage of the inquiry. It may be a phase in the life history of some of the lowest mycetozoa, such as the monadineæ, or it may belong to the group of sporozoa, some of which are pronounced cell parasites. As to the external characters of the disease, we have still to learn how the southern cattle carry the disease-germs while they themselves are immune, how the germs multiply on the pasture, and how they enter the susceptible organism of northern cattle; and whether or not they are ever eliminated from the diseased body to become a fresh centre of infection. These problems are intimately associated with the life-history of the parasite, and will finally be solved when its life is thoroughly known. They are the most important from an economic standpoint, and their solution will without doubt throw a strong light on human malarial diseases.

I think that we may safely formulate a simple definition of this disease with the aid of the foregoing observations. It is essentially a blood disease. There is a continuous or paroxysmal destruction of red blood-corpuscles due to an intra-globular parasite, and the disease results mainly from the incapacity of the internal organs, primarily the liver, secondarily the spleen and kidneys, to transform and re-

move the waste products resulting from such destruction. In milder cases the protracted anæmia, which results from the loss of corpuscles, may become the chief cause of exhaustion and death, even when the organs remain pervious and capable of carrying on their respective functions.

I have purposely omitted in this brief sketch, to refer to the former investigations of Texas fever. I need simply to say that as far as my own have been carried they contradict the results of those who claim to have found germs which can be readily cultivated. Their claims are just, so far as the finding of germs is concerned, but I do not doubt that they all have a *post-mortem* history, and that the investigators have been hampered by difficulties which it was impossible to overcome. There seems to be nothing which literally breeds bacteria so rapidly as a dead body in midsummer.

In conclusion I wish simply to mention a few facts already on record, bearing directly upon what has been claimed in this paper. In glancing over the very excellent report of Dr. Stiles to the New York State Board of Health, in 1867, I find the following statement:

"The red blood-corpuscles when examined immediately after removal from the body were shrivelled and crenated without artificial provocation. In one case many of the disks appeared to have lost a portion of their substance, as if a circular piece had been punched out, the addition of water failing to restore the disk to completeness."

I am convinced that Dr. Stiles had before him the intra-globular bodies, which must have been very abundant to call forth this statement. His description applies exactly to the appearance which was presented by these bodies in a few cases, more particularly when the bodies were relatively large. At that stage of our knowledge it was entirely excusable for Dr. Stiles to pass these bodies by without further attention.

In Virchow's *Archiv.* for January, 1889, V. Babes describes an enzoötic disease among Roumanian cattle along the banks of the Danube, which he calls epizoötic (*seuchenhafte*) hæmoglobinuria. The disease has many features in common with Texas fever, and many peculiar to itself. Toward the end of his investigations, made in the summer of 1888, Babes settled upon an intra-globular parasite as the probable cause of the disease. This he also found in masses outside of the blood-corpuscles in the œdematous hemorrhagic infiltrations about the kidneys, stomach, and intestines. He describes it as a diplococcus, is able to cultivate it, and produces in rabbits by subcutaneous injection a disease fatal in from 1½ to 2 weeks. Without going into detail, I am inclined to consider this parasite, as described by him, quite different from the one found in Texas fever. The Texas fever organism has thus far failed to multiply in culture media. Its appearance did at no time suggest the characters of bacteria. It has not been found outside of red blood-corpuscles in any appreciable numbers. Inasmuch as both his and our investigations must be regarded as just begun, the future will have to decide how near of kin these two diseases are.

THE TREATMENT OF HYPERTROPHY OF THE LINGUAL TONSIL.

BY RALPH W. SEISS, M.D.,

ADJUNCT PROFESSOR OF OTOLOGY IN THE PHILADELPHIA POLYCLINIC; LECTURER ON PATHOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.

MUCH attention has been lately called to this condition, its frequent association with grave respiratory neuroses having attracted the notice of many able observers. Pathologically, it consists of an overgrowth of the glandular tissue at the base of the tongue, accompanied by a varicose condition of the neighboring veins. The new-formed tissue appears to be identical in structure with that found in so-called hypertrophy of both the faucial and pharyngeal tonsils, and may be described as hyperplastic adenoid tissue resulting from chronic *lymphadenitis*.

According to Lennox Browne, the cause is to be found in a general or local vaso-motor neurosis, associated, in females, with menorrhagia or amenorrhœa, and in a similar condition the result of alcoholism. The writer has found lingual tonsillitis to be very common in the over-worked and under-nourished, and quite frequent in patients in whom the gouty diathesis was markedly present; the immediate cause may be said to be dependent on a low bloodvessel tone, combined with a condition of chronic inflammation of the lymphatic tissue from various causes.

Very diverse and sometimes alarming symptoms have been noted by different writers. Gleitsmann mentions the sensation of a foreign body in the throat, *globus hystericus*, interference with voice, pain radiating from the throat, cough and asthma. Alarming dyspnœa and serious interference with deglutition, leading to profound depression of the general health, have been noted by the present writer and others.

It may be here mentioned that Dickson[1] considers varicosity of the ranine and lingual veins a diagnostic sign of value in relation to hemorrhagic lesions of the brain and cardiac weakness. Varicose veins in this situation are, in my experience, also associated with extreme frequence with "irritable heart" and general "neurasthenia."

The diagnosis of this disease depends on a thorough examination with the laryngeal mirror; the tongue is to be drawn well forward, and the glass

[1] Brit. Med. Journ., May 2, 1885, p. 888.

introduced with its lower edge held more forward than when making an ordinary laryngoscopic examination. Hypertrophy of the circumvallate papillæ, associated with dyspepsia, must not be mistaken for the affection we are considering; the lymphatic tissue is situated below the papillæ, at the very base of the tongue, in the glosso-epiglottic fossa. Greatly dilated vessels of a purple or blue color, and often above two millimetres in diameter, will be found radiating in a fan-like arrangement from the fossa over the base of the tongue, the lingual surface of the epiglottis, and the lateral pharyngeal walls. The hypertrophied lingual tonsil may encroach on the epiglottis to such an extent as seriously to hinder its movements and wholly fill up the epiglottic fossa; the two sides may also be unequally affected, and present the brawny look so characteristic of overgrowth of the *pharyngeal* tonsil. In very marked cases the epiglottis appears to be *imbedded* in the base of the tongue, and pressed backward so as to render laryngoscopy very difficult. In a case lately seen by me it was hard to pass an applicator down between the lingual surface and the epiglottis, even with the tongue drawn forward to its fullest extent. The condition is found generally in adults, and most frequently in women, commonly in individuals of poor physique and nervous temperament, who also suffer from rhinitis of advanced sclerotic type.

The above sketch seems to be a fair exposition of our knowledge of the pathology of this interesting subject; more extended observations as to its etiology are, however, much needed.

The results of *treatment* are very satisfactory, but the successful management of the disease calls for a considerable amount of manipulative care to secure good results. As to constitutional remedies, Delavan has obtained most excellent consequences from the administration of small doses of mercury combined with iodide of potassium; when associated with indigestion, he administered "the old-time mixture of rhubarb and soda." Strychnine, preferably given by hypodermatic injection, is advocated by many, and all writers advise tonics in one or another form. It is my habit to prescribe full doses of ammonium chloride and sodium bromide, five grains of the former and ten of the latter salt, three or four times daily. General faradization, regulated bathing, the use of the "salt towel" and similar frictions, and properly directed open-air exercise, are the best measures at our command for restoring vaso-motor tonus. The condition of the digestion must be carefully looked after, and long hours of rest and sleep should be insisted upon, if satisfactory progress is to be secured.

In a case of lingual tonsillitis lately under my care, in which paroxysmal dyspnœa, great emaciation, and blood-spitting were prominent symptoms, the difficulty of deglutition was so extreme, and the exhaustion so profound, that systematic feeding with fluids only was required for some months, the patient finally recovering perfectly. The administration of solids must be begun with extreme caution in such cases, as a serious attack of spasmodic dyspnœa may follow an unguarded indulgence, and the depressing effect of such a seizure on the patient, both physically and mentally, can scarcely be exaggerated. Fortunately such grave neuroses are but seldom found, and in milder cases it is sufficient to regulate moderately the diet. The great importance of the psychical element in these individuals must be remembered, and the patient's mind set at rest, so far as possible, regarding his condition.

Local treatment can only be properly carried out under the guidance of the laryngeal mirror and with approved apparatus. If the hypertrophied tissue is small in amount, applications of iodine, menthol, and thymol, in alcoholic solution or in glycerine, made directly to the diseased glands by means of a curved applicator or forceps, have an admirable effect in controlling symptoms and decreasing the size of the growth. Menthol—ten to thirty grains per ounce of alcohol and glycerin, equal parts—has been somewhat largely used by the writer in cases of dyspnœa and dysphagia, associated with lingual and faucial tonsillitis, with very gratifying consequences. The applications must be made directly to the diseased areas with great care, as, should the solution enter the larynx, alarming, possibly fatal, laryngeal spasm might result. Personally I prefer a light, curved forceps, in which a well-rounded pellet of cotton, saturated with the medicament, is firmly held; the patient holding his own tongue, the laryngeal mirror is introduced with the left hand, and the application rapidly made, under full inspection, with the right.

If the new growth be more advanced and dense in structure, very guarded applications of chromic acid, made only to a very small area of the hypertrophied tissue, or light touching with the curved galvano-cautery knife, at only a dull-red heat, are advocated. When the mass is of large size Gleitsmann uses his cautery snare, and removes it bodily. Whatever means be employed, the extreme tendency to hemorrhage and reactive inflammation of the organ operated upon should not be forgotten. The impossibility of carrying out antiseptic measures in this locality also adds greatly to the dangers of operative procedure, which should, consequently, never be attempted until all milder measures have been thoroughly tried.

All instruments can be used without pain to the patient under cocaine anæsthesia, repeated pencillings with a five per cent. solution being made at intervals of two or three minutes for some ten min-

utes before the operation. The after-treatment consists of the use of antiseptic and sedative gargles, or, far better, of the employment of similar solutions in the down-curved laryngeal atomizer. The tongue is drawn far forward, the instrument introduced, and the glosso-epiglottic fossa thoroughly washed out; this is also an admirable method of applying medicines to the diseased glands, prior to operative interference, in treating lesser degrees of adenoid overgrowth. Whichever therapeutic measure is adopted, the close relationship between *nasal* and pharyngeal disease must be borne in mind by the surgeon, and careful treatment directed to the nasal cavities must always precede operative steps. Especially are those rhinal conditions accompanied by the trickling of morbid secretions into the lower pharynx apt to be associated with advanced disease of the lingual tonsil, and in many cases the latter condition can be effectually controlled by treatment directed solely to the nares and pharyngeal vault. The well-known relationship of intra-nasal disease to inflammation of the *faucial* tonsils, and its close association with impaired vaso-motor tonus,[1] should be remembered in considering the etiology of lingual tonsillitis. The cause of tonsillar inflammation following nasal disease depends on the function of the tonsils being, in large part, to absorb the unused saliva, together with other faucial and pharyngeal secretions. Morbid and septic products are, of course, absorbed along with those of a normal character, inflammatory changes in the lymphatic tissue resulting. Not infrequently the source of the septic secretion will be found in obscure chronic laryngo-bronchitis of mild type, treatment of which is essential to the improvement of the patient's condition. Ten years ago Cohen noticed that enlargement of the lingual glands was not uncommon in *chronic laryngitis*, and gives an illustration of the condition in his classical work.[2] It is more than probable that the lingual tonsil shares with other "lymphadenoid" tissue the physiological property of absorbing waste secretions, and lingual (as well as faucial and pharyngeal) tonsillitis is best accounted for by so plausible a theory.

Hot vapor inhalations of terebene, creasote, and compound tincture of benzoin, in combination, have a very satisfactory influence in controlling the laryngo-bronchial affection, and, secondarily, the lingual disease. It has certainly been the writer's experience that these cases improve far more rapidly and permanently under the proper local treatment of the nares, pharynx, and laryngo-bronchial mucous membrane, along with the vaso-motor tonic measures, than under any therapeutic means directed only to the local disease or the general anæmia.

The greatly dilated veins so characteristic of the disease we have considered, I regard as symptomatic both of some "central" vaso-motor pathological condition and of the local inflammatory changes, and therefore calling for special direct treatment in rare instances only. In this connection it may be recalled that Browne[1] and others have noted slight enlargement, or at least congestion and sensitiveness to touch, of the *thyroid gland*, and, on palpation, the peculiar thrill of venous congestion, in this class of cases. Varicose veins in other regions of the body are also often present, and are "concurrent evidences of the dyscrasia."

CLINICAL MEMORANDA.

PATHOLOGICAL.

Sarcomatous Kidneys in an Infant.—On December 16, 1889, I delivered a woman, after great difficulty, of a dead male child, with an enormously distended abdomen, but otherwise well formed. From external examination, the distention was apparently caused by some solid organ or growth. The mother, though small, was well formed and healthy, has one healthy child six years old, personal and family history of mother and father good.

Autopsy: Weight of child twelve pounds. The distended abdomen was found to be due to large kidneys, whose external surfaces resembled fœtal kidneys in being slightly lobulated. One weighed a few grains more, and the other a few grains less than fourteen ounces avoirdupois. They were highly œdematous, and when cut, an inodorous, yellowish serum exuded, and continued to ooze until the organ was reduced to two-thirds of its former bulk. The renal substance was very spongy, and had the appearance of being made up of a reticulum of connective tissue, containing fluid in the interstices; the bladder contained no urine, neither was there any fluid in the pelves of the kidneys. It was not determined whether the ureters were patulous or not. All the other abdominal organs were apparently healthy. I failed to find, after careful and repeated microscopical examination, tubules or Malpighian bodies. Professor A. J. Ochsner, of the Pathological Laboratory of the Rush Medical College, Chicago, to whom one of the bodies was referred, writes: "The tumor is a sarcoma, but sufficient kidney substance is preserved to excrete sodium urate and uric acid crystals, which show in different portions of the section" (which he sent to me).

I. N. Danforth, in an article on "The Evolution of Cystic Kidney" (*Journ. Amer. Med. Assoc.*, October 20, 1888, p. 541), says: "At rare intervals an infant is born, or is instrumentally delivered, with an enormously distended abdomen, due to the fact that the kidney has been converted into a congeries of cysts. . . They are regarded, and probably correctly, as a peculiar form of cystic degeneration of the Malpighian bodies, but occa-

[1] The Throat, etc., 2d ed., p. 208.

casionally the convoluted tubules appear to be involved. . . The process probably begins during intrauterine life. . . The disease usually invades both kidneys."

Virchow claims that the cause is from an inflammation of the straight ducts, an embryonic nephritis. The walls of the ducts adhere, and the urine cannot escape from the kidney.

Roberts says: "Congenital cystic degeneration almost always involves both organs. . . Generally there is more or less increase of connective tissue. . . Occasionally the kidneys present a spongy or cavernous appearance on section, and the cysts are only visible on microscopical examination."

These extracts very plainly describe the conditions present in my case. Owing to the skrinkage of tissues during the hardening and staining process, the section sent me by Professor Ochsner shows the cellular elements very differently from the appearance of a fresh specimen.

I would add that neither during labor nor following the birth of the child did I detect the escape of any amniotic fluid. It was, emphatically, a dry birth. There was an excessive amount of vernix.

E. H. KING, M.D.

WEST LIBERTY, IOWA.

MEDICAL.

Note on the Treatment of Typhoid Fever.—During the past nine years one hundred cases of typhoid fever have been under my care. Doubtful and abortive cases are not included. With the exception of perforation and peritonitis, most of the usual accidents and complications have been observed. Prolonged rest and liquid food were always ordered, but these orders were not always obeyed. A temperature of 104° was nearly always reduced by means of internal antipyretics (quinine or phenacetine) in moderate doses.

Cold baths were not used in any case, and the so-called specific and antiseptic treatments were not attempted. No routine treatment, except the use of antipyretics in cases with a very high temperature, was employed. Violent symptoms were treated by means of the ordinary palliative remedies, and, for the most part, the cases were let alone. Stimulants were used very sparingly, and only in a few of the more serious cases. The rate of mortality was just two per cent.

The two fatal cases were both in very corpulent women, one aged sixty and the other about thirty-five years. The former died of heart failure, and the latter of "the direct severity of the disease" with coma.

From a very careful study of the cases, it seems to me probable that antipyretics carefully used in selected cases are not entirely without value. The results obtained seem to throw grave doubts on the utility of certain special modes of treatment which are advocated with so much noise in certain quarters. It is somewhat doubtful whether the mortality of typhoid fever, as observed in general practice, can be reduced much below two per cent. by means of cold baths, or, for that matter, by any other means.

O. H. MERRILL, M.D.

CORINNA, MAINE.

MEDICAL PROGRESS.

Prescriptions for Dysmenorrhœa.—For the relief of mechanical dysmenorrhœa, PROFESSOR GOODELL recommends the following mixtures:

℞.—Bromide of ammonium . . . ʒij.
Bromide of potassium . . . ʒiv.
Aromatic spirit of ammonia . . fʒvj.
Camphor-water, sufficient to make fʒvj.—M.

Of this, from a dessertspoonful to a tablespoonful may be given every two or four hours.

℞.—Aromatic spirit of ammonia, Spirit of nitrous ether āā fʒj.—M.

From a teaspoonful to a dessertspoonful every two to four hours.

℞.—Chloral . . . . . ʒij.
Bromide of potassium . . . ʒiv.
Camphor-water . . . . fʒvj.—M.

One tablespoonful every two to four hours.

If nerve prostration is marked, he considers a pill composed as follows very valuable:

℞.—Arsenious acid . . . . gr. $\frac{1}{10}$.
Dried sulphate of iron, Extract of sumbul . . āā gr. j.
Asafœtida . . . . . gr. ij.—M.

One pill after each meal, increasing to two pills after each meal.—*University Medical Magazine*, December, 1889.

The Prevention of Cinchonism.—DR. COGLITORE asserts that if quinine is administered with opium and ergotin the danger of cinchonism is avoided. The following is the formula which he uses:

℞.—Sulphate of quinine . . . grs. xij.
Bonjean's ergotin . . . . grs. v.
Opium . . . . . grs. j.—M.

Divide into three powders, of which one may be given every hour.—*Journal American Medical Association*, December 7, 1889.

Ointment for Scabies.—According to the *Physician and Surgeon*, the following is an efficient ointment for scabies:

℞.—Sublimed sulphur . . . . ʒij.
Beta-naphthol . . . . ʒj.
Peruvian balsam, Vaseline . . āā ʒj.—M.

One-third of this ointment should be rubbed into the affected skin on three consecutive nights, and washed off in the morning. After the first inunction the patient's underclothes should be boiled.

The Administration of Cocaine.—At a recent meeting of the New York Academy of Medicine, Section on Laryngology and Rhinology, DR. KÖHLER, the discoverer of the anæsthetic properties of cocaine, said that he never gave a patient a prescription for the drug, but that, if it was to be used, he himself gave it. For application to mucous membranes he does not use solutions

of a greater strength than five per cent.; which will accomplish as much as stronger solutions, though requiring a little more time.

Menthol in Asthma.—THEODORE JORES relates, in the *Memorabilien*, October 31, 1889, his experience with menthol in a case of asthma which had obstinately resisted all the usual methods of treatment. During a paroxysm he caused the patient to inhale an atomized 20 per cent. solution of menthol in olive oil. Relief was immediate. Dyspnœa was at once replaced by quiet breathing, and the respiratory sounds, which before the inhalation had been noisy and sibilant, became clear. Since then he has used the drug, in the same manner, in all cases of asthma under his care, and invariably with satisfactory results.

Treatment of Tubercular Prostatitis.— According to BERKELEY HILL, in a recent lecture before the Royal College of Surgeons, a good antiseptic solution in the treatment of tubercular prostatitis is two grains of sulphate of quinine to the ounce of water, two ounces being injected and left in the bladder after the pus and urine have been well cleared out by repeated small injections of boric acid solution. Still more antiseptic is an emulsion of iodoform. In cases of chronic cystitis, if the bladder is well washed, and two drachms of this emulsion injected, the most fetid ammoniacal urine is replaced by acid urine, fetor disappears, and the pus rapidly diminishes. In cases of cystitis caused by neglected prostatic retention, the urine in ten days becomes quite free from deposit, and even when a calculus, tumor, or malignant ulceration coexists, the improvement is rapid.—*London Medical Recorder*, August 20, 1889.

Treatment of Syphilis.—In a discussion on the treatment of syphilis at the International Congress of Dermatology and Syphilography, DR. MCCALL ANDERSON said that treatment should not be instituted until unmistakable symptoms of the disease were manifested. Mercury he believed was of value not only in the early stages, but often in tertiary syphilis, especially in lesions of the nervous system, and in cases where the iodides had been found powerless. Hypodermatic injections and inunctions of mercury he preferred to administration by the mouth. Dr. Langlebert said that treatment should commence with the prodromata of the secondary period—headache, fever, etc.—and should be continued during the whole period of eruption. He never gives mercury in the intervals between the manifestations on the skin or mucous membranes, as he regards the drug powerless to prevent such manifestations. On the other hand, the iodides are preëminently suited for chronic syphilis. The average time of treatment by the iodides should be about three years. Arsenic, iron, quinine, and sulphur are of value as tonic remedies, but should always be secondary to mercury and the iodides.—*Journal of Cutaneous and Genito-urinary Diseases*, November, 1889.

Pineapple Juice in Bronchitis.—DR. FLASCHER recommends the juice of the pineapple as an excellent remedy to soften the tenacious mucus of catarrhal bronchitis. In chronic bronchitis accompanied by dyspnœa he has also seen quite remarkable results. The juice is prepared by slicing the fruit, sprinkling with sugar, placing in a jar and bringing to a boil. The juice may then be poured into smaller bottles and kept for some time. It is prescribed in doses of from eight to ten teaspoonfuls.—*Lyon Médicale*, October, 1889.

Sparteine.—LEWASCHEW has recently made a series of careful observations upon the action of sparteine sulphate which he administered to twenty-two patients. In seven of the cases a more or less distinct therapeutic influence was produced, but in the remaining fifteen there was no perceptible effect produced upon either the action of the heart or the excretion of urine. These studies, together with a review of all the literature upon the subject, lead him to the following conclusions:

1. Sparteine strengthens hearts which are simply weak and arythmic, and if the pulse is rapid reduces its frequency.

2. In such cases it causes increase of blood-pressure with decrease or entire abolition of vascular engorgement, increased excretion of urine, lessening of dyspnœa, and removal of œdema.

3. Diuresis is not due to the direct influence of the drug upon the renal epithelium, but to the increased blood-pressure.

4. The effects of sparteine on the heart are similar to those of digitalis, adonidine, and strophanthus.

5. In many cases of long duration with considerable degeneration of the heart-walls, the last-mentioned drugs will be of more service.

6. For the latter reason sparteine should be used only in recent cases.

7. When good effects follow they are often observable within fifteen minutes after its administration.

8. The most generally useful dose is from one-fourth to one grain, three or four times daily.—*Centralblatt für klin. Medicine*, November 9, 1889.

Antiseptic Properties of Ammonium Carbonate.—GOTTBRECHT has lately experimented on the anti-fermentative action of ammonia. In his experiments he used carbonate of ammonium. A two per cent. solution of this salt delayed the decomposition of portions of fresh organs for nine days, a five per cent. solution for nineteen days, while a ten per cent. solution delayed it for sixteen days. In mixtures in which decomposition had already occurred, ammonium carbonate, added to the amount of five per cent., after a time killed the organisms; while a two and one-half per cent. admixture of the salt diminished their activity, smaller proportions of ammonium carbonate, one-fourth to one per cent., not only did not diminish, but actually increased the activity of the organisms, so that putrefaction became more rapid. Sodium carbonate added to the same degree of alkalinity did not show any anti-putrefactive effect.—*Alienist and Neurologist*, October, 1889.

Malarial Fever and the Puerperium.—DR. KRUSENSTERN, of Tiflis, publishes an interesting paper (*The Trans-Caucasian Lying-in Hospital Reports for* 1889, p. 59) on malarial fever appearing in the course of the puerperal period, in which he argues that (1) malarial fever generally, its remittent form in particular, does not in the least retard the post-partum involution of the womb, the organ decreasing in its bulk as it does under perfectly

normal conditions. Though several authors have described cases of uterine subinvolution in malarial puerperal women, the real cause in such cases should be sought, not in the malarial process or virus itself, but simply in an intercurrent endometritis accidentally complicating the fever. (2) On the other hand, malarial fever manifests a very marked influence on the functions of the mammary glands, since the appearance of the disease in puerperal women is invariably followed by a striking decrease in the secretion of milk.—*Provincial Medical Journal*, November, 1889.

Typhlitis and its Treatment.—In a discussion on this subject, at a recent meeting of the British Medical Association, Mr. Treves divided typhlitis into:

1. The mild form, which is the most common, amenable to simple medical treatment, usually terminating in resolution, and probably due to fecal accumulation in the cæcum. With this variety must also be included some cases of appendicitis which terminate favorably. The symptoms are less marked than in the graver cases. It is commonly preceded by constipation, rigors seldom occur, the swelling appears earlier and is comparatively larger, and doughy, is less fixed and cannot so readily be felt through the rectum. This is the form that physicians have in mind when opposing surgical treatment.

2. The severe variety, leading to suppuration and almost invariably dependent on disease of the appendix. The symptoms are more grave than in the former, and progress more rapidly. It is not usually preceded by constipation. There is often a history of cold or injury, pain is severe, vomiting frequent, tenderness and other signs of peritonitis pronounced, and fever high. The tumor makes its appearance more slowly, can usually be felt through the rectum, and is more fixed. The pain radiates to the testicles, thigh, or perineum, and is often accompanied by tenesmus and difficult urination. Pain on moving the right thigh may be great. At varying periods of time signs of suppuration appear. In some cases the first manifestations of the disease are symptoms of perforation, which may terminate fatally in two or three days, or even less. On the other hand, the symptoms may appear very slowly.

3. Relapsing typhlitis, due to disease of the appendix not sufficient to cause suppuration. If an abscess forms and the patient recovers, he is not likely to have another attack. This variety is usually independent of constipation.

The treatment of the mild form should consist in rest, small doses of opium, the least possible amount of fluid food, leeches or counter-irritation, and early evacuation of the colon by enemata.

Surgical treatment is required in the severe forms, but is seldom advisable before the fifth day. The exploring needle is to be condemned as a means of detecting pus. The incision should be made, if possible, directly over the seat of suppuration, a median incision being unsatisfactory.

As a rule, the most convenient incision is one made obliquely from above downward and inward, just external to the deep epigastric artery, terminating a little above and to the outer side of the middle of Poupart's ligament. A careful examination should be made for concretions or foreign bodies, and the condition of the appendix determined, if possible. These investigations should be conducted with the greatest care, the frail character of the abscess wall should be borne in mind, and regard be paid to the fact that it is made up of fresh adhesions, and often of loosely attached coils of bowel. The careless introduction of the finger may break down important adhesions, and cause a perforation into the general peritoneal cavity, or may bare a portion of the exposed cæcum of its serous covering. The less that is done after the abscess has been opened the better.

The cavity should be washed out with a warm, weak antiseptic fluid. A large drainage-tube is then introduced. If a diseased appendix is found, it should be ligated with catgut, unless it is entirely gangrenous or perforated close to the cæcum, in which case it should be left untouched.—*British Medical Journal*, Nov. 9, 1889.

The Bacillus of Whooping-cough.—DR. SEMTCHENKO has recently studied the bacteriology of whooping-cough, and in fourteen consecutive cases of the disease found the bacterium described by Afanasïeff, while it was invariably absent in patients suffering from other diseases of the respiratory tract. The author's conclusions are: 1. Afanasïeff's bacterium is specific. 2. The microörganism makes its appearance in the sputum during the catarrhal stage, about the fourth day of the disease, or possibly earlier. 3. Subsequently, its numerical strength increases, the intensity of paroxysms keeping pace with the increase. 4. The microbes disappear from the discharge, apparently, somewhat before a complete cessation of whoops (about the time when the number of paroxysms sinks to four or two per day). 5. When pertussis becomes complicated with catarrhal pneumonia, the bacilli in the patient's sputa show an enormous increase in number. 6. Altogether the pertussis pneumonia seems to be quite different from other varieties of pulmonary inflammation. 7. The *bacillus tussis convulsivæ* presents a great importance not only in etiological and diagnostic, but also in prognostic regards. 8. As to the behavior of the microbe toward antiseptic agents, its vitality is destroyed when the culture medium contains corrosive sublimate in the proportion of 1 to 60,000, or resorcin in that of 1 to 1200, or phenol in the same strength, or hydrochlorate of quinine of 1 to 800.—*London Medical Recorder*, November 20, 1889.

Peruvian Balsam in Diseases of the Respiratory Tract.—A correspondent of the *British Medical Journal* writes that PROF. SCHNITZLER, of Vienna, has used Peruvian balsam in various affections of the larynx, trachea, bronchi, and lungs, as well as those of the mouth, nasopharyngeal cavity, and nose. The results were good in the vast majority of cases. The drug was used in the form of inhalation, and was also applied with a brush, with the spray-producer, and internally. Finally, the most important constituent of the Peruvian balsam—namely, the cinnamein—was also tried. Inhalations of the Peruvian balsam did not differ in effect from those of turpentine, and they were equally indicated in affections of the bronchi and lungs. Inhalations of the emulsion of Peruvian balsam, however, were, according to Schnitzler, very efficacious in many diseases of the larynx and the trachea.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

PATHOGENIC PROPERTIES OF THE MICROBES FOUND IN MALIGNANT TUMORS.

PROFESSOR VERNEIUL, who for several years past has been prominent among those who have investigated the important question of the relation between microörganisms and malignant tumors, contributes in the *Revue de Chirurgie* for October, a valuable paper, reviewing briefly his earlier work and that of others supporting his views; presenting its practical or clinical application in anything but doubtful language. The points of the paper are clearly summed up in the following conclusions:

"1. The tissue of malignant neoplasms, cancers, sarcomata, epitheliomata, etc., may be invaded at a given moment by various microbes, of which neither the origin, the kind, nor the number can as yet be determined.

"2. This invasion, the causes and mechanism of which are equally unknown, may remain latent for a longer or shorter period of time, but also in certain cases may cause various modifications in the growth and nutrition of tumors, amongst other things, rapid extension, softening, and ulceration.

"3. Microbes are not met with in all varieties of neoplasms, nor in every tumor of the same sort, nor, yet, in all parts of an invaded tumor. One does not find them, for example, in lipomata, in pure fibromata, in beginning carcinomata, or in sarcomata of slow growth, in their normal condition, and covered with healthy skin; on the contrary, one finds them almost constantly in broken-down and ulcerated neoplasms.

"4. These microbes, besides the irritation and inflammation which they cause locally in the tissue of the invaded tumor, possess other pathogenic properties which may concern the entire economy. Thus, in all probability, they are capable of lighting up a more or less intense and irregular fever while still enclosed in a tumor undergoing rapid growth and softening. Moreover, when, during the removal of a tumor which contains them, they are mingled with the fluids of the softened areas, and permitted to spread themselves in the field of operation, they are capable of infecting and inoculating it so as to provoke a septic fever capable of causing death.

"5. The recognition of this latter fact, besides pleading in favor of the early removal of malignant neoplasms, so desirable from all points of view, indicates forcibly to surgeons certain preventive measures before and after the removal of tumors infected by microbes."

Thus it will be seen that Verneuil is not one of those who believe that the etiological relation between microörganisms and neoplasms is one of cause and effect. But it will also be observed that he ascribes to them when present in a growth results of the gravest consequence.

The above conclusions, verified by faithful investigation and drawn from abundant evidence, speak for themselves in a manner so plain as scarcely to need comment.

The support which is given to the plea for early surgical interference in cases of malignant tumor is positive; and the demand for extraordinary vigilance in carrying out antiseptic precautions during the removal of such growths, when they have undergone ulceration or softening, is shown to be of especial urgency.

THE TREATMENT OF GASTRIC CATARRH.

THERE is probably no one ailment of a non-organic character seen by the practitioner of medicine in every part of the United States which is more widely distributed, has a greater variety of symptoms, or is so discouraging to treat, than the one before us. Affecting alike the child and the adult, and the rich and poor, it follows as a result of all manner of exciting causes, from the taking of a simple cold to

the constant or sudden employment of substances irritating to the stomach.

From the title given above many pages might be written, none of which would be wasted by useless descriptions of the pathological changes and the variation in the results, and all of which might be filled with remarks upon the treatment of these conditions. The main object of this editorial is, however, to point out several facts generally overlooked in the treatment of gastric catarrh and in that of similar conditions in the smaller bowel. No disorder can be correctly divided into two distinct portions, called acute and chronic, more readily than this, and no complaint needs more correct diagnosis as to its exact stage than gastric catarrh. Totally excluding all forms of true gastritis reaching more deeply into the tissues than the mucous membrane, we find that very rarely do we see our patients in the acute stage of their attack, but rather in the subacute stage, when the separation of one state from the other is much more difficult. Under these circumstances exactitude in diagnosis is most necessary, for, if it still be in the acute stage, the treatment is utterly different from that of the later periods. If the acute stage is present, there is a condition of hunger, or anorexia, according to the peculiarity of the individual, but the taking of food increases any distress which may be present and delays the cure. Partial or total abstinence from solid food is urgent; extremely hot and cold fluids are of evil effect. The treatment of this stage is really made up of rest of the stomach and entire body, and in the use of mild nutrient drinks of a quieting character—such as predigested warm milk. A slight counter-irritant—such as a spice plaster over the belly may be used. These are points universally recognized, but there are others that are not. Constantly one sees some of the bitter tonics prescribed under those circumstances, with entire disregard of the name of the class to which those drugs belong, namely, the "tonic." The fact is forgotten that during the acute stage of an inflammation the tone of the part is above par, not below it, and that it is only after the inflammation passes by that a state of atony or depression is developed. By the use of a so-called tonic during the first stage we spur on to a more angry state a membrane too readily prepared to excessive activity of a perverted type. It is in the second stage, not the first, in which the pendulum has swung to the other side of the abscissa line of health that calls for a stimulating, toning, or tonic treatment—always to be given before meals, so as to affect the stomach itself when it is not covered by food. In the still more advanced stages of this condition, tonics become useless and incapable of action. As well might one supply a lancet for an amputating knife as to attempt to buoy up to the normal line by ordinary tonics a gastric mucous membrane so depraved and depressed into the slough of abnormal activity as is that of chronic gastric catarrh of long standing. If there be much eructation of yeasty matters, or sour gases, or other evidences of fermentation, let pills of nitrate of silver and hyoscyamus precede the meals by half an hour or an hour, or employ hydrochloric acid, in ten-drop doses, in its place, if such symptoms are not present. The remembrance of such ordinary rules of common sense will prevent a large amount of bad treatment and disappointment.

REVIEWS.

CHEMISTRY: GENERAL, MEDICAL, AND PHARMACEUTICAL. By JOHN ATTFIELD, F.R.S. Twelfth Edition, 8vo., pp. 770. Philadelphia: Lea Bros. & Co., 1889.

A work which has reached twelve presumably large editions since 1867 has demonstrated its suitability for the field for which it was designed. Attfield's *Chemistry* has, indeed, divided with Fownes's the honors of a standard work of reference for medical and pharmaceutical students, and has been rather better suited to medical and pharmaceutical laboratory work. In recording the appearance of the present edition, the reviewer can do little else than repeat the encomiums that have been bestowed upon all the editions of recent years. The work is comprehensive, and highly accurate. The practical, analytical portions are brought up to date. The theoretical matter is distributed over the entire work, different topics being introduced in association with those departments of descriptive chemistry by which they are best illustrated.

It is, perhaps, to be regretted that the author has not seen fit to adopt completely the modern nomenclature for salts, and to write, therefore, "magnesium sulphate" in preference to "sulphate of magnesium." The latter form, dependent essentially on a mistranslation of the French phrases, has been slowly disappearing from the writings of chemists, and the progress of the reform is delayed when a manual of acknowledged excellence and extended use tends to perpetuate the older method.

The arrangement adopted by Attfield has always been somewhat less systematic than other manuals of its size and style, and in the earlier editions this fact interfered with the satisfactory use of the work as a lecture companion or for regular study; but in the more recent editions, and particularly in the present, a copious index enables all necessary references to be made quickly. It is not unlikely that for the purposes of American medical and pharmaceutical students the more extended use of different sizes of type would be advantageous, and that

portions of the descriptive chemistry—for instance, the account of the various essential oils—would be more suitable for reference if expressed in condensed tabular form.

The mechanical execution of the book is excellent. The type is clear, and free from error. The work of revision for the present edition has been especially extensive in the department of organic chemistry. A valuable feature is the attention given to the etymology and significance of scientific terms. Such matters tend to give vitality to terminology, and to assist the student in remembering.

SURGICAL BACTERIOLOGY. By NICHOLAS SENN, M.D., Ph.D. 8vo., pp. 259. Philadelphia: Lea Brothers & Co., 1889.

BUT a short time since there was an almost universal smile of ridicule at the announcement of the discovery of the cancer microörganism, and now other writers besides our author deal respectfully with the idea, even if the most of them cannot accept even its probability. Reviewing with Dr. Senn the literature of this subject, and accepting his conclusions as to the utter lack of proof of the existence of this germ, one can scarcely help thinking, nevertheless, of what might have been the consequences had Scheuerlen's announcement been capable of corroboration. Such consequences have followed with uniform regularity the absolute acceptance of every specific microörganism; and with the same regularity have our various text-books, medical and surgical, been forced to general revision, or have been neglected as unsound and unscientific. With such circumstances in view, the appearance of such a work as Dr. Senn's seems well-timed and appropriate.

The author introduces his prime subject after a careful review of the literature of such general considerations as the hereditary transmission of microbic diseases, infection by microörganisms, and the localization and elimination of these germs. Inflammation, while recognized by the author as frequently of a simple nature, is evidently regarded from a surgeon's point of view as almost uniformly of microörganismal origin. Such view, too, is intimated in the definition of "that condition called inflammation, a restorative process which has for its object the repair of injured tissues, or the neutralization or removal of the primary microbic cause"—the specification of microörganisms as a primary cause being evidently introduced as a feature of importance in the definition. As secondary to microbic activity in the production of inflammation, and later in pus formation, the results of these activities, ptomaines, are accepted by the author; and the formation of inflammatory abscesses is regarded as practically never occurring without the presence of microörganisms or their results. The wound fevers are treated of in some detail. Septicæmia is recognized by Dr. Senn as occurring both clinically and experimentally either as a true progressive septicæmia caused by the introduction of microörganisms into the tissues, and their subsequent activities, or as sapræmia, a putrid intoxication in which the prime factor is not the bacteria, but ptomaines to which they have given rise, or to other substances the result of tissue disintegration. The origin of pyæmic disturbances the author believes to be due primarily to microörganisms different from those of septicæmia, but he acknowledges the possibility of its being identical with a form of sapræmia. In harmony with his belief in the duality of these two wound fevers, the author accepts Leube's combination of the two under the name of septico-pyæmia—a condition in which post-mortem appearance as well as clinical symptoms point to septic and purulent infection.

In the consideration of tuberculosis the author happily goes to some pains to point out the identity of this condition and that of lupus. In the surgical relations of tuberculosis Dr. Senn urges the frequent local occurrences of the process, and advocates a thorough surgical procedure in such instances as proper—although he adds a word of caution as to the likelihood of traumatic disseminations following operations imperfectly performed, both in tuberculosis and in other mycotic processes as well. Considerable attention is paid the subjects of anthrax, glanders, actinomycosis, tetanus, gonorrhœa, and syphilis, both in their general features and in their possible relations to surgical measures. Speaking of tetanus as an infectious disease, it has occurred to us as rather curious that more mention of the curious epidemics of this disease has not been made in the literature, epidemics, or possibly endemics, being frequently met with in certain parts of Cuba, Brazil, and other localities.

Considered generally, Dr. Senn's book is to be highly commended. While, of course, a work of its nature must, at this period of our knowledge of bacteriology, be largely a review of more or less conflicting literature, there need be no mistaking of the author's teaching and position in the mass of compilation necessary to the full purpose of the volume. The arrangement of the subject-matter is admirable; and the method of treating each subject, noticing the history of the microbe in question, the technique necessary to its demonstration, and the culture and inoculation experiments, must be regarded as serving an excellent object. The printing is excellent, and the illustrations add considerably to an already well-made book.

NEW INVENTIONS.

A NEW ROTARY PRISM.[1]

BY S. D. RISLEY, M.D.,
OPHTHALMIC SURGEON TO THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA.

I PRESENT here a new, and I think a more convenient, form of revolving prisms than those heretofore in use. Adopting the principle first put in practice by Volkmann, and latter by Cretes, two prisms of fifteen degrees each are superimposed, with their bases in opposite directions. They are mounted in a delicately milled-edge cell, with a diameter the same as those employed in the Nachet trial-glasses, which, therefore fits readily into the ordinary trial-frame. The milled-edge permits its convenient turning in the frame, so that the base or apex of the prism can be readily placed in any desired direction. The prisms are caused to rotate over each other in opposite directions by means of a milled-head screw projecting from the front of the cell. The strength of the successive prisms, resulting from the rotation, is read off on the graduated scale engraved on the front plate of the containing cell, extending from zero to thirty

[1] Presented at the American Ophthalmological Society, July, 1889.

degrees, the combined value of the composing prisms. (The strength of these prisms has since been increased so that the combined value is forty-five degrees.) As constructed, it will usually be found most convenient to place the instrument before the left eye, when the rotating screw, with the zero mark vertical, will stand at the upper and outer quadrant and can be readily manipulated without the hand of the operator obstructing the patient's vision. In this position, turning the screw to the right or left will cause the base of the resulting prisms to be inward and outward—that is to say, toward the nose or temple—as may be desired, when the strength of the adducting or abducting muscles is to be determined. If the vertical muscles are to be examined, the zero points may in like manner be placed horizontally, by simply turning the containing cell in the trial-frame. The main features of the instrument are well shown in the accompanying cut.[1]

Since writing the above description of the instrument I have found great advantage from its use in conjunction with the Maddox double prism. For this purpose I have had the latter mounted in a Nachet cell, which is then placed in a trial-frame, or preferably in some fixed form of apparatus, and the rotary prism on the opposite side. The revolving prism being at zero, any deviation of the images, in the resulting tripolopia, whether lateral or vertical, can be rapidly measured, its value being read off on the scale of the rotary prism. If preferred, the displacement prism can be employed as usual. If the double prism is used, it should have a strength of at least six degrees. The examination, especially when the triplopia test is employed, is greatly facilitated by some fixed form of apparatus, so that a constant relation can be maintained between the test object, the prisms, and the eyes of the patient, conditions not readily secured when the trial frame is used.

NEWS ITEMS.

Pharmacopœial Statistics.—The *National Druggist* states that according to statistics presented at the late Congress of German Naturalists and Physicians, there are now in use in the world twenty pharmacopœias, which, with their official supplements and commentaries, make about forty volumes. The French *Codex* contains the greatest number of subjects, viz., 2039, and the Norwegian *Pharmacopœia* the least, 519. In the French there are no fewer than 106 syrups, while the German has but twenty, and the Norwegian only 9. England is the only country that still retains the old system of weights, all the others using the decimal system. Only 150 articles or titles are common to all of the pharmacopœias.

Prosecution of Unregistered Dentists.—The New York State Dental Association has instituted proceedings against dentists who have failed to register. The prosecutions were begun in Brooklyn, five convictions being secured at the first day's trial. The minimum fine of fifty dollars was imposed; the largest possible fine for the offence under the registration act is two hundred dollars.

Football Fatality.—The *Lancet*, November 23d, reports a death at Bootle, England, following "rough play" at football. The player who lost his life was thrown violently and sustained an injury to the spinal cord. The index of the *Lancet* for the first half of 1889 shows that there have been sixteen paragraphs relative to the "accidents" in this athletic sport.

Hygienic Institute at Heidelberg.—The University of Heidelberg has inaugurated an Institute of Hygiene, with Professor Freidreich Knauff at its head. Dr. Knauff has written upon the subjects of hospital administration and the water-supply of cities.

Vienna Clinic for Mental Disease.—Dr. Richard von Krafft-Ebing, of Gratz, has been appointed to succeed the late Dr. Leidesdorf at the Vienna Clinic for Mental Diseases. A brochure on hypnotism by Professor von Krafft-Ebing has recently been translated by Dr. Charles G. Craddock, of the North Michigan Asylum.

The Care of the Insane.—At a stated meeting of the Chester County Medical Society, held in West Chester, October 8, 1889, the matter of the administration and medical treatment in the hospitals of the State for the cure of the insane was fully and ably presented by Dr. Hiram Corson, of Montgomery County. After full discussion, Dr. Jacob Price moved the following resolution: "That, in the opinion of this Society, the medical administration in these institutes should be separated from the secular duties pertaining to them; and, second, that medical care of female patients should be confided to properly skilled women physicians.

"*Resolved*, That the foregoing resolutions be embodied by the Secretary in his report to the State Society, and also that they be published in THE MEDICAL NEWS."

The Babies' Hospital.—Dr. L. Emmett Holt has been appointed attending physician to the Babies' Hospital, in place of Drs. Sarah J. and Julia McNutt, resigned. The Hospital is now permanently located in a building of its own, on the corner of Lexington Avenue and Fifty-fifth Street. It has a capacity of thirty-five beds, and is devoted exclusively to the care of sick children under two years of age. It receives any non-contagious case. In connection with the Hospital, a Training-school for Nurse-maids, which has been organized by Mrs. R. W. Chapin, will be opened in December. The Hospital has been in active operation in its new quarters since October. It was formally opened on December 6th.

Donation to the Pasteur Institute.—The *British Medical Journal* of November 9th states that a donation of

[1] Manufactured by Borsch & Rommel, Walnut and Juniper Streets, Philadelphia.

40,000 francs from English subscribers has been made to M. Pasteur, for the use of the Pasteur Institute at Paris. It was given in recognition of the services rendered to over two hundred British subjects who had been successfully treated there after having been bitten by rabid dogs. The *Journal* also states that some have proposed to establish a Pasteur Institute at Cambridge, and an estimate has been made that with the sum of £700 the running expenses of the first year can be met.

American Physicians Abroad.—A writer in the *London Medical Recorder* remarks, with some surprise, that at the last summer session of the Vienna University there were sixty-two American physicians and students in attendance, and not one from England on the catalogue. The physicians of the latter country seem to enter practice earlier, and do not give themselves that *Wanderjahr* "without which," thinks the writer, "no American physician seems to be able to settle down in practice." Little does that writer know of the hundreds of graduates of our interior colleges who never come even far enough eastward to get the smell of salt-water.

Yellow Fever in Brazil.—If sanitary reasons are allowed to rule, no naval vessel of the United States will be sent to the new Brazilian Republic at present. The condition of Rio, and of a number of other ports, in regard to the prevalence of fever, indicates a most unhealthy season. Whatever may be the indications from a political standpoint, the sanitary, prudential view would impel everyone to give Brazil a wide berth during the next six months.

Influenza in Paris.—It is stated that the epidemic of influenza in Paris is spreading. The disease has made its appearance in the barracks, the markets, and the Ecole Centrale. The medical report upon the epidemic shows that there are 670 cases among the employés in the great dry-goods store, the Magasin du Louvre. These are all cases of simple benign influenza, with an average duration of four days. Complications arise in some cases which make it more serious. In other large stores it also prevails. A dispatch from Berlin says that the disease is also epidemic in that city, and that Professor Virchow is one of the sufferers.

The "Italian Virchow."—Dr. Guido Baccelli, of Rome, Professor of Clinical Medicine, and formerly Minister of Public Instruction, is an extremely popular member of the party of progress. The *Lancet*, comparing Baccelli's position in Italy with that of Virchow in Germany, says that he is a public-spirited and intelligent statesman, and the friend and promoter of every measure of substantial reform. Dr. Baccelli is an ex-president of the Roman Academy of Medicine.

The Result of Recommending a Patent Nostrum.—According to the *Medical Press*, the Colleges of Physicians and Surgeons, Ireland, have resolved to restore the diplomas which they had withdrawn from one of their Licentiates, for having allied himself with Warner, the "Safe Cure" man, and having allowed his name to be used in the advertisement of the nostrum. The Licentiate asseverated that the letters purporting to have been written by him in eulogy of the "Safe Cure" were forgeries, and in order to prove this statement, he commenced action against the manufacturers, which, however, he was unable to bring to an issue for want of funds. Notwithstanding these representations by the Licentiate, and the most humble apologies offered by him for his conduct, the Colleges on two occasions refused to reinstate him.

The American Physiological Society.—The American Physiological Society will hold its annual meeting at the College of Physicians and Surgeons, New York, on December 27 and 28, 1889, and will join the American Society of Naturalists, which meets at the same time, in an annual dinner.

The International Medical Congress.—It is stated that the German Government has appropriated 80,000 marks ($20,000) for the International Medical Congress which meets in Berlin in 1890.

Surgeon Porter and His Resignation.—Surgeon Joseph Y. Porter, whose resignation from the Army was accepted by Secretary Proctor last summer, after a difficulty arising from his being ordered from Florida to New Orleans, has petitioned Congress, through Senator Gibson, to place him on the Retired List of the Army.

Diphtheria at May's Landing.—It is stated that diphtheria of a malignant type is epidemic at May's Landing, New Jersey. Strong efforts are being made to prevent the disease from spreading.

The Growth of Cremation.—According to *Science*, there are now thirty-nine crematories in various parts of the world. Italy has twenty-three; America has ten; while England, Germany, France, Switzerland, Denmark, and Sweden have one apiece. In Italy there were two cremations in 1876; the number rose to fifteen in 1877, and in 1888 the number was 226. Since 1876, 1177 cremations have taken place in Italy, while the combined numbers in all other countries brings the total only to 1269.

The Surgeon of the Emin Relief Expedition.—Mr. Henry M. Stanley thus eulogizes Surgeon Thomas H. Parke, of the English Army, who accompanied the Emin Relief Expedition: "The hardest-worked man in the expedition was our surgeon. Ever since leaving Fort Bodo in December Surgeon Parke attended over a hundred sick daily. There were all kinds of complaints; but the most numerous, and those who gave the most trouble, were those who suffered from ulcers. So largely had these drained our medicine chests that the surgeon had nothing left for their disease but pure carbolic acid and permanganate of potash. Nevertheless there were some wonderful recoveries during the halt of Stairs' column on the Ituri River in January. . . . I do not think I ever met a doctor who so loved his 'cases.' To him they were all 'interesting,' despite the odors emitted and the painfully qualmish scenes. I consider this expedition in nothing happier than in the possession of an unrivalled physician and surgeon. . . . "Nothing happened during the long journey from the Albert Lake to cause us any regret that we had taken this straight course, but

we have suffered from an unprecedented number of fevers. We have had as many as 150 cases in one day. Aukori is so beswept with cold winds that the expedition wilted under them. Seasoned veterans like the Pasha and Captain Casati were prostrated time after time, and both were reduced to excessive weakness like ourselves. Our blacks, regardless of their tribes, tumbled headlong into the long grass to sleep their fever fits off. Some after a short illness died; the daily fatigues of the march, an ulcer, a fit of fever, a touch of bowel complaint, caused the Egyptians to hide in any cover along the route, and, being unperceived by the rearguard of the expedition, were left to the doubtful treatment of natives with whose language they were utterly ignorant. In the month of July we lost 141 of their number in this manner."—*Lancet.*

Dr. H. Newell Martin's Lectures.—DR. H. NEWELL MARTIN is delivering a series of lectures upon the "Relations of Psychology to Physiology," at Johns Hopkins College.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 19 TO DECEMBER 9, 1889.

By direction of the Secretary of War, the extension of leave of absence, on surgeon's certificate of disability, granted LEONARD Y. LORING, *Major and Surgeon*, in S. O. No. 241, October 16, 1889, from this office, is still further extended one month, on surgeon's certificate of disability.—Par. 3, *S. O. 268, Headquarters of the Army, A. G. O.*, November 16, 1889.

MOSELEY, EDWARD B., *Captain and Assistant Surgeon.*—Is relieved from duty at Whipple Barracks, Arizona, to take effect upon the expiration of his present leave of absence, and will report in person to the commanding officer Fort Clark, Texas, for duty at that station, reporting by letter to the commanding general Department of Texas.—Par. 4, *S. O. 268, A. G. O.*, November 16, 1889.

FISHER, WALTER W. R., *Captain and Assistant Surgeon.*—Is relieved from duty at the Presidio of San Francisco, California, and will report in person to the commanding officer Fort Assinniboine, Montana Territory, for duty at that station, reporting by letter to the commanding general Department of Dakota.—Par. 4, *S. O. 268, Headquarters of the Army, A. G. O.*, November 16, 1889.

EBERT, RUDOLPH G., *Captain and Assistant Surgeon.*—The leave of absence, on surgeon's certificate of disability, granted in S. O. 109, May 11, 1889, from this office, is extended six months, on surgeon's certificate of disability.—Par. 13, *S. O. 270, Headquarters of the Army, A. G. O.*, November 16, 1889.

By direction of the Secretary of War, the extension of leave of absence granted VALERY HAVARD, *Captain and Assistant Surgeon*, in S. O. 240, October 15, 1889, from this office, is further extended one month.—Par. 1, *S. O. 272, A. G. O.*, November 21, 1889.

BALL, R. R., *First Lieutenant and Assistant Surgeon* (Fort Riley, Kansas).—Will proceed to Fort Sill, Indian Territory, and report to the commanding officer, for temporary duty at that post.—Par. 2, *S. O. 173, Department of the Missouri*, November 21, 1889.

By direction of the Secretary of War, JAMES E. PILCHER, *Captain and Assistant Surgeon*, is relieved from duty at Fort Ward, New York Harbor, and will report in person to the commanding officer Fort Clark, Texas, for duty at that station, reporting also by letter to the commanding general Department of Texas.—Par. 3, *S. O. 276, A. G. O.*, November 26, 1889.

COCHRAN, JOHN J., *Captain and Assistant Surgeon.*—Is granted leave of absence for fifteen days, to commence about December 1, 1889.—Par. 8, *S. O. 272, Division of the Atlantic*, November 27, 1889.

WOLVERTON, WILLIAM D., *Major and Surgeon* (Fort Douglas, Utah Territory).—Is hereby granted leave of absence for one month, to take effect on or about December 18, 1889, with permission to apply at Headquarters Division of the Missouri for an extension of seven days.—Par. 2, *S. O. 114, Department of the Platte*, November 30, 1889.

By direction of the Secretary of War, JOHN DE B. W. GARDINER, *Captain and Assistant Surgeon*, will be relieved from duty at Fort Reno, Indian Territory, upon the arrival at that post of Captain and Assistant Surgeon James C. Merrill, and will report in person to the commanding officer Fort Supply, Indian Territory, for duty at that post.—Par. 8, *S. O. 279, A. G. O.*, November 30, 1889.

MCCAW, WALTER D. *Captain and Assistant Surgeon* (Fort McPherson, Georgia).—Is hereby granted leave of absence for fifteen days.—Par. 3, *S. O. 276, Division of the Atlantic*, December 3, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING NOVEMBER 7, 1889.

RUSH, W. H., *Passed Assistant Surgeon.*—Ordered to U. S. S. "Saratoga."

URIE, J. F., *Assistant Surgeon.*—Detached from Coast Survey Steamer "Gedney," and ordered to the U. S. S. "New Hampshire."

BRYANT, P. H., *Assistant Surgeon.*—Detached from the Norfolk Hospital, and ordered to the Coast Survey Steamer "Gedney."

SMITH, GEORGE T., *Assistant Surgeon.*—Detached from the Army and Navy Hospital, Hot Springs, Arkansas, and ordered to the Naval Hospital, Norfolk, Virginia.

STONE, E. P., *Assistant Surgeon.*—After examination for promotion, await orders at Boston, Massachusetts.

GUNNELL, F. M., *Medical Director.*—Placed on the Retired List, November 27, 1889.

GAINES, J. H., *Surgeon.*—Ordered to duty at the Army and Navy Hospital, Hot Springs, Arkansas.

NEILSON, J. L., *Surgeon.*—Detached from the U. S. S. "New Hampshire," and ordered to the U. S. S. "Portsmouth."

BEYER, H. G., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Portsmouth," and placed on waiting orders.

SIEGFRIED, C. A., *Surgeon.*—Detached from the Naval Station, New London, Connecticut, and ordered to the "New Hampshire."

HALL, JOHN H., *Passed Assistant Surgeon.*—Ordered to the Naval Station, New London, Connecticut.

KITE, I. W., *Assistant Surgeon.*—Detached from the Naval Hospital, Philadelphia, Pa., and ordered to the Naval Hospital, Pensacola, Florida.

ROSS, J. W., *Surgeon.*—Detached from the Naval Hospital, Pensacola, Florida, and placed on waiting orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM NOVEMBER 9 TO NOVEMBER 30, 1889.

FESSENDEN, C. S. D., *Surgeon.*—To inspect unserviceable property at Cincinnati, Ohio, November 18, 1889.

MURRAY, R. D., *Surgeon.*—Granted leave of absence for thirty days, November 30, 1889.

PURVIANCE, GEORGE, *Surgeon.*—Detailed as Chairman of the Board of Examiners, November 20, 1889.

GASSAWAY, J. M., *Surgeon.*—Granted leave of absence for twenty-nine days, November 13, 1889.

GODFREY, JOHN, *Surgeon.*—Detailed as member of the Board of Examiners, November, 1889.

IRWIN, FAIRFAX, *Surgeon.*—Detailed as Recorder of the Board of Examiners, November, 1889.

CARTER, H. R., *Passed Assistant Surgeon.*—Granted leave of absence for fifteen days, November 29, 1889.

NORMAN, SEATON, *Assistant Surgeon.*—Ordered to New York Marine Hospital, for temporary duty, November 21, 1889. To examination for promotion, November 22, 1889.

FATTIC, J. B., *Assistant Surgeon.*—Ordered to examination for promotion, November 22, 1889.

HEATH, F. C., *Assistant Surgeon.*—Ordered to examination for promotion, November 22, 1889.

MAGRUDER, G. M., *Assistant Surgeon.*—Ordered to examination for promotion, November 22, 1889. Granted leave of absence for twenty-seven days, November 29, 1889.

PERRY, T. B., *Assistant Surgeon.*—Granted leave of absence for twenty-five days, November 29, 1889.

COBB, J. O., *Assistant Surgeon.*—Granted leave of absence for thirty days, November 29, 1889.

ORIGINAL LECTURES.

FACIAL PARALYSIS. PERIPHERAL EPILEPSY.

A Clinical Lecture,
Delivered at the Rush Medical College, Chicago, Ill.

BY HENRY M. LYMAN, M.D.,
PROFESSOR OF PHYSIOLOGY AND DISEASES OF THE NERVOUS SYSTEM IN THE RUSH MEDICAL COLLEGE.

FACIAL PARALYSIS.

GENTLEMEN: Observe the difference between the eyes of this patient, one of which is shut closely, the other partly open. This indicates weakness of the orbicular muscle of the eye, which is innervated by the seventh nerve, so that there is disease in the seventh, or facial nerve, which is distributed to the side of the face.

As he smiles one side of his face is drawn up, while the other is motionless, and it is impossible for him to pucker up his lips—a movement which is effected by the action of the orbicularis oris muscle. As he cannot close the eyelids on account of lack of contractile power in the orbicularis palpebrarum, so in the mouth he cannot adjust the lips because the right half of the orbicularis oris is paralyzed. He is able, you notice, to blow out his cheeks. He says that in eating the food gets between the teeth and gums.

The patient informs us that in June last he fell from a second-story window some twenty feet upon a stone slab, breaking his wrist. Blood came from his ears, which indicates that rupture of the tympanic membrane had occurred. Whatever hemorrhage took place must have been due to rupture of the bloodvessels in the middle ear.

This history leads us to infer that the injury was to the nerve where it lies in the bony canal, and that, perhaps, there was fracture of the bone with consequent compression of the nerve trunk. If this were the case we should expect the chorda tympani to be involved.

His sense of taste is unimpaired on the left side, but on the right it is diminished. If in a case of this kind the sense of taste is preserved, we infer that the injury is outside of the point where the chorda tympani springs from the main trunk, and that the lesion is a peripheral one, involving one portion of the nerve, and leaving the other intact. Where the sense of taste is involved the lesion is nearer the brain than the origin of the chorda tympani nerve.

This patient perceives the taste of an acid applied to the right side of the tongue, so that the paralysis is not complete. There are some who believe that the glossopharyngeal nerve is the only nerve of taste, but this varies in different persons.

The structures of the inner ear are not destroyed. The probability is that the tympanum was ruptured, which was followed by thickening, so that the drum-head is no longer capable of taking up sound vibrations and communicating them from the ossicles of the ear to the internal structures.

What is the proper treatment for such a case? It is not an uncommon thing to find patients suffering with paralysis of the facial nerve consequent upon simple exposure to damp or cold, but such patients are predisposed to rheumatism and demand specific treatment. But it would be useless to treat this patient with salicylate of sodium, or with other remedies given for the purpose of curing rheumatism. You must recognize the fact that there is injury to the nerve within the bony canal through which the nerve passes from the base of the brain, and endeavor to remove the exudation that probably causes compression. It is possible that we may not succeed in doing this, for there may have been sufficient displacement of the walls of the bony canal to produce permanent compression analogous to what occurs in the spinal cord where there is caries of the vertebræ. You know how patients suffer from caries of the vertebræ. After a time the vertebræ collapse, an angular curvature of the spine is produced, and the cord is compressed at the point of curvature. The pressure is sufficient to cut off all functional power in the cord, and the lower part of the body is consequently permanently paralyzed. We have a similar condition of things in the case before us, and it is possible that we may never succeed in relieving the nerve from the pressure.

Mercury and the iodide of potassium are efficient for this purpose, and in this case I would advise doses of five grains of the iodide of potassium, and one-thirtieth of a grain of the bichloride of mercury. Let the patient make use of these remedies as long as symptoms of deafness or paralysis exist. Electricity should also be applied to the face. The faradic current should be used, not because it will cure the disease, but because it will keep the muscles of the face exercised. What we desire is to preserve the muscles from atrophy while we are endeavoring to relieve the nerve from pressure. This is the only line of treatment that can be used with any prospect of success in such a case.

EPILEPSY OF PERIPHERAL ORIGIN.

The next patient I present to you is a girl ten years of age. About a year age, while apparently perfectly well, she was seized with convulsions. The first attack came on about nine o'clock in the morning, the mother finding her lying on the floor. She bit her tongue, frothed at the mouth, and, her mother says, remained unconscious for half an hour or more. After recovering from the fit the patient continued in a more or less feverish condition the remainder of the day. This was doubtless a typical epileptic convulsion. The next day she had two convulsions, one immediately following the other.

It is important to ascertain, if possible, whether she had fever, or whether the pulse grew more rapid during

the attacks and remained so, because we must make a distinction between convulsions that are epileptic in their character, recurring rapidly one after another, and constituting what is technically known as the *status epilepticus*, in which there is a rise of temperature, and those cases where we have simply a succession of eclamptic fits unattended by any febrile movement. The former is much more dangerous to the patient.

The mother did not bring the child here wholly on account of the epileptic convulsions, and we learn that there are other interesting points in connection with the case furnished us by her physician.

The child, you remember, is ten years of age, and you observe that she presents a maturity beyond her years. The mother informs us that in her family the occurrence of puberty is earlier than in the majority of families. Usually menstruation does not develop before the twelfth or fifteenth year, but from the appearance and development of this girl, I should say the commencement of menstruation was not far distant. Again, her physician has made a vaginal examination, and has discovered an ulcerated condition of the cervix uteri. This seems almost incredible in a child of her age, but is, of course, possible, and does sometimes occur.

We do not know positively the cause of these convulsions, but the probability is that they are due to the ulcerated cervix. It must not be forgotten that in some of these cases we have hysterical epileptiform paroxysms, or there may be a combination of the two disorders in a delicate and exceedingly nervous organization, producing all the convulsive manifestations common to *hystero-epilepsy*. But in epilepsy we have certain marked symptoms which enable us to discriminate between it and true hysteria. *True* hysteria is very rarely accompanied by unconsciousness. In a complete hysterical convulsion the patient preserves a certain amount of consciousness; in fact, she knows under what circumstances the convulsion is to take place, and, therefore, guards herself against a fall when the fit comes on. Again, the tongue and lips are not bitten. There are some physicians, however, who claim that this latter may occur, but I should want strong confirmatory evidence to make me believe that a patient bites her tongue and becomes entirely unconscious in a true hysterical convulsion. Hysteria manifests itself in the day-time, during the hours when the nervous system is exposed to excitation; in other words, it belongs to the waking period. The convulsions do not occur during sleep. This patient has convulsions in the night and while asleep, which is characteristic of true epilepsy.

Whatever may be said as to the general condition of her nervous system, its excitability, perhaps its hysterical predisposition, I think we have in this case an element of true epilepsy governing and controlling the manifestations. If that be the case, where is the source of irritation that excites the convulsions? This is not a case of congenital epilepsy, for, according to the statements of the mother, it is only a year ago since the convulsions first manifested themselves. Having, as we are told, an ulcerated condition of the cervix uteri, the probability is that *there* was the starting-point of the irritations which were communicated to the brain centres and brought about the convulsive movements. We may call this a case of *peripheral epilepsy*.

The treatment should, of course, be directed principally to the peripheral organ, and the ulcerated condition of the cervix must be remedied before we can hope to relieve the convulsions. It is highly probable that the occurrence of menstruation and the periodical relief that is obtained through that function will help to relieve the patient of the seizures. She must be cured of all swelling, inflammation, and ulceration about the cervix. In addition, the ordinary treatment of central nervous diseases must be resorted to, which I have detailed in previous lectures.

CARTWRIGHT LECTURES.

Delivered before the
Association of the Alumni of the College of Physicians and Surgeons, New York, November 22, 1889.

BY JOHN S. BILLINGS, M.D.,
U. S. ARMY.

LECTURE III.

ON VITAL AND MEDICAL STATISTICS.

THOSE of you who are familiar with the history of medicine in the early part of this century will remember the great anticipations which were formed and expressed by prominent physicians as to the results which might be expected from what was called the system of statistical medicine introduced in the Paris school by Louis and his contemporaries. This was not exactly a new system, but rather an attempt to methodize an old one—*i. e.*, to present the experience of different physicians in such a way that comparisons might be accurately made and the results mathematically expressed.

In this so-called numerical method all the details of each case observed are to be noted, as far as possible, without any special regard to whether these details may appear to the observer to have any special connection with the course of the case or its termination, or not. When a number of such cases have been collected, they are to be compared in all their details, showing in round numbers how many present such and such particular circumstances, and how many do not.

In order to make a useful application of this method, it is, of course, necessary that the different observers shall be describing substantially the same thing; that is to say, the disease to be observed must present a definite series of symptoms, so that a person properly qualified will recognize its existence without any liability to error. It should also be a disease which follows a tolerably regular and definite course, having a commencement which can be recognized. Such forms of disease include the so-called specific diseases and acute affections of particular organs. The method is most applicable to surgical cases of all kinds, including those which come under the domain of the various specialties.

As regards details of pathological anatomy, it has been pointed out by Dr. Flint that the statistical method can only apply to those changes which can be appreciated by the senses after death, and that, there being but one constant lesion found in typhoid fever, viz., the softening of Peyer's patches in the small intestine, the statistical method gives us little assistance in the investigation of the pathological condition of this disease.

We may note, however, that if it be admitted that typhoid fever is due to a specific bacillus, as seems now

to have been fairly demonstrated, and that this bacillus has been discovered and verified mainly by the application of experimental methods, it is, nevertheless, true that the results thus obtained have met with a general and prompt acceptance, mainly because the application of statistical methods to the circumstances of outbreaks of this disease in different communities is in perfect accord with the bacillus theory of its causation.

This merely illustrates the general law that the experimental and the statistical methods must be used together, and that their results must be in accord to produce full confidence in the results obtained by either alone.

The sanguine advocates of the numerical system of Louis supposed that all that was necessary to discover all the laws with regard to the propagation of any disease, and the true value of any or of all methods of treatment proposed for that disease, was simply the collection by different observers of all the data which could be obtained from individual cases, and the tabulation of these, according to a certain fixed and almost mechanical system of permutations and combinations, by means of which the various symptoms are brought together in groups, in connection with the results observed, and that thus would be obtained a true scientific basis, or, as they commonly phrased it, "the science of medicine."

We can now see plainly enough that this is, from the nature of the case, impossible; that the data obtained by different men can hardly ever be made fully comparable; and that, however complete they may be, the number of factors which combine to produce such a result as the production of a particular form of disease in a healthy organism is so great that, from mere statistics of observation, we can never obtain any scientific knowledge as to the relative part which each factor has taken in producing the result. This can only be done by experimental methods, in which the influence of one particular factor can be applied and those of others eliminated as far as possible; and the great advances which have been made toward obtaining a scientific basis for practical medicine within the last twenty-five years are, in the main, due to the experimental method. So soon, however, as we have, by the investigation of particular cases and by experiments, obtained a more or less probable theory as to the cause and mode of diffusion of a particular form of disease, the outbreaks of that disease in a community afford an invaluable means, in many cases, of testing the truth or falsity of the theory.

It must be admitted that the probabilities of error are much greater in medical than in vital statistics, and this for a number of reasons. The first is, that no two observers examine or interpret a disease in precisely the same way, and hence it is extremely difficult to collect a mass of observations sufficiently large to form a basis for statistical reasoning. Those who wish to be scientifically accurate in the use of such material, are usually compelled to deal with a very limited number of observations, because they cannot obtain a large number upon which they can fully rely.

The best data are, for the most part, those which lie in the field of surgical observation, since here the symptoms observed, the methods of relief applied, and the results obtained, are tolerably definite, and there is not likely to be much difference in the methods of recording them.

The methods of medical statistics differ fundamentally from those used by the vital statistician in that they usually have no relation to the phenomena observed in the normal, healthy, living population. The physician inquires, out of a thousand cases of children or of old persons that have been treated, how many times this particular disease has been met with; or, in a given number of cases of this disease, what proportion have died. This method is, in fact, practically the only one which is available to the physician; but the vital statistician, if dealing with disease, will want to know the probabilities that a male between twenty and thirty years of age will contract a given disease, such as phthisis or typhoid fever; and for this purpose he wishes to know the whole number of cases observed in a given population, and the number of the population furnishing those cases, in order to establish the ratio.

Bertillon illustrates this in his comment that the small number of deaths of old men attributed to typhoid fever might lead the physician, from his point of view, to say that typhoid fever in old age is a rare disease; but the vital statistician might conclude that the rarity of the disease in old age was simply due to the small number of those living at that period.

In discussing the tabulation of the returns of cases of acute rheumatism, in the *Collective Investigation Record*, Dr. Whipham gives the number of cases in each occupation out of 655 cases recorded. Of these, 71 were domestic servants, 16 agricultural laborers, 13 farmers, 10 grocers, etc. He comments that the number of domestic servants (71) is a remarkable occurrence, and proceeds to account for it by the consumption of alcoholic drinks, etc.

It is evident, however, that absolutely no conclusions can be drawn from these figures, since there is no definite proportion between the number of domestic servants attended by the physicans who made the reports and the number of domestic servants in existence, nor is there any relation between any of these figures and the number of domestic servants attacked by rheumatism. The only way in which this factor could be brought in in such statistics would be with reference to frequency and character of complication, or to relative fatality of the attacks in comparison with other occupations.

The fact that in each case of sickness there are many different circumstances which combine to produce the result is not, as Louis remarks, a valid objection to the use of statistical methods for the purpose of estimating the influence and relative importance of each of these influences; it is rather an argument in favor of their employment. Counting is better than guessing, and when it gives contradictory results as applied to two groups of cases, it indicates that some circumstances have not been taken into sufficient account, and that further inquiry is necessary. In the body of the sick man, as in the test tube, like causes under like circumstances will produce like effects.

Admitting that the chances of error in medical statistics are very much greater than in those relating to vital statistics, it does not follow that they have no value. It simply increases the desirability of collecting a large number of facts before proceeding to draw any definite deductions.

In statistics in regard to therapeutics we have to take account of the various influences which the condition of

the organism exerts upon the results, before we can fairly estimate the action of the new and special influence which has been introducted in the shape of an action of a drug or a particular mode of treatment. In any event, such statistics, even when derived from a small number of cases, serve to indicate lines of investigation, and to ask questions, if they do not answer them.

The greater part of our pathology and therapeutics has not been derived from statistical observation. Whenever a necessary and logical connection between a particular cause and the resulting phenomena has been established, statistics are of little or no value in demonstrating the connection. In every case the result must follow the cause, as it does in a chemical experiment, and a few repetitions of such experiments give as great a degree of certainty as a thousand or more.

The chances of the occurrence of a certain event in relation to cause can only be mathematically calculated when the totality of the possible causes of the result remains the same under the different circumstances investigated. This is one of the chief reasons for the impossibility of drawing positive conclusions from medical statistics, properly so called.

The consequent condition is one that I have already mentioned, viz., the application of the law to large numbers and the consideration of the limits of positive error.

The services rendered by statistics to medical science are by no means so great as was hoped by those who first proposed the application of this method; partly from the nature of the case, partly from the wrong application of statistical methods to groups of cases to which they are in nowise applicable. What result, in fact, can we expect from statistics applied, for example, to a number of cases of fever before the distinction between typhus, enteric, and relapsing fevers was understood.

"The results of medical statistics will not apply to the treatment of any particular case. They can never prove that bloodletting should be employed in all cases of pneumonia, or that it should never be applied in any case of pneumonia. Even the results obtained from the most satisfactory medical statistics will only be found useful to the physician in directing his treatment, in the absence of any special indication in the particular case which he has before him."

The data upon which to base medical statistics must be obtained either from published records, from unpublished memoranda collected by means of correspondence or by the so-called collective investigation methods, or from personal experience. The published data include such records of private practice as are given in journals, transactions, monographs, etc., records and statistics of hospitals, statistics of public medical services, and of medical and life insurance societies.

In many respects the crude data, in the form of records of individual cases, are the most reliable, but the labor of collecting and combining them is great, and we desire, therefore, to use the statistical tables prepared by previous workers, as far as they are available, for the particular inquiries which we have on hand.

Detailed reports of cases, such as are suitable for use in statistical work, are not over-plentiful. In the majority of cases the individual data are not given. We have only summary statements of tables of results. This is the case with regard to much the larger part of the great mass of reports of results of hospital and asylum practice, either in the form of separate annual reports or in summaries for journals or societies. These reports give some information as to the prevalence of certain diseases in certain places at certain periods of time, and in this way have some historical value; but they do not show the proportion of cases of disease or death to the living population in which these occur, and very few of them give the data by sex and age in the manner required by the statistician. Some of these calculate death-rates with reference to the total number admitted during the year; others, to the total number treated, which includes those remaining on hand at the beginning and those admitted during the year; and others, to the total number disposed of during the year by discharge, transfer, or death. A few of them give the average daily number under treatment during the year, and the average number of days' treatment for each case, sometimes making a distinction of sex, but almost never of race or age.

Comparison of gross death-rates of different hospitals, however calculated, are of little value for the purpose of determining either the sanitary condition of the place, the skill of the medical staff, or the merits of the particular system of treatment, owing to the great variations in the class of patients admitted. Of course, the statistics of hospitals for special classes of diseases can only be compared with those of the same kind; and even for general hospitals, the fact that the gross death-rate of one is higher than that of another, proves very little.

In a paper by Dr. Guy on the rate of mortality prevailing in the general hospitals of London, he compares the death-rates of King's College Hospital, with which he was connected, for the first five years of its existence —1840 to 1844—with the five years from 1857 to 1861. During the first period it was an old building, in a bad locality, and greatly crowded, and without any reputation as a hospital or as a medical school. During the last five years it was in a new building with excellent sanitary arrangements, and with an excellent reputation. He calculated the death-rates on the number of admissions to the hospital. The rate for the first five years was 8.4 per cent.; during the last five years it was 10.85 per cent. He concludes that a higher rate of mortality may be due to causes very different to sanitary defects in the building and want of skill in the medical staff; and that in a large city, in the case of a hospital enjoying similar sanitary advantages, the rate of mortality is mainly determined by the reputation of its hospital staff among the public at large and among its own pupils, which reputation influences the proportion of grave and dangerous cases which are sent to it.

In comparing hospital death-rates, it is now generally agreed that it is best to make use of the death-rates in relation to the total number of persons disposed of by discharge, transfer, and death for a series of years. Comparison of the number of deaths with the admissions only is apt to give very misleading results. A better method than this is that of Bertillon, who adds to the number at the beginning of the year one-half of the sum of those admitted and of those going out. It is also desirable to know the ratio of deaths and discharges to the mean population of the hospital, which is obtained by dividing the number of days of treatment by 365; but in this connection it is to be remembered that when

the mortality is calculated with relation to the number of days' sojourn in the hospital, those physicians who keep their patients the longest will show the lowest death-rates.

In his prize essay on *Hospital Statistics*, Dr. Steele substantially agrees with the remarks of Dr. Guy above referred to, and says that the hospital which confers the greatest benefit upon the community is that having the highest death-rate, as it is the one which admits the most critical and incurable affections. As the population of a city increases, the demand for hospital accommodation also increases, and unless more of this is provided, the tendency is to select the more serious cases for admission, and thus to procure an increased mortality rate.

I cannot assent to the proposition that a high mortality is any proof of the utility of a hospital, or of the skill of its staff; but it is certainly not a proof of the contrary.

"In all large hospitals from one-half to three-fourths of the deaths in the surgical department are due to accidents. The ordinary death-rate of surgical cases ranges from 5 to 7 per cent. If the deaths from accidents be deducted from the total deaths in surgical cases, there will be but a small percentage left. The mortality of the non-accident cases averages from 4 to 5 per cent. But the fame of the hospital, the reputation of its staff, especially for difficult and hazardous operations, may tend to increase the ordinary death-rate."

An increased mortality in the surgical ward may be due to special provision for permanent residence of patients with incurable diseases, such as the establishment of a ward for cancer cases.

There have been a number of reports and discussions in statistical congresses and societies with regard to the best forms to be used in publishing hospital statistics. The following are the *desiderata* for hospital statistics as given by Miss Nightingale:

1. Remaining in hospital on the first day of the year.
2. Admitted during the year.
3. Recovered or relieved during the year.
4. Discharged incurable, unrelieved, for irregularities, or at their own request.
5. Died during the year.
6. Remaining in hospital on the last day of the year.
7. Mean duration of cases in days and fractions of a day.

In each of these headings the data are given for each disease, for each sex, and for each of a number of groups of ages; the primary object being to ascertain the total sick population—that is, the number of beds constantly occupied during the year for each disease and each age and sex; 2d, the number of cases of each disease for each age and sex submitted to treatment; 3d, the average duration of each disease for each age and sex; 4th, the mortality of each disease for each age and sex; and, 5th, the proportion of recoveries for the same.[1]

Prior to the discovery and employment of antiseptic methods in obstetrics the records of lying-in hospitals were very unsatisfactory. It is true that we have no very definite standard of death-rates in childbearing in private practice with which to compare them, but this rate is given by the Registrar-General of England as being at the rate of five per thousand children born alive for the 28 years, 1847 to 1874.

The summary of the returns of the extern maternities in connection with Guy's, Bartholomew's, and St. Thomas's Hospitals for the 21 years, 1856 to 1876, comprising an aggregate of 74,580 cases, gives a mortality of 4.1 per 1000.

The largest lying-in hospital and the oldest is that known as the Rotunda, or Dublin Lying-in Hospital. In 198,481 cases of confinement in that hospital, the death-rate was 13.2 per 1000.[1]

It is not an easy matter to determine what may be called the normal or average mortality of women in chilbirth in order to determine the probable utility of a particular mode of managing cases of labor, as, for example, the so-called aseptic method. From the mortality statistics of the late U. S. Census (Report on Mortality and Vital Statistics, Pt. II., lxx.) we find that in 1,577,173 births 5646 deaths of the women are reported, being in the proportion of 3.57 per thousand births. This proportion was higher in the rural districts than in the large cities, and in negroes than in whites.

For the same year (1880) the Registrar-General of England reports the death-rate of women in relation to births as 2.07 per thousand. If, now, we compare these figures with those given by obstetricians and physicians, we shall find that the latter give death-rates from two to four times as great. Thus, Duncan gives the death-rate in private practice as from 8 to 10 per 1000 births, while Le Fort gives the figures from maternity hospitals as 30,594 deaths in 888,312 births, or over 34 per 1000; while Ehlers, using the statistics of Prussia from 1816 to 1886, gives the rate as from 5.8 to 9.4 per 1000.

How are we to explain these differences? Is the reported great mortality in rural districts, in certain races, or in physicians' reports due to peculiarity in the cases reported, or to the surroundings, or to the method of making reports and collecting data? Evidently the latter is first to be considered. In the data furnished by the Census and the English registration reports, the cases attended only by midwives and "wise-women" are included as well as those attended by physicians, and it is among the negroes and the Germans that the proportion of cases thus attended is the greatest. Moreover, in the cities where there is a regular registration of deaths upon physicians' certificates there is less tendency to give the vague term of childbirth as the cause of death than in the rural districts where the cause of death is returned by non-professional persons; but this does not apply to England, and it is not probable that it greatly influences the results in this country.

The deaths reported in the census as due to childbirth are those which occur during or soon after labor, including those due to hemorrhage, exhaustion, acute uræmia, etc., while those which occur at a later period may be reported as due to peritonitis, septicæmia, etc., although the physician in reporting the results of his private practice would include all these as deaths due to labor.

While the physician will usually consider only the relation between the number of cases of labor and the number of deaths in childbirth, the vital statistician will

[1] See paper on Hospital Statistics and Hospital Plans, by Florence Nightingale: Transactions of the National Association for the Promotion of Social Science, 1861, p. 554.

[1] Summarized from Dublin Medical Journal, 1869, and from Dr. Johnston's Annual Reports from 1868 to 1875.

study the relations of deaths in childbirth to the number of women living between the ages of 15 and 50 years, or to the total number of deaths from all causes. The figures of the last U. S. Census show that of every 100,000 women between the ages of 15 and 50 living in our large cities 16.21 died in childbirth during the year, while in the rural districts the corresponding figure is 51.56.

If, then, we are to judge as to whether the death-rate in childbed in the practice of a particular physician is to be considered as high or low, we must first know whether the figures relate to hospital or to private practice, and, if the latter, whether it was in the city or in the rural districts. To obtain some standards for comparison, we may use the numerous reports found in medical literature, in which physicians have given the statistics of their private obstetrical practice, and compare the results with those given in the statistics of maternity hospitals.

For prisons and asylums the death-rates should be given for the average daily population in the institution, and not for the number of admissions or for the number of cases disposed of; but in these cases gross death-rates for the whole population are of very little use. It is necessary to have them with distinction of sex and age, in order to make comparisons with the death-rates of the general population coming under the same groups.

(To be concluded.)

THE CAUSES AND TREATMENT OF INFLUENZA.

BY ROBERTS BARTHOLOW, M.D., LL.D.,
PROFESSOR OF THERAPEUTICS AND MATERIA MEDICA IN THE JEFFERSON MEDICAL COLLEGE.

Influenza considered from the historical standpoint.—The reappearance of influenza in one of its cyclic manifestations, or epidemics, is an interesting event. With the improved methods of study and determination of bacteria, its character of the development will now be arrived at with some certainty. Already the study is bearing fruit, and the pathogenic organism has been announced again as it was many years ago. All the facts in the behavior of successive epidemics can be accounted for on this hypothesis only: that some microörganism is the real *materies morbi;* and as no theory can be true that omits facts that are essential, and as it is not theoretical discussion I purpose entering on, I content myself with saying that there is every reason for the belief that some microörganism or its ova is deposited on the mucous membrane of the nares, bronchial surfaces, and fauces, which, proceeding on its course of development, induces a local irritation and systemic poisoning attended by the complexus of symptoms known as influenza. It is necessary, however, before we can finally accept an organism as the genuine one, that proper cultures be made

There are many singular points in the history of influenza epidemics which may be used here merely to illustrate the nature of the malady and its cause:

In the first place, as to the manifestations of the disease in history. Four centuries have certainly witnessed true epidemics, and the periods of recurrence have shown that a real plan has been followed; but there have also been numerous apparent visitations of the epidemic activity which can only be explained on the hypothesis of a minute organism.

There are, it is clear, two great periods of wide diffusion of the *materies morbi*—one in which the maximum length of the interval between the rise and spread of the influenza is from forty to fifty years, and the other from fifteen to twenty years. As, however, there are many minor epidemics, it must be explained how these are accounted for on the principle that a living organism—a microbe—is the morbific agent. The minor epidemics of variable periods are restricted to certain localities where the conditions of soil and climate, or other special influences, favor the stay of microörganisms—their reproductive activity and their action on the mucous membrane; but in these instances they do not develop, in the course of their physiological growth, sufficient momentum to spread beyond the parts to which they are restricted. Another restraining influence is the limitation of those local climatic peculiarities which have been the efficient cause of those favoring influences to be hereafter described.

It is quite evident that certain climatic conditions have existed in the areas of diffusion occupied by the microbe, as there are cycles of time connected with the changes in the "sun-spots." Herschel pointed out long ago that these cycles of sun-spots occupied periods of time of eleven years and seventeen years, which a common multiple will bring into harmonious relations with the periodical activity of the epidemic power or influence, and whatever climatic characteristics must exist to secure the necessary power of diffusion to the microbe or poisonous material, this power must be general or universal in our atmosphere to satisfy one principle—that is, the principle of universality—for no restrictions in the atmospheric areas exist as against the appearance of influenza.

The one great fact of the epidemic influence is its *universality*. The great epidemics have prevailed in all climatic areas from the equator to the poles, through isothermal, isotheral, and isoclinal lines, and the special peculiarity of these divisions, of the temperature lines, which would otherwise be considered accidental, is the extent of humidity, of rainfalls and fogs, and of those peculiarities of soil and climate set up by them. As respects the climatic changes, they must be such as have connection with great periodical disturbances in the great source of changes in temperature—the sun with its photosphere and magnetic storms.

It has often been remarked that the direction of prevailing winds may be wholly against the general direction taken by the microörganism in its diffu-

sion. This phase of an epidemic presents no difficulties, now that it is proved that the direction taken by the higher currents in our atmosphere may be pretty generally opposed to those of the air strata in which we live. The Eiffel tower has had a meteorological station on its highest point, and even at this point it has been ascertained that the prevailing wind is in the opposite direction to that on the earth's surface. The diffusion of a pathogenic microbe, the conditions below being favorable, may take place from a higher portion than it were otherwise possible to do and thus wide distribution be attained. As damp and foggy weather is the only variation in the usual course of things climatic in character, that seems to be a necessary condition to the development of the disease, we may assume that the diffusion of the germs is probably facilitated by this state of the atmosphere.

As regards individual susceptibility or insusceptibility, the only known conditions besides those above mentioned that appear to influence the attacks of influenza are infantile life and sex. An infant is, clearly, less liable to have attacks, and delicate women more susceptible than males. There is no difference due to condition of life, and those insanitary surroundings that increase the tendency to seizures of infectious diseases do not appear to have any influence over the progress of influenza.

It is conceded by Hirsch and Lombard[1] that the various epidemics have quite uniformly had the characteristic qualities exhibited in the above outline. That the pathogenic material exists in the form of a microörganism must be considered as the only true explanation of the nature of influenza, as studied from the historical standpoint. Not less, also, must it be the conclusion when the question is to be answered from the pathological standpoint.

Pathology and morbid anatomy.—In respect to its pathology, we find that epidemic influenza is allied to the recurring catarrh known as hay-fever, at one end of a series, and to diphtheria at the other end. In respect to the severity of the morbid complexus, the relationship with diphtheria is more intimate.

The changes in the tissue are in the same order as those attendant on an acute catarrh caused by such local irritants as the powder of ipecacuanha, the odors derived from certain flowers, and the pollen of grasses, giving rise to hay-fever as the hyperæmia and catarrhal process of those points of mucous membrane where the *materies morbi*—a microbe or poisonous matter produced by a microörganism is lodged. When such an organism or its spores come in contact with the mucous membrane, it begins its development—living and growing, and reproducing its own kind. As the mucosa is the soil from which it extracts its own nutriment, so to this soil it returns the product of its own physiological activity. The question whether a given germ itself caused any morbid complexus has been asserted and denied, but the weight of authority is unquestionably in favor of the view that ascribes the symptoms resulting from the action of germs to some product of their own growth. Numerous examples may be given, but a few of the more important must suffice. Thus in infectious diseases, a poison produced by a peculiar microbe is formed from the mucosa where it is deposited. It is held, for the most part, that the poison is a chemical one; that local ulcerations may be formed partly by this substance, and systemic action is caused when the poison enters or diffuses into the blood. The maladies caused in this way are typhoid fever, the eruptive fevers, and some others.

As respects the severity of the consequences which result from the action of specific microbes, there are various differences between the several forms both in the local and systemic actions. Thus in the case of Eberth's typhoid bacillus the local action is severe and the systemic also; but in the case of the germ of influenza the local action is far less important than the systemic disturbance.

The mucous membrane may be attacked at any point where the access of air is secured by the anatomical arrangements—the nasal, faucial, bronchial, and Eustachian tube tracts of mucous membrane and the intestinal canal. Here are to be seen the various stages in the process of mucous inflammation, according to the time of original contact—the dry stage of congestion, followed by increased secretion, first of serum and leucocytes, and, third, the addition to the second of the ordinary purulent materials. According to the severity of the disease is the extent of the mucosa affected. In the severer cases we find, besides the same changes of the mucous membrane, capillary bronchitis, catarrhal and croupous pneumonia, the products of the catarrhal process containing some peculiar opaque masses. Although catarrhal and croupous pneumonia are said to be "complications" they should be regarded as occasional conditions, and when present are, properly speaking, constituted parts of the malady. Whatever peculiar appearances in the products of the inflammation may be seen, are no doubt due to some form of the parasitic growth. The chief importance of croupous and catarrhal pneumonia is that the development of these, out of an existing catarrh of the bronchi, is frequently a cause of death.

Similar lesions are found in the œsophagus and stomach, and rather rarely are the intestines reached, whence it may be concluded that the parasites deposited on the mucous membrane of the mouth

[1] Traité de Climatologie, tome iv. p. 400.

are swallowed with food and drink, and thus come into contact with the mucous surfaces below.

The changes effected by the action of the morbific matter on diffusing into the blood have not been studied, and, also, the effects upon the circulating organs and the lesions of the nerve centres remain as yet unexplained. That the ptomaine formed by the development of the microbe exerts an influence on those organs upon which it seems to have a selective action can hardly be doubted; but until the special form of the microörganism has been determined the nerve pathology must continue obscure.

The symptom-complex of influenza.—This malady has the general character of an acute mycosis, has a local action on the point of deposit, forms a chemical ptomaine, and by the absorption of this the systemic affection results. It follows, therefore, that two kinds of symptoms result: local symptoms and systemic symptoms.

Influenza comes suddenly; goes as quickly. The least robust, at any age, and women seem to be the first victims. It is here a question of bodily condition, not of the sex. The large numbers simultaneously attacked attracts general attention, and thus those most impressionable are seized, the onset being facilitated by any depressing emotion like fear or illness. There is no rigor, properly to be thus designated, but rather a series of light chills and a feeling of heat therewith. Sometimes *malaise* of a general kind is experienced, but, like the attack itself, is short in duration—lasting but a few hours. When the air loaded with the microörganisms reaches a given population, down upon all human creatures fall these bodies, and by the air they are carried into all the recesses and crevices of the naso-pulmonary mucous membrane. This being a soil favorable for their growth and multiplication, these processes begin, and immediately a poison is formed and diffuses itself into the blood. Some local action is exerted by the poison, of a chemical nature, probably; but for the most part the production of this material necessitates the action of the germ on the parts where it is living and growing. Hence it is that a morbid state of these parts is induced.

With some bad feeling, not developed immediately, however, there are heat and burning of the nose and fauces, tickling with heat of the Eustachian tube, and a similar sensation in the tear duct. The eyes feel hot, the lids swell, and tears begin to flow. The most unpleasant of these sensations is a stuffing of the upper parts of the nares and even in the frontal sinuses.

With the first access of the nasal and faucial irritation comes the chilliness, which is followed by some feverishness, with more pronounced *malaise*, and, in general, the headache, weakness, and soreness of the members, especially of the larger joints. With the progress of the case in some epidemics there is considerable general weakness, even marked depression, of the vital powers. The pulse becomes small and weak, the mind gloomy, and restlessness ensues. There is little disposition to exertion at any time, and mental hebetude coincides with physical depression. The indisposition to exertion is a conservative state, in so far as quiet is necessary, owing to the enfeeblement of the cardiac ganglia and the centres of the respiratory and cardiac systems.

When a fatal termination is to occur, as a rule, an extension downward into the trachea and bronchi takes place. The cough in all cases has, at the outset, a brassy, rough, or ringing character; it is not paroxysmal; it is frequent, almost incessant, as is the tickling of the throat, the tickling of the nares, and the itching and tickling of the middle ear. With the downward spread of the disease a good deal of mucus is expectorated, at first grayish, tough, and gelatinous, becoming afterward merely purulent and watery, and rather rarely, brownish-gray, with crystalline masses mixed in. Rather rarely, however, casts of the lesser bronchi and bronchioles are brought up, after most prolonged and distressing coughing, and such an access is followed by feebleness and by extreme weakness. In fatal cases, as a rule, the phenomena of catarrhal pneumonia and of croupous pneumonia supervene; but, as they offer no special differences in their symptoms and course, they do not require further consideration here.

Course and duration.—The rapidity with which the disease supervenes—its preliminary development being hours, and its whole career but a matter of three or four days, is remarkable. It must be remembered, however, that those already suffering with an acute catarrh are apt to have the epidemic seizure fastened on it, or that the true influenza may excite, especially in those with a phthisical tendency, a catarrhal process, which, in the ordinary form, may continue. The variations in severity in the local symptoms, in the character of the cough, in the expectoration, are considerable in ordinary cases, and in those of mixed character cannot be reduced to fixed rules, especially in the phthisical and in those with disordered nervous systems.

As respects the heart and circulation, it is to be noted that at first the pulse is not much affected; a little fuller, with moderate fever, but in the severe cases becomes weak and often intermittent, changing to thready and extremely irregular in a few hours. As, in the days of the chief epidemics, the thermometer was not used, the only evidence in the matter of temperature is derived from the more or less graphic statements of the medical writers of the past generation. It was not often increased more than 2° F., we may suppose, and rarely above 5° F. when catarrhal and croupous pneumonia were added to the morbid complexus. There is reason to be-

lieve that in those cases characterized by the predominating nervous element headache, dizziness, mild delirium, pains in the limbs, and obstinate wakefulness, and most commonly seen, although extreme somnolence and prolonged sleep have been observed in many instances.

Relapses are common, usually each succeeding seizure being milder, but not a few pass by easy transition into chronic bronchitis, emphysema, asthma, etc. The secretion of the urine is generally unaffected, except by those simple changes belonging to a mild febrile attack; but in not a few, the urine becomes albuminous and scanty, and anuria is added to the other morbid conditions and symptoms. Obviously a catarrhal process so extensive and severe may contribute immensely to chronic disease of the middle ear, Eustachian tube, nose and throat, and thus permanently damage the parts.

In a small proportion of cases, the stomach is disordered, diarrhœa supervenes or a dysentery appears, all due to the microbes which pass down with drink or food.

Something may be said, and very profitably, of the catarrhal epidemic epizootic which prevailed amongst horses in 1870 or about that time.

As an owner of some driving horses, and needing their service, I was necessarily a close observer. The horses well fed and carefully "stalled" were much less severely attacked than those in crowded stables and badly used in all ways. All were weak and had an aspect of suffering, were cool to the touch, had a little fever, but usually a subnormal temperature, some swelling of the neck glands, and the other symptoms of a catarrh, including a very purulent discharge.

The mortality was considerable in the severer cases, and the causes of death were the same as in man. It appeared to me that this epidemic disease is the parent of the affection in man, but modified by transition through so many, it has become milder, and each succeeding epidemic is less aggressive.

In the case of my own horses, I found atropine sulphate an efficient remedy.

Treatment.—Though having had no personal experience the general principles are such as to permit an authoritative expression. When the great epidemic of 1845–46 prevailed, President Tyler's personal experience was so unhappy that the popular name of "Tyler's grip" was given to that epideimic.

Persons suffering from catarrhal affection of the naso-pulmonary mucous membrane should adopt the most effective means to keep in good condition —for the impressionability is increased by anything that lowers the vital tone. Are there not microbes that may be used to lessen this susceptibility and any special readiness to receive a new morbid process to be engrafted on the old? It seems to me that the best manner of securing immunity is by the inhalation of sulphurous acid gas daily when the approach of the epidemic renders it necessary, and by taking five grains of salicylate of cinchonidine three times a day, and by so living as to avoid taking cold.

When the attack has begun, it seems to me desirable to give one or two grains of calomel at night, inhale some sulphurous acid gas, and have the patient sit in a room where steam containing eucalyptol can be inhaled in large quantity.

Local applications are useful as furnished in gases, in vapors, and in powdered solids by the method known as insufflation.

Of the gases, sulphurous acid is one of the more efficient against such troubles as tuberculosis, where a conclusion is reached by test of cultures. To give this, burn some sulphur in an apartment. The amount of the gas to be inhaled depends on the person and his condition. To determine these points, trials are necessary. Ordinarily, some constriction of the throat and a pronounced metallic taste—"brassy"—indicate the limit. The frequency may be twice or thrice a day. Peroxide of hydrogen, oxygen, or ozone will no doubt act well in suitable cases.

The best vapor to use during the preliminary dry stage is steam, and the patient may inhale constantly by filling the air of the apartment. With steam may be included the vapors of creasote and oil of eucalyptus, or turpentine. A simple method of using these remedies is to put into some water a sufficient quantity of eucalyptus leaves and add from time to time creasote or turpentine, or both. The water in the vessel containing these medicaments is made to simmer all the time. The heat may be obtained from a gas stove a gas-burner, or the common stove. The amount to be disengaged may here be ascertained by noting the effects on the local trouble.

Of the vapors, those most useful are ethyl-iodide, creasote, turpentine, iodine, carbolic acid, iodine with creasote or carbolic acid, etc. These are most useful in the stage when the dryness of the mucous membrane is becoming moist and relaxed.

By insufflation—that is, by projecting fine powders by blowing on the affected parts. An insufflator is an easy method for applying the powder; it has a cavity reservoir, a tube straight or curved, and an air-bag for forcing the air through.

Of the powders, those most useful are iodoform, salycilate of bismuth, tannin, iodo-tannin, and especially resorcin. The last-mentioned will be found to have an excellent effect, by dusting over the whole area as far as practicable.

The internal remedies that will do most good are, first, atropine in solution—gr. j to ℥j of water—

each minim containing $\frac{1}{480}$ to $\frac{1}{400}$ grain, and the dose will be from one to five minims, the minimum being for little children (after first dentition). The tincture of belladonna may be used — from one to ten drops twice a day. As this medicament is both prompt and prolonged in action, it should be given not more than twice a day, unless the dose be much smaller than is advised above. Salicylate of cinchonidine and quinine should be given as a prophylactic remedy, if there be reasons to suppose that such power is really exerted by it. My own conviction is that as a prophylactic the combination of cinchonidine with salicylic acid is preferable to quinine. For the depression and melancholy it is probable that atropine will do better. For the distressing headache, joint pains, and wakefulness, antipyrin, acetanilid, phenacetin, and other germicides and antiseptics, will, no doubt, be found useful.

SECONDARY BONE IMPLANTATION BY A MODIFICATION OF SENN'S METHOD.

By JOHN B. DEAVER, M.D.,
DEMONSTRATOR OF ANATOMY AND LECTURER UPON SURGICAL ANATOMY, UNIVERSITY OF PENNSYLVANIA; SURGEON TO THE GERMAN, ST. MARY'S, AND ST. AGNES'S HOSPITALS, PHILADELPHIA.

Annie H., aged seventeen, a native of the United States, was admitted into the wards of the German Hospital in September of the present year, with a diagnosis of necrosis of the lower third of the right femur. The history of the case is as follows: Family history negative; the patient was entirely well until two years ago. At that time she was occupied in household duties on a farm. One day, while scrubbing the floor in a kneeling position, she felt some pain which was referred to the right knee. The pain increased during the following day, when the joint became swollen and red. Three days later she was unable to stand or walk, when she was put to bed and confined there for the following thirteen months. Her treatment at that time consisted mainly in extension. The pains, which had been acute at first, became dull in character and shifted gradually from the front of the joint to the outer and lower aspects of the thigh. It was decidedly worse at night, the patient being frequently awakened from sleep by sharp, spasmodic, starting pains. Ten months ago she was permitted to get out of bed and move about on crutches. Soon after this an abscess formed on the outer side of the lower portion of the thigh, which was incised and evacuated by her physician, Dr. John Wentz, of Jeddo, leaving a sinus still present at the time of her admission to the hospital.

The affected knee had not regained its normal function. It was weak, "loose," and movements of flexion and extension were impaired, according to the patient's statement on admission. The above facts were found to be the case; also, coexisting lateral motion and soft crepitus were detected. On probing the sinus in the soft parts, the probe was readily brought in contact with exposed bone, which appeared solid. An examination of the other joints and of the secretions of the lungs and kidneys was negative. October 4, 1889, my colleague, Dr. J. William White, made a free incision, in the long axis of the thigh, opening up the sinuous tract, exposing the deeper structures. No necrosed bone could be felt under the periosteum, but upon chiselling out the compact substance somewhat deeply, a large cavity was discovered filled with débris and a sequestrum. After the cavity was thoroughly cleaned out it measured five inches in length and about one inch in breadth; the cavity trespassed on the spongy tissue of the external condyle. The wound was irrigated and the cavity packed with iodoform gauze wrung from a solution of bichloride of mercury, 1 : 2000.

The antiseptic bandage which enveloped the limb had to be reinforced several times, as there was considerable oozing from the wound. The limb was kept in an elevated position for several days. The second dressing was applied on the third day after the operation, and the third dressing on the tenth day. No pus was to be seen at either time. In spite of careful attention to the wound, a well-regulated diet, absolute rest, tonic and alterative medication, the process of regeneration was very slow. Dr. White's term of service having expired for the year, the case was placed under my care. Finding that the patient was not improving as rapidly as she should, I therefore decided to perform the implantation of decalcified bone chips (Senn's method). Dr. Senn, in an article in the *American Journal of the Medical Sciences*, September, 1889, states that a secondary implantation of decalcified bone chips can be as successfully performed as the primary operation, providing certain precautions (which I will state a little later on) are carried out. Having decided to operate, the granulations being in a healthy condition, I requested my resident, Dr. Gerlach, to irrigate the wound for several days previous to the operation with a solution of bichloride 1 : 1000. On the evening before the operation the patient was thoroughly bathed and an antiseptic dressing applied over the site of the operation. On Saturday, November 24th, the patient was brought before the clinic, the anæsthetic used being ether.

My assistant, Dr. Brinkman and my resident surgeon Dr. Gerlach, having rendered the patient and surroundings aseptic, I proceeded to the operation by first applying an elastic tube above the seat of operation, to prevent the blood from obscuring the wound. The operation consisted of four stages: First, thoroughly curetting the bone cavity to remove the granulations, so as to render it as clean as after a primary operation; second, separating the soft parts from the bone and dissecting off the cicatricial tissue around the cavity by free use of the scalpel; third, carefully dusting the entire cavity with sterilized iodoform, then placing therein a layer of decalcified bone chips, and repeating the iodoform, layer after layer, until the cavity was entirely filled, covering the last layer of bone chips with a layer of iodoform; fourth, the introduction of a deep set of sutures of aseptic catgut through the deep fascia, the perios-

teum having been removed by the primary operation, and completing the closure of the wound by bringing the skin and superficial fascia together with interrupted sutures of silver wire, observing the precaution to secure perfect coaptation. The final dressing was made by dusting the wound with sterilized iodoform, over which was placed a strip of aseptic protective (silk), and over this several layers of bichloride gauze wet in a solution of bichloride 1 : 2000, bichloride cotton held in position by an aseptic gauze bandage. The elastic tube was now taken off and the limb placed on a padded posterior splint, which was held in position by a muslin bandage which had been soaked in ninety-five per cent. alcohol for twenty-four hours. The entire limb was then placed in a fracture box and the patient returned to bed. The evening of the day of the operation the patient developed a violent conjunctivitis of the left eye, no doubt due to accidental contact with the ether. During the same evening she became decidedly delirious, with vivid visions, and fear alternating with ecstasy. With the mental disturbance she had an increase in bodily temperature which ranged between 99° and 101° F. The mental excitation lasted about forty-eight hours. The first dressing was removed on the tenth day after the operation, when it was found stained by the oozing following the removal of the elastic tube. The wound was perfectly aseptic. Some of the stitches, which were commencing to cut, were removed. The wound redressed with as great care as at the first dressing. The second dressing was removed seven days later when, with the exception of the ulcerating points in the skin caused by the remaining sutures, it was aseptic: these were removed at this dressing and the wound dressed antiseptically as above, the limb being still kept at rest by the use of the splint and fracture box.

Precautions and preparation of the bone-chips.—The precautions for the above operation are: first, that the granulations must be perfectly healthy; second, that the wound be thoroughly irrigated twice daily for several days previous to the operation with a solution of 1 : 2000 bichloride of mercury; third, that the iodoform should be sterilized; fourth, that the bone-chips should be aseptic; and last, but the most important of all, complete and thorough asepsis.

The bone-chips should be prepared as follows: The bone to be preferred is the tibia or femur of a freshly killed bullock, which can be easily procured at an abattoir. It should be immediately wrapped in a wet aseptic towel or several layers of wet aseptic gauze to prevent infection while being carried.

Arriving at the office the bone is to be sawed into segments two inches long, the articular extremities being discarded. Place the segments in a fifteen per cent. solution of hydrochloric acid in distilled water, after having removed the periosteum and marrow. This solution should be changed every twenty four hours, until the segments become decalcified, which requires from two to four weeks. When this process is completed the segments are to be washed in distilled water, then immersed in a dilute solution of caustic potash to remove the excess of acid. After the acid is neutralized, the segments are again immersed in distilled water for twenty-four hours, when they are then taken out and the cancellous structure in the medullary canal removed. The segments are now to be cut into strips in the direction of the long axis of the bone, of one-half to three-quarters of an inch in width. They are then ready for the last step in the process of their preparation, that of slicing them into chips of one millimetre in thickness. The chips are now to be placed in a glass-stoppered bottle containing a solution of bichloride of mercury in alcohol 1 : 500 and kept there until used. At time of operation the necessary amount of chips is to be placed in a five per cent. solution of carbolic acid.

Conclusions.—On reviewing the above case carefully, several points have been forcibly impressed on my mind: First, that the delirium following the operation was due entirely to the iodoform, as free iodine was found in sufficient quantity in the urine to warrant such a conclusion. But this action of iodoform need not give the surgeon any alarm, as it is only temporary. I wish here to state, that in my experience I have found iodoform, if properly sterilized, of very great advantage in the dressings of all surgical wounds, but especially in those made upon scrofulous tubercular and syphilitic subjects. Second, the liability to wound infection at the second dressing caused by the cutting of the sutures, which happened in this case, there being absolutely no pus present until the sutures were removed, when the tracks left by them became the seat of superficial ulceration. Third, that the cutting of the sutures is a complication which should not occur in primary operations, but in secondary operations it may occur, owing to the increased tension in approximating the soft parts caused by the removal of the cicatricial tissue surrounding the cavity. Fourth, that the symptoms of iodoformism, which were present in this case, were evidently due to the additional amount of the drug used in modifying Senn's method of alternating layers of iodoform and bone-chips, yet personally I think that this manner of packing the cavity is the preferable one, and in operating on subsequent cases I shall practise it until I have stronger evidence of its being detrimental to the welfare of the patient. Fifth, that unless the surgeon practising bone implantation after the above method is perfectly familiar and experienced in the technique of thorough aseptic surgery he need anticipate nothing but disappointment. Sixth, that drainage is not essential.[1]

[1] Patient at time of writing of this paper is up and around, ready to go home.

DIOXIDE OF HYDROGEN IN GENERAL SURGERY.

By THOMAS S. K. MORTON, M.D.,
PROFESSOR OF CLINICAL SURGERY IN THE PHILADELPHIA POLYCLINIC, ETC.

Having for some time past been making use of peroxide of hydrogen in all sorts of surgical conditions, and thinking that the agent is to find a definite and wide field therein, and, further, believing that the profession at large has not as yet been introduced sufficiently to its many applications and apparent benefits, I submit this clinical note.

What is known and sold as dioxide or peroxide of hydrogen consists of a more or less strong solution of peroxide of hydrogen gas in water. The strongest solution sold at present is termed the 20° or saturated solution. Practically we may call the substance water plus an atom of oxygen. Under almost any conditions the solution and the gas itself are unstable, but especially so in the presence of heat or organic matter; furious is its attack upon the lower vegetable forms of life and upon organic secretions or products such as pus, blood, serum, lymph, and saliva. The chemistry of its action depends upon the oxygen of the gas entering into new combination whilst its hydrogen is set free, causing great ebullition. It is this property of so readily parting with large quantities of oxygen (of course, in a nascent state) which renders it the substance of value in surgery.

Peroxide of hydrogen was introduced into medicine by Dr. B. W. Richardson, of London, who, so long ago as 1860, recommended and used the agent for almost all external and internal purposes to which it is now being, or about to be, applied. But, surprisingly, for some reason—possibly lack of pathological and bacteriological knowledge—its medicinal employment was soon totally discarded, and its valuable properties forgotten until a few years since, when the drug again came into use as a cleansing and sterilizing agent among laryngologists and otologists; whence, indeed, came the hints leading to its employment in general surgery.

Its field in the latter department of medicine is as a cleansing agent, wherever dead or living organic matter of low degree exists. The peroxide will not affect living tissues even to the stage of irritation, hence does not destroy most recently formed epithelial cells, while at the same time it burns up by oxidization all adjacent organic material of lower degree, such as microörganisms, their products, and their means of sustenance. This is more than can be said of other antiseptic agents, for, taking bichloride of mercury as an instance, a solution of it sufficiently strong to kill bacteria will also destroy newly organized cells. Then, again, our standard antiseptics do not remove the sterilized organic matter, nor penetrate into it so deeply as does the peroxide, which will eat through almost any depth of pus, lymph, etc., burning them as it goes, not, especially as in the case of sublimate, precipitating an almost impermeable layer of coagulated albumen which may screen septic matter beneath.

I am aware that certain bacteria act with vigor only in the presence of oxygen; but that form of oxygen to which they are subjected when hydrogen peroxide is used is *nascent*—a vastly more powerful element, the destructive energy of which in all probability they cannot resist, much less be enlivened by.

On the other hand, we can predict with much certainty that tubercular disease, which depends for its very existence upon a bacterium to which oxygen is most deadly, will afford a great field for the use of the peroxide. I have treated tubercular abscesses and sores by washing them out with the hydrogen solution and had them close up almost like simple incised wounds, and this, too, without use of the curette.

In ulcers of all kinds the effects have been surprising. The new epithelial cells cover over the denuded surface in a length of time occasionally almost incredibly brief. So, also, in burns have the effects been most satisfactory.

In practice, the surroundings of the sore, wound, or abscess are cleansed with turpentine, soap, and water, then the peroxide is poured on or injected until bubbling ceases, then protective in strips and an aseptic or antiseptic dressing is applied as usual. If bichloride is also to be used, the peroxide should be poured on first, as the latter will not act in presence of the former, whereby, also, the coagulum film usually produced by bichloride is likewise avoided.

In keeping drainage-tubes and deep cavities, as abdominal or pleural abscesses, drain tracks, or fistulæ, sweet and clean the solution is superior to anything that I have heretofore employed; principally for the reasons that while it is extremely effective yet it is absolutely innocuous and free from toxic effect. So safe, indeed, that even spoonfuls can be swallowed, and I am willing to leave it in the hands of nurses to use freely.

Why peroxide has not been used in the eye I cannot comprehend. One case of purulent ophthalmia which had resisted all efforts for several weeks in the hands of others, at once cleared up after but two instillations of the drug. Having, therefore, proved so useful in other purulent processes, I think it will likewise be found beneficial in gonorrhœa, gonorrhœal and other septic ophthalmiæ, and all tubercular processes where we can get the drug to the affected locality, as well as to many other of the innumerable septic conditions which are daily

presented to the surgeon or physician. In septic conditions of the mouth, thorax, abdomen, uterus, bladder, and vagina, it should be of especial worth from its non-poisonous yet powerful properties. In special regions. such as the conjunctiva, previous use of cocaine will prevent even the slightest pain. For cleansing surfaces where skin grafting is to be employed, or is going on, this drug is invaluable.

Further, peroxide appears to have a marked hemostatic effect: in contact with blood the latter is first turned to a brilliant scarlet hue of superoxygenation, and a second afterward is blackened by the cremative action of the nascent oxygen.

I have, as a test, used the oxidizing agent alone upon a few simple wounds, and they have progressed as well as would have been expected had other antiseptics been used.

It is not the belief of the writer that peroxide of hydrogen is to supplant bichloride of mercury, except in certain fields where the employment of the latter is undesirable or unsafe: more is its function to be as an adjuvant to the sublimate.

Recognizing that bacteriological investigation should precede clinical application of an antiseptic; but not being aware of such experimental facts, and not having time or facilities to elaborate them, I simply offer here the results of a limited clinical experience with the drug, hoping thereby to direct attention and investigation to the subject, and ultimately to call forth more exact knowledge of its properties, powers, advantages, and disadvantages.

SIMPLE METHODS OF PHOTOGRAPHING WITH THE MICROSCOPE.[1]

BY B. ALEX. RANDALL, A.M., M.D.,

PROFESSOR OF DISEASES OF THE EAR IN THE PHILADELPHIA POLYCLINIC; OPHTHALMIC AND AURAL SURGEON TO THE EPISCOPAL AND CHILDREN'S HOSPITALS.

THE praises of photography direct from the microscope have been already rung by men whose success in the employment of this means gives the best possible support to their claims of its value,[2] and the number of those who are using it is daily growing; yet there remain a large number of microscopists who fail to perceive its merits, or who regard the matter as lying outside of their field of work. They look rather scornfully at the best photographs of microbes or diatoms over which photographic experts grow enthusiastic, and incline to regard as a failure any photograph which falls short of giving the conventional picture of the diagrammatic drawings of the text-books. Even when unprejudiced examination has shown the exquisite fidelity and the diagrammatic clearness which may be obtained by photography, they still regard it as the province of the photographic enthusiast rather than of the practical microscopist. One reason for this is that they rarely see direct photographic illustrations used in actual publication, since it must at once be conceded that the reproductive methods now available are far from satisfactory; but probably the most potent obstruction to the widening of the use of photography is the prevalent impression that good results are obtainable only at great expense of time and money. Men glance, for instance, into Sternberg's treatise, only to lay it down with a sigh because all this apparatus is unobtainable; and, overlooking all that may be said about simple or improvised appliances, they resign all thought of entering the field.

Such considerations long withheld the writer from essaying the attractive task; but a single demonstration by Dr. Piersol of the possibilities of work by lamplight at once removed his misgivings and opened up the matter to him; and later work has fully confirmed him in the view that there is no reason why any microscopist should not obtain photographic pictures surpassing the highest skill of the draughtsman, not only in their unimpeachable accuracy, but even in their schematic sharpness. And as the demand increases for the direct reproduction of such pictures, there is every reason to believe that the mechanical arts will succeed in furnishing them with a perfection and a cheapness which no present method affords. It may safely be predicted that the time will come when photography will be employed to represent adequately all that the microscope can *show*, and that drawings will be needed only to demonstrate the points which *may be inferred but cannot be seen* in the preparation.

The two questions that most concern microscopists are: What apparatus is necessary in order to obtain good results? and, How may good photographs be gained with a practicable expenditure of time?

Let the beginner first decide what he specially wishes to photograph, and he will be wise not to choose the most difficult possible subject at the outset. Microbes that are almost beyond the highest resolving power of his instrument, do not offer the most favorable opportunities for success, however attractive they may be in this "cocco-phobic" age—objects that are resolved rather by the brain than the objective had better be deferred until some experience has been gained. Low-power work—too generally neglected—with good, clear sections, well-stained and thin, forms a more reasonable starting-point; and here apparatus of almost absurd simplicity will be all-sufficient. Some sort of camera is requisite; and, while it may be improvised, most men will do better to buy one of the many forms in

[1] Read before the Philadelphia Pathological Society, Nov. 14, 1889.

[2] Vide Piersol, Medical Photography, Trans. Phila. Path. Soc., xiii. p. 243.

the market, some of which are especially designed for this purpose. A "long draw" is a great convenience, since it permits of much choice in the amplification and size of the field, but it may be substituted by several cones of different lengths for uniting the camera to the microscope. These cones are easily made of pasteboard or any light-tight material, and constitute the only peculiar essential to photomicrography. Any camera and any microscope thus linked together may be successfully used, and no great skill is requisite in order that the usefulness may be limited to no narrow field. Good objectives are, of course, essential to first-class work, and any defects in transparency, definition, correction for color, or flatness of field, are apt to show in the results. But specially corrected lenses, like heliostats and other special appliances, are unessential, though valuable, and may be left to the expert who has unlimited time and money to devote to the matter, and aspires to the infallible conquest of every object which may be presented to him. The practical microscopist who takes up photography not as an end, but as a means, will usually find that his stand and lenses are equal to his needs in achieving good, and perhaps the very best, results within a fair range of subjects.

As an illumination sunlight is probably unapproachable, not only in its possibilities, but in the extreme simplicity of its employment. "But I have no daytime to give to the work," may seem a crushing answer to that; yet there are few microscopists who in the course of a week could not find one hour of leisure while the sun shone, and one hour of sunshine well used may give thirty or forty exposures, with the possibility of as many good negatives. The north light, which serves so admirably for most microscopical work, must be abandoned in favor of a window into which the sun shines; and, in the absence of a specially adapted table, an inch-plank, about six feet long by a foot wide, must be so adjusted that the sunlight shall fall upon the mirror of the microscope as it stands upon it, with the tube horizontal and connected with the camera. A vertical position is possible, of course, and may be compulsory in case the microscope-stand has no joint for horizontal inclination, and some fluid preparations may perhaps be thus better managed. In any event, it will be found convenient to secure the camera to the board or table top by small blocks and buttons, and it can then be used in any position, and when out of service may be stood up in a corner. For powers under 100 diameters, the reflection of the sun by the plane-mirror of the microscope, without any accessory apparatus, is all that is required—no condensor is requisite, and without it the heat-rays need not be cut off by a blue-cell. A mirror placed a couple of feet behind the ground glass of the camera (a standing toilet-glass answers admirably) is a great aid in adjusting the illumination, the field, and the approximate focus—then the fine adjustment is made with the aid of a magnifying glass. For this last purpose one of the microscope-oculars deprived of its eye-lens serves admirably, its tube being just the right length to allow of accurate focussing of the rough inner surface of the ground glass. For very high-power work a smoother surface than is furnished by the ordinary ground glass of the camera is said to be requisite, but for moderate-powers this answers perfectly. On either side of the true focus the image appears stronger and better defined than at the right point, because its outlines have an appreciable breadth instead of being mathematical lines—"where the image seems to melt into the ground glass" (Piersol) is the point of most perfect adjustment.

Unless the distance to which the image is projected is short, the arm will not reach the fine adjustment so as to allow of the necessary accurate focussing. Dr. Piersol's arrangement is, therefore, advisable—of a cord with weights carried across the head of the fine adjustment-screw (taking a turn around it, if it move stiffly), and passing through rings on the base-board, to be carried back along the edge, where it will always be within reach. A similar arrangement for the rack and pinion is rarely needed, since almost perfect focus can be made while standing by the microscope and looking in the mirror back of the ground glass. As this mirror allows in the same way of exact adjustment of the field to be photographed, no arrangement need be made to detach the microscope so as to search for this with the ocular. In photographing, an ocular may be used to increase the power, or an amplifier may be introduced into the tube; but the beginner will do better to work without either until he has learned to use his objectives by themselves, and has found them in need of such aids.

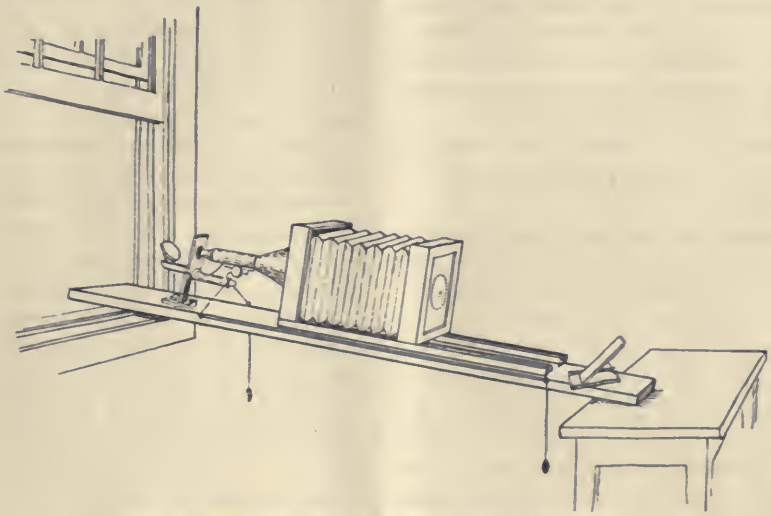
As to the exposure—use the slowest plate obtainable (such as Carbutt's A), as it gives the greatest latitude, and gives the shortest time that will afford a picture—vigorous development will then give a crisp negative with strong contrasts. If your negatives lack this quality, ask an expert photographer about them, or perhaps take him one or two to develop with you. The microscopist had better develop his own plates—any spare time can be utilized for it, and if night-time be chosen, any room with only a red light in it becomes a photographic dark-room. But he had better have a dark-room, if only a suffocating closet, since he can thus test at once the accuracy of his exposure, etc., and make another trial before changing his apparatus, if the first has not been satisfactory. A negative can be covered up light-tight in its developing-pan, while the operator runs in and out continuing his work, making new exposures, and trying new subjects; but mottl-

ing of the plate may result if it is left in the developer without occasional agitation. Such methods are unsystematic and indefensible from a photographic point of view; but the busy microscopist may find that he can by such unwarrantable measures sometimes treble the number of his successes without notably lessening the value of any one of them. Thus developing, one here and there, of a series which he wishes to make, the microscopist can photograph thirty or more preparations in a single hour of good sunlight; and as he puts away his apparatus at its close, he can count four or five finished negatives and some two dozen exposed plates that give promise of being as good as soon as he finds time to develop them. If this time is lacking, they may be turned over to a professional photographer, as may also the tedious process of making paper prints from the negatives.

How long to expose? will always be the cardinal question, and the learner will generally be disappointed at the vague answers he receives from the expert. Hold to one brand of plate (the same emulsion if possible) and one developer, as giving two constants in the problem, and note carefully the lens, the distance to which the object is projected, and the clearness of the atmosphere when the exposure is made; and study your results with an expert when you can. Over-exposure is most usual in working with sunlight, and the developer needs restraining. "Bromide of brains is the best restrainer." In making the exposure some opaque object may be held so as to cut off the light from the mirror while the slide is withdrawn, the exposure made by moving it aside and again interposing it, and then the plate-holder is closed once more. In the writer's work using a 1" Reichert lens with good sunlight and Carbutt A plates (sensitometer 10), and obtaining an amplification of 25 diameters, the correct exposure is about one-fourth of a second. The light is inversely as the square of the projection distance—so with similar conditions, except double length of draw and 50 diameters, the exposure should be one second. A quick hand can limit the exposure to one-fourth of a second or less—as short as has been found necessary—but a drop-shutter can be improvised to give a smaller fraction as may be desired. Summer sunshine is several times as rapid as that of winter; that of noon is far faster than when the sun is low; very little haze in the atmosphere lessens greatly the actinic power. These are facts in a problem that must be left to the judgment of the operator.

The field embraced in the picture is often an important matter, requiring considerable attention, and care must be taken that the plate shall receive all the essential portion of the image visible upon the ground glass. To this end, the point corresponding to the centre of the plate when exposed should be marked upon the ground glass, and a circle drawn around this to mark the minimum dimension of each size of plate to which the camera is adapted. Since the margins of the plates as bought are frequently faulty, the circle had better be only three inches for a 3¼ x 4¼ plate, etc.; though the full size of the plate can often be used without unwise economy. The draw-tube of the microscope is generally furnished with a diaphragm, which is of value in giving definition and flatness of field, but reduces materially the size of the field; the entire draw-tube can, therefore, be removed at times in order to bring the periphery of an object into view without any serious compromise of the sharpness.

The method of work thus laid down has one car-



An improvised apparatus for photographing with sunlight.

dinal difference from every other—it is working with the parallel rays of sunlight, and the effect is practically to photograph the disk of the sun with the preparation silhouetted against it. Every opacity which intervenes between the sun and the sensitive plate will make its mark upon the negative—dust on mirror, slide, or lens, scratches on the lens-front or bubbles in the balsam between the lenses, floating moats in the air, perhaps even sunspots, will show in the result. Stringent cleanliness is therefore requisite. To outweigh these disadvantages, the penetration thus obtained in a thick preparation, by the searching character of the light, will at times far surpass the performance of the same lens with an ocular; while, on the other hand, detail that is out of focus will often be drowned out by the flood of light—just as by the Abbé condenser when used to seek stained microbes in the tissues. A thick, poorly differentiated specimen may thus give a good photograph; yet well-stained, thin and even sections are none the less preferable. Although non-actinic colors have great theoretical advantages, admirable pictures can be obtained from hæmatoxylon preparations. Orthochromatic and other stained plates, as well as Dr. Piersol's method of actinic contrast, may prove a great addition to our refinements; but these are points which need not concern the beginner, who will do better to concentrate his attention on the simpler methods.

If the microscopist must confine himself to night-work, his task will be more difficult. Any lamp will serve as a source of light, and a little night-lamp, costing twenty-five cents, has been the writer's choice. It is to be placed, with its flame turned edgewise, in the line of the microscope-tube, and, except for very low-powers, some concentration will be required. For this purpose a bull's-eye or some form of substage condenser, or both, will be needed. One of the objectives can be adapted as a substage condenser, or the B ocular, which Dr. Piersol recommends, may be so employed, if the microscope lacks an Abbé or other regular apparatus; but with any form the problem of an evenly and strongly lighted field will demand careful, painstaking solution. The heat-rays emanating from even a tiny flame can by no means be neglected; or the operator may find his balsam melting, and a most singular streaky picture resulting from movement of the specimen while the exposure is going on. A mere piece of interposed plane-glass or isinglass will cut off much of the heat, or a blue-glass may be used below the stage, but at times the cell of ammonio-sulphate of copper may be needed. Rapid plates are in place for this work, since the time of exposure must always be considerable—averaging at least as many minutes as the sunlight required seconds. A convenient dark-room, however, will enable the operator to carry on several processes at once, and two dozen good negatives may often be made in an evening. With powers above 100 diameters the writer has done rather better work with lamplight than with sunlight; but this is because he has never prepared himself for high-power work. Concentration of the light is needed for such work, and can be used with safety to the objective and preparation only when the heat-rays have been eliminated—a matter easier with lamplight than with sunlight.

A few words in recapitulation. By securing a camera, with a cone to connect it with his microscope, a piece of plank, a developing solution, some hyposulphite of soda, a ruby light, a few pans, and some dry-plates, the microscopist has the needed outfit for beginning his photographing. The outlay will be from $20 up, but may be greatly lessened if the camera is made, borrowed, or bought second-hand. Fastened to its base-board, the camera may stand out of the way in a corner until wanted; then in five minutes all can be gotten into readiness for work. The apparatus is to be so placed that the sunlight falls upon the plane substage mirror (projected out of the window if necessary), and the light reflected into the instrument. The standing-mirror is placed at the far end of the apparatus, so that the operator as he stands by his microscope can see the ground glass reflected in it; then it is easy to adjust the illumination, find and centre the field, and get an approximate focus. Accurate focussing is then done with the aid of a magnifying glass, and the plate-holder charged with its sensitive plate is substituted for the ground glass. An opaque object is held so as to cut off the sunlight while the slide is drawn, is removed and replaced, so as to make the brief exposure desired, and then closing his plate-holder, the operator detaches it, and seeking his dark-room proceeds to develop his negative, and reloads. A miss may call for another shot—a hit will open the way to a long series of results more or less successful. Taking careful note (written as well as mental) of each exposure, the microscopist will quickly become master of one situation at least; and, while he must expect varied fortune when he changes the conditions and enters unknown territory, he will find much of it open to ready conquest, and having once entered the field, he will not quickly be willing to quit it. Let him begin with sunlight and a good low-power objective, and he will quickly achieve brilliant results, which the expert can hardly excel; and even though he makes no attempt to enter other fields, he will find that he has made a most valuable addition to his powers as a microscopist.

THERAPEUTICAL NOTES.

The Treatment of Acute Catarrh of the Rectum.—Quite frequently the practitioner of medicine sees cases in which the entire list of remedies generally found of value in the treatment of diarrhœa have proved useless, or merely palliative in effect. While they may control the frequent movements of the bowels for a time, the trouble reasserts itself, as soon as the medicine is withdrawn, at the best in a somewhat modified form. Careful inquiry will show, in such cases, several points of value as to diagnosis and treatment. The attack has probably been preceded by a few days during which there has been a sensation of weight or fulness in the rectum and about the anus; following this, a sensation of bearing down asserts itself, accompanied by violent pain referred to the region of the stomach, or small gut. So severe is the pain in its paroxysms that the patient may cry out with it, and the perspiration break out over the body. At first small passages may occur, but after a few stools they consist of wind and a few drops of mucus, which is expelled after a period of agonizing pain and tenesmus. Opium makes the state ultimately far worse than before, and nearly all astringents are valueless. Under these circumstances, small doses of chlorate of potash injected into the rectum are most serviceable, only one or two injections being necessary in some acute cases to produce a cure. A saturated solution of the potash in water should be employed, and about half a tumblerful injected each time, very slowly and without force, and retained for ten or fifteen minutes. Large injections will cause pain and expulsion of the liquid, and no result will be attained.

MEDICAL PROGRESS.

Treatment of Hairy Moles.—Dr. Arthur Jamison has found ethylate of sodium the most satisfactory remedy for the removal of hairy moles. The hair is cut short and the ethylate is rubbed in with a glass rod till the surface assumes an orange or black hue. The crust so formed is allowed to separate spontaneously, for which a period of three weeks is sometimes needed. Most of the hairs will then be found destroyed, and a white smooth scar left. Any hairs which remain can be dealt with by the same method *seriatim*. In using the ethylate care must be taken that it does not run down on the sound skin, and the part treated must not be touched with water till the crust comes off.—*Edinburgh Medical Journal*, December, 1889.

The Treatment of Placenta Prævia.—Dr. J. Braxton Hicks thus summarizes his opinions upon the treatment of placenta prævia:

1. After a diagnosis of placenta prævia is made, proceed as early as possible to terminate pregnancy.

2. If the os be fully expanded and placenta marginal, rupture the membranes and wait to see if the head is soon pushed by the pains into the os.

3. If there be any slowness in this respect, employ forceps or version.

4. If the os be small and placenta more or less over it, the placenta is to be carefully detached from around the os; if no further bleeding occur, wait an hour or two. Should the os not expand, and if dilating bags are at hand, the os may be dilated. If the forceps can be easily applied, they may be used; but if not, version by the combined external and internal method should be employed, and the os plugged by the leg or breach of the fœtus; after this is done the case may be left to nature, with gentle assistance, as in footling and breech cases.

5. If the os be small, and neither forceps nor dilating bags are at hand, combined version should be resorted to, leaving the rest to nature, gently assisted.

6. If during any of the above manœuvres much bleeding should occur, it is best to turn by combined method in order to plug by the breech.

7. Where the fœtus is dead, or labor occurs before the end of the seventh month, combined external and internal version is the best method.

8. If, however, a routine method is employed in all cases, it will be found that version by the combined method—no force following—gives a result as good, if not better, than any.

After-treatment.—The after-treatment must be conducted on the modern principles: should oozing occur after the expulsion of the placenta, the swabbing of the lower uterus by styptics will be easy; and inasmuch as the outlet of the uterus is liable more especially to be blocked by adherent clots, it will be wise to irrigate the uterus daily with some antiseptic solution, or insert iodoform pessaries in the vagina, particularly if the irrigation cannot be done.—*British Medical Journal*, November 30, 1889.

Somnal: the New Hypnotic.—In the *Zeitschrift des Apotheker-Vereines* of November 10, 1889, is a notice of a new hypnotic, introduced by Herr Radlauer, of Berlin, to which he has given the name of somnal. This body is formed by the union of chloral, alcohol, and urethan; it is a true chemical combination, and differs from the already known compound chloralurethan. It occurs in clear, colorless crystals, which have a slightly bitter taste, and are very soluble in water and alcohol. It is given in two-gramme doses, and in half an hour after its administration a sound natural sleep is produced, which lasts from six to eight hours, and the patient experiences no unpleasant effects upon awakening. It does not derange the digestion, and has no influence upon the pulse or temperature. In fact, it combines the excellent qualities of chloral and urethan without any of their unpleasant effects. It is already in use in the hospitals of Berlin and Moscow, and appears to have given satisfaction.—*British Medical Journal*, November 30, 1889.

Early Surgical Treatment of Perityphlitis.—In a paper read by Drs. E. W. Lee and J. B. Murphy before the Chicago Medical Society, November 4, 1889, the latter said that as it is impossible to make experiments on the vermiform appendix in the lower animals, it being present only in the ourang-outang and a species of bat, our knowledge of its physiology and pathology must depend on observations made upon it in man. Its absence in such a large number of omnivorous animals would lead to the belief that it has no influence on digestion. Notwithstanding our inability to attribute to it any special function, we still see the evil effects produced by its diseases. From its form, its valve, its position, and the different mechanical influences to which it is subjected,

there may occur a retention of feces or foreign body within its lumen. These feces become solidified and by their presence induce hyper-secretion of mucus, which deposits its phosphatic and other salts as a concretion around the retained nucleus in the appendix.

The authors then endeavored to demonstrate that *perityphlitis vermicularis* belongs always to the province of surgery, and that its dangers are avoidable and its recurrence preventable only by surgical interference. Such a statement may appear radical, but they sustained it by two facts which may be considered as positively proven: (1) That perityphlitis is *always* accompanied by the development of a pus-cavity. (2) That with medical treatment the patient is liable to a recurrence of the disease. Within the past three years they had made autopsies on three cases which showed that fatal peritonitis was caused by the rupture of the perityphlitic abscess into the peritoneal cavity, where its existence had not been previously diagnosticated.

The dangers are:

1. Perforation of the appendix, permitting escape of its contents into the peritoneal cavity directly or indirectly by a rupture of the circumscribed suppuration.

2. Where the abscess is extra-peritoneal, by the formation of a septic phlegmonous cellulitis and death from sepsis.

3. By the emptying of the contents of the abscess into some of the neighboring organs or cavities, as the bladder, kidney, or thoracic cavity.

Perityphlitis treated on the expectant plan is a frequently recurring disease. Paulier states that the first recurrence came from the twentieth day to the twentieth month (Thèse de Paris, 1875). From the 106 cases which were collected by Krafft, of Lausanne, 24 had previously experienced attacks. In one case the attack occurred twenty years previously, in another seven, and in another three. One case had a previous attack in 1863, lasting thirty-two days; in 1864, a recurrence, lasting twenty-eight days; in 1865 another, lasting nineteen days; in 1866 still another, making in all four seizures in three years. The frequency of recurrent attacks of perityphlitis the authors could sustain, as their observation coincides with Krafft's. Krafft, in 106 cases in which the diagnosis was verified either through autopsy or direct incision into the abscess cavity, found that in all of them greater or smaller accumulations of pus were present at the seat of the appendix or cæcum. Out of the 106 cases there were 84 autopsies, in all of which abscesses were found in the ileo-cæcal region. Eight times he operated in the absence of fluctuation, redness, or swelling of the abdominal wall, and eight times he found pus. In the remaining 14 cases, the abscess emptied into the cæcum or other organs. Drs. Lee and Murphy found pus in each of their 13 cases. Bull had collected 67 cases of perityphlitic abscess, 38 of which opened externally through the abdominal wall, 8 into the peritoneal cavity, 2 into the thoracic cavity, 2 into the bladder, 2 into the internal iliac vein, 1 produced chronic peritonitis, 1 pyæmia, and in 1 the result was not ascertained. Of Paulier's 49 cases, 4 opened into the peritoneal cavity, 6 into the retro-cæcal cellular tissue. Of Krafft's 106 cases, 17 opened into the cæcum, and 1 into the bladder. His cases operated on by direct incision into the abscess cavity all recovered.

That the cause of perityphlitic abscess is perforation of the appendix is sustained by the fact that among 645 recorded autopsies there were 324 perforations. It is recorded in cases of perityphlitis that the cæcum is frequently peforated from within outward, but Krafft is convinced that if a careful examination of the opening be made it will be seen that the *perforation occurs from without inward, and not from within outward*, showing that the opening in the cæcum was not caused by an ulceration of the mucous membrane, but by an ulceration of the abscess wall into the cæcum. In Weir's 100 cases there were only 4 perforations of the cæcum; 2 of these were openings from without inward. The vermiform appendix is not only perforated, but part of it entirely destroyed, as is shown in two of the cases reported by the authors. Perforation usually occurs at the free end, but when it occurs in the middle the ulceration is circular and the appendix can be amputated as shown in one of their cases.

The cause of the perforation is found to be most commonly fecal stones. Of Matterstock's 146 cases, in 63 he found fecal stones, and in 9 foreign bodies. Of the 49 autopsies on children, 27 fecal stones were found, and 3 foreign bodies. Of the 106 cases of Krafft, 86 were fecal stones, and 9 of other foreign bodies Of the 13 cases reported by the authors, fecal stones were found in 5; a fragment of bone was found in one case. The fecal stone is a small bean-shaped body, rounded at both ends, usually smooth on the surface, and varies in size from that of a small pea to that of a peanut. Some of them are hard, others soft and friable. The centre is usually of a yellowish-gray color.

Toft states that in one-third of the autopsies made between the ages of twenty and seventy there were pathological changes in the vermiform appendix. In 5 per cent. of these cases there had been ulceration of the appendix.

Dr. Ludvig Hektoen, of Chicago (pathologist to Cook County Hospital), in 215 consecutive autopsies on adult cases at the Cook County Hospital, found adhesions of the appendix. He did not note the number in which there had been previous ulceration. In 9 of the cases the appendix was adherent to the parietal peritoneum, which elucidates the frequency with which the abscess is extra-peritoneal.

The question When shall we operate? is an important one. Deahna operated on 7 cases in which there was neither fluctuation nor phlegmon in the abdominal wall, and in only one case did he fail to find pus. He operated from the ninth to the twenty-first day from the onset of the attack. In one case he failed to reach the abscess, but the pus emptied itself through the wound on the second day afterward. Usually at the end of the fourth day symptoms of general peritonitis subside, and there can be felt a slight induration in the right iliac region; then is the time to operate. Willard Parker has suggested performing the operation from the fifth to the twenty-first day, but only in the presence of phlegmon and induration. Eichhorst also says that operation should not be performed where fluctuation is not present. Drs. Lee and Murphy do not consider those cases in which fluctuation is present, for they have always been successfully operated upon. They desire to call the attention of the profession to cases where there is only a small induration in the ileo-cæcal region, with the accompanying symptoms of perityphlitis before

there is the slightest evidence of fluctuation or phlegmon in the abdominal wall. As yet, the number of cases operated upon have been too small to lay down any definite rule as to the time for operating, notwithstanding it is their conviction that before many years every case of perityphlitis when diagnosticated will be immediately opened, the appendix ligated, if possible, and amputated. The one sign in their cases invariably was a small induration in the right ileo-cæcal region, and in this induration the authors invariably found pus. The surgeon must not depend upon the number of days from the beginning of the attack, as a guide to operative interference. The cases differ so widely that often after forty-eight hours from the onset of the attack it is too late; in other cases weeks or months may elapse before an operation is demanded. Of the 76 fatal cases collected by Fitz, 56 died from perforation in the first week, 31 in the second, 4 in the third and fourth. His statistics show how early a fatal termination can take place and how *imperative* an early operation is. In general, it could be said that as soon as the diagnosis was made, too early an operation was impossible.

"Of the mortality in the number of cases operated on early, we have: Bull, 17 cases, with 15 recoveries; Krafft, 8 cases, 8 recoveries; Deahna, 8 cases, 8 recoveries; their own 8 cases, 6 recoveries. Weir's 26 cases operated upon cannot be included in the early cases, as he says that the operation was frequently postponed for a long time, not as a matter of choice, however, but because he saw the patients only in consultation, or because they would not submit to an operation. Noyes found in examining the statistics of 100 cases operated on, that of those operated on after the eighth day, 17 per cent. died. Of those operated upon before the eighth day, 8½ per cent. died, there being 50 per cent. more recoveries in the cases operated upon early—that is, before the eighth day."

Some Incompatibilities of Antipyrin.—If fluid extract of cinchona be added to a solution of antipyrin in distilled water, a dense reddish-brown precipitate is formed, which contains tannic acid and antipyrin. The greater part of this precipitate dissolves on the addition of dilute sulphuric acid, the insoluble portion being probably the coloring matter of the bark, for if a solution of tannic acid be used instead of the fluid extract of cinchona as a precipitating agent, a pure precipitate forms, which entirely and easily dissolves on the addition of the dilute sulphuric acid. It follows, therefore, that decoctions, infusions, and tinctures containing tannic acid should act in the same manner. The effect, however, produced by these preparations is very small compared with the fluid extract of cinchona. Antipyrin is not precipitated by solutions of the alkaloids, quinine, cinchonine, or cinchonidine. Therefore, it can be prescribed in a mixture containing sulphate of quinine and dilute sulphuric acid. When strong solutions of chloral hydrate and antipyrin are mixed a white precipitate is formed, which soon becomes resolved into globules of oily-looking liquid, which sink to the bottom in a distinct layer. This layer, in the course of some hours, changes into a crystalline mass, from which the clear upper liquid can be drained off. These crystals are soluble in water, but considerably less so than either antipyrin or chloral hydrate. They have a distinct taste of chloral without its pungency, and they are not so bitter as antipyrin. This precipitation does not occur in dilute solutions, and it is possible to mix a solution containing sixty grains of antipyrin to the fluidounce with one containing the same proportion of chloral hydrate without any precipitate being immediately formed, although in a few hours small crystals begin to appear. A solution containing fifteen grains each of antipyrin and chloral hydrate to the fluidounce appears to be a permanent one, for at the end of a week there is no appearance of crystalline matter. Clinical experience alone can determine whether mixtures of these two bodies possess any therapeutic properties different from those of the constituents. In prescribing them together, it is to be borne in mind that the solutions must be dilute.—*British Medical Journal*, November 16, 1889.

Treatment of Albuminuria and Eclampsia of Pregnancy.—Dr. E. P. Hurd writes upon the treatment of albuminuria in pregnancy, and its complications, thus: The treatment of puerperal eclampsia includes the prophylactic treatment and the treatment of the convulsive seizures. Many pregnant women have albuminuria and nephritis, and go to their full term without convulsions In other cases there are early warnings that there is danger ahead. Among the symptoms of renal insufficiency are headache, drowsiness, tinnitus aurium, perhaps more or less dimness of vision, or blindness of one or both eyes, dizziness, dyspnœa, especially on exertion, nausea, and vomiting; the urine is scanty and loaded with albumin, while the percentage of urea is not more than one-half or one-fourth the normal.

Here the duty is plain. The patient must refrain from work, be put on a diet of milk, with or without Vichy water, and fruits, with a minimum of animal food. Saline diuretics, as cream of tartar or acetate of potassium, may be prescribed, and tincture of chloride of iron in full doses three times a day. Also a full dose of Glauber salts in the morning to promote free elimination by the bowels. It may be expedient to give at bedtime a full dose of fluid extract of jaborandi to produce profuse sweating, or to administer hypodermatically one-eighth of a grain of pilocarpine, or even resort to the wet-pack or hot-bath. If, in spite of these efforts to relieve the engorged kidneys and protect the irritated nerve-centres, the patient becomes worse, and convulsions seem imminent, premature labor should be induced.

When called to treat a woman already in convulsions, if labor has not already commenced, it must be expedited by artificial means under chloroform. If labor is advanced, and the os is dilated or dilatable, the patient must be immediately delivered by the forceps or by version. A ten-grain calomel powder may be placed on the patient's tongue, and, if the vascular tension seems high, sixteen ounces of blood may be taken from the arm. It will seldom be desirable to repeat this venesection. Chloroform should be administered to complete anæsthesia, and the patient should be kept under its influence as long as convulsions threaten. As adjuvant to the chloroform, a full dose of chloral may be given by mouth or by rectum. Possibly, in obstinate cases, a hypodermatic of morphine may be advisable.—*Therapeutic Gazette*, November 15, 1889.

Laveran's Organisms in the Diagnosis of Malaria.—Professor Osler thus summarizes his later conclusions

upon the organisms found in the blood of persons suffering from malaria:

First. In the acute forms of malaria there exist, within certain of the red corpuscles, amœboid bodies, usually pigmented, which undergo a definite evolution, increasing in size, gradually filling the entire corpuscles, and which prior to and during the chill, undergo a remarkable segmentation. There are also, in some cases, free pigmented bodies. To the form within the corpuscles, which undergoes changes, the term *plasmodium* has been applied. Occasionally, in acute forms, flagellate bodies are seen free in the blood, presenting from three to eight long, actively moving cilia. According to Councilman, these are much more common in blood withdrawn from the spleen.

Second. In more chronic cases, particularly in the forms of remittent fever, which are so apt to be taken for typhoid, the corpuscles do not so often present the intercellular forms, but there are remarkable ovoid, rounded, and crescented bodies deeply pigmented. These are, in all probability, related to and developed from intercellular forms. From certain of these, particularly the ovoid and rounded forms, the flagellate bodies may be seen to develop. Unfortunately for the general practitioner, the determination of the inter-cellular forms requires a tolerably high power with good illumination. A one-twelfth immersion lens is preferable, but with care a good eighth is sufficient, and in the chronic cases, with the crescents in the blood, a sixth suffices. It is important to have the finger-tip, from which the blood is drawn, thoroughly cleansed, and it is best to take a very small drop of blood, so as to have the layer uniformly thinly spread out with the corpuscles isolated, not in rouleaux. —*Johns Hopkins Hospital Bulletin*, December, 1889.

Influenza.—A writer in the *Internationale klinische Rundschau*, December 8, 1889, who has studied the recent epidemic of influenza at St. Petersburg, classifies the varieties of the disease as follows:

1. The nervous form, in which neuralgic pain, often simulating pleurisy, etc., is a prominent symptom. The mucous membrane of the gastro-intestinal and respiratory tracts are normal. This form is very common, and in the beginning is frequently mistaken for typhoid fever.

2. The form characterized by catarrh of the respiratory tract. Bronchitis, coryza and conjunctivitis develop with fever, and frequently continue for some days after the fever has disappeared.

3. The gastric form, in which there is a catarrh of the gastro-intestinal tract, often with severe vomiting, which lasts about two days.

Other symptoms occasionally present are herpes of the lips, nose or eyelids, erythema, roseola, and urticaria. More serious complications, fortunately very rare, are meningeal irritation and pneumonia. The latter is the cause of death in the few fatal cases.

Besides these well-marked varieties there are many others which run a slight course or are abortive.

Convalescence is usually rapid, many patients feeling quite well within one day after the temperature has fallen to normal. With others the catarrhal or nervous symptoms continue a few days longer. Relapses have been observed occurring between the fifth and seventh day of convalescence, ushered in, as is the primary attack, with a chill followed by fever.

In treatment the most useful drugs are quinine, antifebrin, antipyrin, salicylate of sodium, and diaphoretics.

Œsophagotomy with Pleurotomy.—DR. FISCHER, of Hanover, in the *Medicinische-chirurgische Rundschau*, December 1, 1889, reports an interesting case in which a small piece of bone lodged in the œsophagus and finally ulcerated its way into the pleural cavity. Two weeks after the bone had been swallowed, the patient, a man of fifty years, began to suffer from difficult deglutition, offensive expectoration, and a diffuse painful swelling on the left side and somewhat below the thyroid cartilage. Fischer opened the œsophagus and nourished the patient through the fistula. Fetid expectoration, however, continued, the left vocal cord became paralyzed, and fever appeared with dulness and crepitant râles over the entire left chest. Puncture in the ninth intercostal space was followed by a discharge of thick, offensive pus. Free drainage of the pleural cavity was secured by resection of a rib, but death followed from collapse. The foreign body was not found.

Prescription for the Expulsion of Tapeworms.—The following is recommended by the *Deutsche med. Wochenschrift* as an efficient tæniacide:

℞.—Croton oil . . . . 1 drop.
Chloroform . . . . 1 drachm.
Glycerin . . . . 1¼ ounces.—M.

One-half of this should be taken in the morning on an empty stomach; half an hour later, the remainder. The patient's diet should have been light on the previous day.

Antiseptic Treatment of Puerperal Eclampsia.—*L'Abeille Médicale* of December 2, 1889, details the following treatment for this affection:

Preventive treatment:

1. A milk diet and the prevention of the formation of poisons in the intestinal canal by the use of the following prescription, one powder of which is to be given every six hours:

℞.—Naphthalin, Sugar, Salicylate of bismuth . . . āā 30 grains.—M.
To be made into eight powders.

2. Administer on the third or fourth day a wineglass of some purgative water, or two teaspoonfuls of sulphate of soda or magnesia in a little water.

3. Favor the action of the skin and kidneys by warm baths twice a week.

Curative treatment:

1. Quiet and absolute rest.

2. Bleeding, from one to many ounces.

3. Give by the stomach a dessertspoonful of the following mixture:

℞.—Chloral . . . . . 6 drachms.
Bromide of soda . . . 6 "
Distilled water . . . 4 ounces.—M.

If the convulsions continue, push the chloral and use chloroform inhalations to the point of anæsthesia.

THE RESUSCITATION OF PERSONS WHO HAVE STOPPED BREATHING.

WITH the advent of the production of artificial anæsthesia by the use of certain chemical compounds the importance of this subject necessarily became enormously increased, and no one can doubt but that the majority of cases of arrested respiration depend for their exciting cause upon some such agency. It is of the greatest importance that a clear idea of the necessities of the case be before the physician under such circumstances, and that his action be one of rapidity and clearness so far as the ultimate result is concerned. By some curious fallacy of teaching the greater part of the profession have been taught to faradize the diaphragm into contraction with the rapidly interrupted current by the application of one pole over the phrenic nerve in the neck and the other over the abdomen. It requires but little thought to show that such a method is ludicrous in the extreme, for by using such a current on any muscle we produce a condition of spasmodic contraction or tetanus. Every one knows that the diaphragm relaxed by paralysis or contracted by spasm, so long as it is immovable, is equally harmful to the patient. If any current is to be employed, let it be that which is slowly interrupted and which will alternately contract and relax this important respiratory muscle. There can be little doubt but that the rapidly interrupted current has caused persons to renew their respiratory movements, but in these cases the result has been dependent almost certainly upon the reflex excitability of the cells in the spinal cord and medulla rather than on action upon the phrenic nerve. If such an action is required, let the poles be swept over the body so as to cause peripheral irritation.

The absurdity of the application of the rapidly interrupted current to the phrenic is not alone dependent upon the points we have named. It has been proved by careful observation (*University Medical Magazine*, November, 1889) that the application of the electrode over the phrenic nerve in the neck will cause cardiac arrest through diffusion of the current to the vagus nerve, and Griswold reached conclusions of an identical character in the year 1885.

If electricity is used, it should be employed solely as a peripheral irritant, with the object of arousing the patient, as would a dash of cold water.

The question at once arises as to what is the best thing to do under such circumstances. If the arrest has occurred when the patient is under chloroform, his head should be lowered and the feet raised, almost perpendicularly. The neck should not be extended but held in the normal position so that the chin is somewhat shot forward and at a right angle to the body line. If the neck be extended the glottis does not open as well as when the position named is assumed. While one assistant supports the head another should use artificial respiration by Sylvester's method, and it will then be readily seen that there is an increased volume of air passing in and out of the chest. The drawing forward of the tongue is not so important as is imagined, unless it is turned with its tip toward the glottis. The use of ammonia as a rapidly acting respiratory and cardiac stimulant, when given intravenously into the leg, may be resorted to, and dashes of cold and hot water should be employed, not only for their excitation of the peripheral nerves, but also for the purpose of keeping the bodily temperature from rising above or falling below the normal line, the latter danger being the most pressing, of course. The hypodermatic injection of ether is a ridiculous therapeutic attempt, for if the system and respiratory centres are so depressed by the ether taken into the blood through the lungs as to have their functions in abeyance, why should we add still greater depression by injecting more of the

same drug. Let everything that is done be born of sense and thoughtfulness of the exact action and result desired, and let nothing be done simply because some other person has done it, great though he may be in the practice of the healing art. Measures for the relief of persons suffering from any malady depend not upon empirical laws, but upon the good common-sense of the physician in charge, even if the measure is a most revolutionary one in character. The sooner this is realized the sooner will better results be attained in the practice of physic, and the more thoroughly will disease and all its concomitant states be combated.

CORRESPONDENCE.

NEW YORK.

To the Editor of THE MEDICAL NEWS,

SIR: At the last meeting of the New York County Medical Association, Dr. von Donhoff, the surgeon who came to this city a few months ago from Louisville, Ky., threw a bombshell, as it were, into the camp of our New York surgeons, who have of late become so enthusiastic over the McBurney operation for the radical cure of hernia, by the declaration that the latter was neither a safe nor a perfect operation. The occasion of this sensation was the exhibition by Dr. T. H. Manley of a patient seventy-three years of age upon whom he had recently performed the McBurney operation on both sides, with the result, thus far at least, of complete success; and in his remarks upon the case Dr. Manley spoke particularly of the applicability of this procedure to all kinds of patients, whether old or young, provided no organic disease was present.

In defence of his assertion Dr. von Donhoff stated that since he had come to New York he had had the opportunity of seeing a considerable number of these operations, particularly at the Roosevelt Hospital, and that he had examined the results with special care. These results he considered anything but satisfactory, and as to the applicability of the operation to all subjects, he said that he had noticed some of the worst results in young persons of more or less robust habit. The most unfortunate case of all that he had observed was one in which the McBurney operation was performed by Dr. S. T. Armstrong, a most careful and accomplished surgeon. The success of the operation when he first saw the patient, perhaps ten or twelve weeks ago, was apparently very brilliant. But, notwithstanding the fact that the man was able to perform all sorts of contortions without inconvenience or disturbance of the parts, Dr. von Donhoff made the remark that the essential character of the operation was based on facts which would annihilate it as a scientific procedure. And in this instance, at least, his prognostication had been verified; for at the present time the condition of the patient was such that he was totally unable to wear a truss, while any operation that could be undertaken for the closure of the opening would necessarily have to be of so extensive a character that it seemed hardly likely that the man would submit to the incident risk.

Dr. von Donhoff further said that some years ago he had reported thirty-four cases of hernia operated on by a method of his own, in all of which the conditions recurred. The want of success, he was confident, was due to the fact that the same principle was involved as in the McBurney operation; for it was an indisputable dogma that it is impracticable and impossible to secure a union of structures which are not histologically analogous, and the failure of such attempts will be immediate or not according to the special conditions met with in different cases.

Of course, Dr. von Donhoff's strictures drew a spirited rejoinder from Dr. Manley, who had done the McBurney operation fifteen times, thus far with complete success: and it was learned with satisfaction that Dr. von Donhoff proposes at no distant date to read a paper himself on the radical cure of hernia before the Association. This will certainly prove an occasion of unusual interest, and there can be no question that Dr. McBurney and his followers will be on hand and in full force to defend their position with facts as well as arguments.

At the same meeting Dr. Manley also presented a young man who had been thrown down and run over in the street by a wagon, both wheels of which passed over his neck. In consequence of the injury, violent inflammation of the larynx and the adjacent structures resulted, which was followed by increasing difficulty of respiration. Various topical applications having failed to relieve the dyspnœa, Dr. Manley, fearing that at any moment fatal spasm might occur, (as he had seen in another similar case), at first attempted intubation by O'Dwyer's method, but, unfortunately, the only set of tubes at the hospital was for a child, and it was found impossible to secure retention of even the largest of them. In the meanwhile the patient's sufferings and struggles were constantly increasing, and tracheotomy was performed without further delay, with the result of saving the man's life. Under such circumstances, when the patient is strangling to death, Dr. Manley said he knew of no more trying operation in surgery. Under the administration of ether the respiration grew weaker and weaker, and it was necessary to operate very rapidly. Before the tracheotomy tube could be inserted the patient ceased to breathe altogether; but by blowing into the tube and resorting to artificial respiration death was averted. In commenting on the case, Dr. Manley said that he believed that trachotomy might probably have been avoided if an O'Dwyer tube of the size for adults had been obtainable, and expressed the opinion that every hospital ought to be supplied with full sets of these instruments for such cases of emergency.

In the course of his anniversary address before the New York Academy of Medicine, on "The Relation of Medicine to some of the Questions of the Day," Dr. William M. Polk took up the subject of socialism, which, he said, was rapidly becoming a question of classes in this country. The same human inspiration was at the bottom of the present social agitation, he believed, as underlay the French Revolution, and we have got to see what the outcome would be under the changed conditions. The content of a people is largely dependent

on its physical well-being, and in this country one social order—that which was most widely separated from the class from which social agitation sprang—had the means to compel healthful conditions. Therefore, he held that it was the duty of physicians to speak out plainly to the class which held the surplus wealth in regard to the physical conditions surrounding the working classes. Physical well-being was the result of obedience to natural laws; the demand for knowledge of those laws was constantly growing, and the medical man's duty to society was to satisfy it. "Let us present the facts," he said, "to the class which commands the surplus capital. Let us show them that the viciousness and laziness from which socialism draws its strength are the result of bad physical conditions which those surrounded by them are unable to change. We shall then have taught the means of self-preservation; we shall have taught man his duty toward God, and toward that temple of God which was created when he entered the world."

Mayor Grant recently re-appointed the widow of the late Dr. Cornelius R. Agnew, the distinguished ophthalmologist, a member of the Board of Education; and in the place of Miss Dodge, daughter of the late William E. Dodge, whose term had also expired, appointed Mrs. Clara M. Williams, who has the advantage of having herself gone through all the grades of the public schools and having been graduated from the Normal College. Considerable opposition was manifested to the re-appointment of the lady commissioners, and, in consequence, two large petitions were forwarded to the Mayor, urging him to take this action. One was signed by Bishop Potter, the Rev. Dr. Morgan Dix, ex-President Cleveland, Vice-President L. P. Morton, Rufus Choate, and other prominent citizens, and the other by a long list of physicians, who were convinced that such action would be for the best hygienic interests of the schools. In this connection it may be stated that at the last annual meeting of the Medical Society of the County of New York, held during the past autumn, the Committee on Hygiene made an elaborate report on the overcrowding of the public schools, which has excited considerable interest.

It states that five years ago the committee submitted a report on the same subject, and that this year a more thorough effort has been made to detect possible defects. After giving the statistics in reference to attendance, seating capacity, the refusal to admit pupils, etc., the report goes on to say that the facts presented make it plain that the school administration must be watchful and efficient to be safe. The necessity of vigilance is further emphasized by the result of the examination of the water-closets at the schools, which are said to be well constructed, but badly kept; also by the reports from various quarters of children being kept in school when suffering from whooping-cough and other infectious diseases; indicating that there have been serious abuses in this direction. The teachers' interest in keeping their classes full and up to the standard, it is pointed out, has been mainly responsible for the attendance of children who should not have been permitted to mingle with the other pupils. In conclusion, the committee recommend that:

First. The system of marking and awards for regular attendance of school children should be so adjusted as to impose no avoidable penalty for absence on account of illness.

Second. The recess at noon should last at least one hour and one-half. No scholar should be detained for any reason during the noon recess.

Third. The salaries of principals and teachers should be less directly dependent on the average attendance than it now is.

Fourth. The regulations which are in force regarding vaccination and contagious diseases among public school children should be extended and rigidly enforced in all day schools, including all private and denominational schools of every description.

At the last meeting of the Section on Laryngology and Rhinology of the Academy of Medicine, Dr. George H. Fox read the report of a case of erythematous lupus of the face and oral cavity; after which a general discussion on lupus of the respiratory mucous membrane took place. On the same evening Dr. H. Holbrook Curtis presented the report of a case of cocaine-habit with remarks on the dangers of the use of cocaine which were based on about two hundred cases which he had collated from various sources. The fact that Dr. Karl Köhler, of Vienna, to whom the discovery of the valuable anæsthetic properties of cocaine is due, was present on this occasion, lent an additional interest to the subject, and in the discussion he stated that he made it a rule never to prescribe the drug in his practice. "Whenever I use it," he said, "I administer it myself, and then the patient cannot procure more of it by simply having a prescription refilled." He also stated that, as a rule, he never used a solution stronger than five per cent., since he found the results obtained from it quite as good as from a stronger solution. It only required a little more time to act. In subcutaneous injections even a weaker solution should be employed, and he had found a two per cent. solution quite effective.

NEWS ITEMS.

Statistics of Leprosy in the United States.—With reference to the increase of leprosy in this country the following request has been received: In view of the general impression that leprosy is spreading in this country, it is desirable, in the interest of the public health, to obtain accurate information upon this point. The undersigned is engaged in collecting statistics of all cases of leprosy in the United States, and he would ask members of the profession to aid in this work by sending a report of any case or cases under their observation, or coming within their knowledge. Please give location, age, sex, and nationality of the patient, and the form of the disease—tubercular or anæsthetic; also any facts bearing upon the question of contagion and heredity. Address, DR. PRINCE A. MORROW, *Journal of Cutaneous and Genito-Urinary Diseases*, 66 West Fortieth Street, New York.

Prizes of the Spanish Medico-Chirurgical Academy.—The Spanish Medico-Chirurgical Academy offers prizes for the best essays on the following subjects: 1. Modern Discoveries in Physics applied to Medicine: have they Advanced the Science of Diagnosis? 2. Limits of the Expectant Method and the Therapeutic Value of Hygiene

in Chronic Diseases of the Stomach. Each prize will consist of 250 pesetas ($50), with the title of Corresponding Member of the Academy. Essays may be written in Spanish, Portuguese, French, Italian, English, or German. Each essay must bear a motto, the name and address of the author being sent in a separate sealed envelope. All essays must be in the hands of the Secretary (Montera, 22, *bajo*, Madrid), on or before September 15, 1890.

The Carriage of Infection by Physicians.—With reference to the communication of contagious diseases by physicians, a question that is now being agitated in England, a correspondent of the *British Medical Journal* writes that "although it cannot be denied that it is possible for a medical man under some circumstances to convey infection from one patient to another, the risk of this taking place is, if ordinary precautions be taken, almost *nil*. This is clearly shown by the experience at the London Fever Hospital, where the resident medical officer in the discharge of his duties is constantly passing from the scarlatina department to the departments for measles, typhoid, diphtheria, etc., and yet it has never been found that he transfers these different contagia, although he would be much more likely to do so than an ordinary practitioner, inasmuch as the poison is necessarily more concentrated in a fever ward than in a room where only one patient is treated. The medical attendant is not, as a rule, brought into sufficiently close and prolonged connection with his patient for his clothes to receive any very large amount of the contagion, and a short exposure to the open air is generally sufficient to disinfect him. Nurses, no doubt, whose clothes from prolonged and constant contact with the patient become saturated with the poison, may readily convey infection. The only precautions taken by the physicians to the fever hospital—and a long experience has shown them to be quite sufficient—are to wear a special outer garment and cap in the wards, but even this is not done by the resident medical officer.

"For all ordinary purposes washing the hands in a disinfecting solution and a short exposure to the fresh air will, I am sure, sufficiently disinfect the practitioner, though it is advisable that he should change his coat, and he ought, as far as possible, visit his infectious cases last.

"In the case of smallpox, however, where the poison is present in a liquid form, and may possibly get smeared on the clothes, a change of clothes is necessary."

College Athletics.—There is a tendency in college sports and athletics that is the reverse of commendable. Foot-ball, the bicycle, and the cane-rush have each resulted, of late, in death or serious injury. Some of the players at foot-ball enter a game knowing that the chances are against their being able to participate in a second match, as they expect to be laid up for the rest of the season. It is idle to assert that the players when excited cannot control their energies within the limits of gentlemanly contention. It has been done here formerly, it is done elsewhere now, and it must be done by such professional athletes as ball-players, or they will become unpopular, and there should be no leniency shown to that sort of college athletics which will not courteously obey such rules as have been devised to prevent the maiming and disfigurement of those who engage in the college contests. Those who have been in the habit of contributing to the athletic funds of the collegians will do well to admonish their young friends that what they wish to countenance is not brutality, but a fair and knightly competition. That this point is not too fine-spun is shown by the accounts of two recent foot-ball matches, in which two of the contestants were kicked in the head.

A Balneological Investigation.—Dr. L. Blanc, of Aix-les-Bains, and medical director of the principal sanitarium at that place, has been sent to this country by the French Government for the purpose of investigating the properties of the medicinal mineral springs of this country and the British Provinces.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 10 TO DECEMBER 16, 1889.

HALL, JOHN D., *Major and Surgeon* —Is granted leave of absence for ten days, to take effect upon being relieved from duty at Fort Niagara, New York.—Par. 11, *S. O. 255, A. G. O., Washington*, December 7, 1889.

By direction of the Secretary of War, EDWARD C. CARTER, *Captain and Assistant Surgeon*, will be relieved from duty at Willett's Point, New York, upon the arrival at that station of Clarence Ewen, Major and Surgeon, and will then proceed to Fort Walla Walla, Washington Territory, and report in person to the commanding officer of that post for duty, reporting also by letter to the commanding general Department of the Columbia.

BALL, R. R., *First Lieutenant and Assistant Surgeon.*—Is relieved from temporary duty at Fort Sill, Indian Territory, and will return to his proper station, Fort Riley, Kansas.—*S. O. 182, Headquarters Department of the Missouri, Fort Leavenworth, Kansas*, December 12, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE TWO WEEKS ENDING DECEMBER 21, 1889.

ROSS, J. W., *Surgeon.*—Detached from the Navy Yard, Pensacola, Florida, and placed on waiting orders.

KITE, I. W., *Assistant Surgeon.*—Detached from the Naval Hospital, Philadelphia, Pa., and ordered to the Navy Yard, Pensacola, Florida.

ROGERS, B. F., *Surgeon.*— Ordered to special duty at Norfolk, Virginia.

LEACH, PHILIP, *Passed Assistant Surgeon.*—Ordered to duty at the Naval Academy, Annapolis, Maryland.

PICKERELL, GEORGE MCC., *Assistant Surgeon.*—Ordered to the Navy Yard, Washington, D. D., for temporary duty.

PROMOTIONS.

KITE, I. W., *Assistant Surgeon.*—Promoted to be a Passed Assistant Surgeon.

STONE, E. P., *Assistant Surgeon.*—Promoted to be a Passed Assistant Surgeon.

NORTON, O. D., *Assistant Surgeon.*—Promoted to be a Passed Assistant Surgeon.

HENRY, CHARES P., *Assistant Surgeon.*—Placed on the Retired List.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*
